ABSTRACT: The molecular determinants of substrate specificity and selectivity in the proprotein convertase (PC) family of proteases are poorly understood. Here we demonstrate that the natural serpin family inhibitor, serpin B8, is a specific and selective inhibitor of furin relative to the other PCs of the constitutive protein secretion pathway, PC4, PC5, PACE4, and PC7 (PC4−PC7, respectively), and identify reactive-site (P6−P5′ residues) and exosite elements of the serpin that contribute to this specificity and selectivity through studies of chimeras of serpin B8 and α1PDX, an engineered serpin inhibitor of furin. Kinetic studies revealed that the specificity and selectivity of the serpin chimeras for inhibiting PCs were determined by P6−P5 and P3−P2 residue-dependent recognition of the P4Arg-X-X-P1Arg PC consensus sequence and exosite-dependent recognition of the reactive loop P2′ residue of the chimeras by the PCs. Both productive and nonproductive binding of the chimeras to PC4−PC7 but not to furin contributed to a decreased specificity for inhibiting PC4−PC7 and an increased selectivity for inhibiting furin. Molecular dynamics simulations suggested that nonproductive binding of the chimeras to the PCs was correlated with a greater conformational variability of the catalytic sites of PC4−PC7 relative to that of furin. Our findings suggest a new approach for designing selective inhibitors of PCs using α1PDX as a scaffold, as evidenced by our ability to engineer highly specific and selective inhibitors of furin and PC4−PC7.

Proprotein convertases (PCs) are ubiquitous calcium-dependent serine proteases of the subtilisin fold. In mammals, PCs are complex multidomain proteins that carry out the proteolytic posttranslational modification of many secreted peptides and proteins and regulate central cellular processes like growth and proliferation.[1,2] The PCs of the Kexin-like subtype, furin, PC4, PC5, PACE4, and PC7, localize to the trans-Golgi network and endosomes of the constitutive protein secretion pathway and cleave precursors of a large diversity of proteins at polybasic sites consisting of the general P4Arg-X-X-P1Arg PC substrate specificity motif. Many important viral and bacterial pathogens exploit these PCs to promote and regulate their own growth. For this reason, specific PC inhibitors are sought as potential therapeutic agents.[3]

Furin reactivity is regulated by changes in pH and calcium concentration to impact enzymatic activity and autocatalytic activation.[4,5] Protein crystallography and molecular dynamics simulations (MDS) revealed that the furin catalytic site is in equilibrium between active and inactive conformations.[6,7] Given the similarities at the catalytic site among PCs,[8] it is predictable that furin shares with PC4, PC5, PACE4 (PC6), and PC7 (PC4−PC7, respectively) similar mechanisms for regulating reactivity.

The assignment of natural substrates to individual PCs has been speculative due to the great deal of cross-reactivity among these proteases, and substrate preferences have been assumed to depend mainly on differences in expression and cell-type distribution among PCs. Efforts to identify amino acid residue preferences at the substrate cleavage site by individual PCs have been attempted with the use of peptide libraries with limited success.[9] We developed a more robust approach in which the serpin-type protease inhibitor, α1-antitrypsin, was used as a model PC substrate to engineer changes in its reactive center loop (RCL) site of cleavage.[10] The validity of this approach is supported by the fact that serpin B8 is the only mammalian natural furin inhibitor known so far, and PCs from a variety of organisms are regulated by serpins.[10−14] Here, we found that serpin B8 is a selective furin inhibitor and used the serpin α1-antitrypsin as a scaffold to graft serpin B8 RCL and

exosite amino acid residues to elucidate the basis for this selectivity. α1-Antitrypsin is known to inhibit furin efficiently when arginine residues are engineered at its RCL P4 and P1 positions (α1PDX).[15,16] This approach is supported by our previous study showing that RCL and exosite determinants of serpin B8 reactivity, when substituted into their homologous regions in α1-antitrypsin, regulate reactivity with furin.[10] The same approach was here extended to the other PCs of the constitutive secretion pathway to identify the serpin B8 determinants responsible for the specific and selective inhibition of furin compared to PC4−PC7. Knowledge of these determinants enabled us to engineer α1PDX derivatives that were highly specific and selective inhibitors of furin and PC4−PC7.

MATERIALS AND METHODS

Production of PCs. Recombinant proprotein convertases were produced in truncated form as described for furin.[10] They included the first 579 residues of furin (UniProtKB entry P09958), 584 of PC4 (UniProtKB entry Q6UW60), 605 of PC5 (UniProtKB entry Q92824), 638 of PACE4 (UniProtKB entry P29122), and 621 of PC7 (UniProtKB entry Q16549), up to the end of their P domains. The gene constructs were synthesized (Integrated DNA Technologies) with a 10-His tag extension at the C-terminus. The proteins were expressed for 24 h in 1 L of Hi5 or sf9 insect cells using the baculovirus expression system. The PCs were purified from secreted proteins to homogeneity using nickel-affinity and size exclusion chromatography as shown previously for furin.[10] Protein yields were between 100 μg and 1 mg of purified protein. PC4−PC7 were expressed less abundantly than furin, especially PC7.

Production and Engineering of α1-Antitrypsin Mutants. The serpin α1-antitrypsin (UniProtKB entry P01009) was expressed in bacteria, refolded from inclusion bodies, and purified by ion exchange chromatography as described previously.[10] Mutagenesis of the serpin was achieved by polymerase chain reaction using specifically designed oligonucleotides (Integrated DNA Technologies) and *Pfu* Ultra II HF DNA polymerases (Agilent Technologies).

Production of Serpin B8. Recombinant serpin B8 (UniProtKB entry P50452) was produced in insect cells using the baculovirus system as described previously.[10] Five of its cysteine residues were mutated into serine and five into alanine (serpin B8-5S5A) to improve stability.

Protease Activity Assay. Protease activity assays and determinations of Michaelis−Menten enzyme kinetic parameters (K_m and k_{cat}) with the fluorogenic substrates, Boc-Arg-Val-Arg-Arg-7-amido-methylcoumarin and pyr-Arg-Thr-Lys-Arg-amido-methylcoumarin (Bachem), were performed in 100 mM Hepes (pH 7.5), 1 mM $CaCl_2$, 1 mM β-mercaptoethanol, 0.5% Triton X-100, and 0.1% polyethylene glycol 8000 at 25 °C employing the same methodology as described previously for furin.[10] The same conditions were used with all PCs to compare their activities.

Protease Active-Site Titrations. Concentrations of active enzymes and turnover numbers were determined from titrations of fixed enzyme concentrations with the inhibitor dec-Arg-Val-Lys-Arg-chloromethyl ketone (Bachem) to reach end points of zero activity at pH 5.5, as described previously.[10] The stoichiometric inhibition of PCs can be achieved only under acidic conditions. At the commonly used neutral pH of the enzyme activity assay, the competing hydrolysis of the inhibitor results in a curved line instead of a straight line, stoichiometric titrations, due to depletion of the inhibitor. Specific activity values of 6.4, 1.9, 1.8, 1.3, and 1.5 $\Delta F\ min^{-1}\ (nM\ PC)^{-1}$ were measured for furin, PC4, PC5, PACE4, and PC7, respectively, with 10 μM pyr-Arg-Thr-Lys-Arg-amido-methylcoumarin under protease activity assay conditions and used to calculate the concentration of the enzyme from changes in fluorescence.

Protease Inhibition Assays. The second-order association rate constant (k_a) values for the reaction of PCs with serpin B8 and α1-antitrypsin variants were determined from the kinetics of protease inhibition by the serpins as described previously.[10] All reactions were performed under protease activity assay conditions and under pseudo-first-order reaction conditions in which the inhibitor concentrations exceeded that of the enzyme by at least 10-fold. Measurements of fast reactions (k_a in the range of $10^5-10^7\ M^{-1}\ s^{-1}$) were obtained from the continuous exponential loss of enzyme activity observed under protease assay conditions that consumed minimal amounts of the 10 μM fluorogenic substrate pyr-Arg-Thr-Lys-Arg-amido-methylcoumarin present in the assay. The observed first-order rate constants (k_{obs}) were obtained by fitting the time-dependent increase in the observed fluorescence (ΔF_{obs}) in reaction progress curves to the exponential rise equation $\Delta F = \Delta F_{max}[1 - \exp(-k_{obs}t)]$, where ΔF_{max} is the maximum fluorescence change at the end point. Apparent association rate constant values were derived from slopes of the linear dependency of the k_{obs} values versus inhibitor concentrations that were corrected for the competitive effect of the substrate by dividing by the factor $1 + [S]_o/K_m$. For slower reactions (k_a values of $<10^5\ M^{-1}\ s^{-1}$), longer time assays of discontinuous protease inhibition were performed and residual activities determined from aliquots removed from the inhibition reaction mixtures. Plots of time-dependent residual protease activity (A_{obs}) were fitted to exponential decay equation $A_{obs} = A_o \times \exp(-k_{obs}t)$ to obtain k_{obs} values. Apparent association rate constant values were derived from slopes of the linear dependency of the k_{obs} values on inhibitor concentration. For those reactions in which the initial Michaelis encounter complex was formed rapidly and the subsequent chemical step was comparatively slow, association rate constant (k_a) values were determined from k_{cat}/K_d ratios (equal to k_{cat}/K_m), where $k_{cat} = k_{obs}/$(fractional occupation of the Michaelis complex). Apparent association rate constant values were corrected by factoring the stoichiometry of protease inhibition (SI) to yield the true association rate constant (k_a) value. The stoichiometry for protease inhibition was determined under protease assay conditions as the serpin:protease molar ratio that yielded zero enzyme activity and was obtained from the linear decrease in enzyme activity as a function of the increasing inhibitor concentration.

PC−Serpin Binding Affinity. The reaction of some of the α1-antitrypsin variants with PCs yielded fast enzyme activity decreases that were dependent on the concentration of the inhibitor in a manner that reflected equilibrium formation of the Michaelis complex. The rapid loss of reactivity was followed by a slower loss of the remaining activity that reflected acylation of the Michaelis complex to form the conformationally trapped covalent serpin−enzyme complex. Equilibrium binding dissociation constants for the Michaelis complex (K_d) were determined from nonlinear least-squares computer fits of plots of the dependency of residual PC activity, calculated from the initial linear segment of residual activity, to inhibitor concentration to the tight binding

[a]Michaelis–Menten constant (K_m and k_{cat}) values were determined from initial velocities of product formation from the catalyzed hydrolysis of two fluorogenic peptide substrates. Reactions were carried out under protease activity assay conditions as described in Materials and Methods. Errors represent the standard error from linear regression fits of data. Fixed concentrations of active-site-titrated PCs were used in reactions with substrate concentrations ranging from 0.2 to 5 times the K_m values. Parameters defining the dependence of initial velocities on substrate concentrations were obtained from fits of data to the Michaelis–Menten equation.

[a]Second-order association rate constant (k_a) values for the reaction of PCs with serpin B8 and α1PDX and their stoichiometry of inhibition (SI) were measured under protease activity assay conditions as described in Materials and Methods. SI measures the partition between the inhibitory and substrate pathways of the serpin mechanism of protease inhibition. A value of 1 corresponds to an efficient inhibition (Figure S1). Errors represent the standard error from linear regression fits of data. The k_a and SI values for furin were taken from ref 10.

Figure 1. Amino acid residue sequences at the RCL of α1-antitrypsin derivatives and serpin B8. The amino acid residue sequences from the RCL of α1-antitrypsin variants and of serpin B8 were aligned on the basis of the location of the protease cleavage site between residues P1 and P1′. A natural mutant of α1-antitrypsin, the Pittsburgh variant, has an arginine substitution at the P1 residue that changes the serpin specificity to inhibit trypsin-type proteases.[20] The α1-antitrypsin Portland variant (α1PDX) was engineered with arginine residues at the P4 and P1 positions to inhibit furin.[15,16] The serpin B8-5S5A variant is a stabilized form of serpin B8 in which cysteine residues were mutated, five to serine and five to alanine, including the one at the P1′ position.[10] The α1PDX–serpin B8 P6–P5′ chimera is now designated the Chicago 1 derivative (α1ORD) due to its high furin selectivity. The α1PDX+YE exosite variant is now designated the Chicago 2 derivative (α1MDW) due to its high selectivity for PC4, PC5, PACE4, and PC7 over furin.

quadratic equation of Morrison, $[E]/[E]_o = 1 - \{[E]_o + [I]_o + K_d - [([E]_o + [I]_o + K_d)^2 - 4[E]_o[I]_o]^{0.5}\}/(2[E]_o)$, where $[E]$ and $[E]_o$ are the residual active and total PC concentrations, respectively, and $[I]_o$ is the total inhibitor concentration.[21] Inhibitor concentrations were corrected for the competitive effect of the substrate by dividing by the factor $1 + [S]_o/K_m$.

Molecular Dynamic Simulations. Principal component analyses on two furin crystal structures and models of the catalytic domain of PC4–PC7 were carried out as described previously.[7] MDS were performed using the GROMACS (version 5.0.3) molecular simulation package as described previously.[7] Models of the catalytic domain of PC4, PC5, PACE4, and PC7 were obtained using the SWISS-MODEL tool for protein homology modeling and on the basis of the X-ray crystal structures of the ligand-free form (Protein Data

[a]Amino acid sequences in the RCL of α1PDX were substituted with the homologous sequences from the RCL of serpin B8. Second-order association rate constant (k_a) values for the reaction of PCs with α1PDX−serpin B8 chimeras were determined as described in Materials and Methods. Errors represent the standard error from linear regression fits of data. The k_a values for the reaction of furin with α1PDX and the P6−P5′, P6−P1, and P1′−P5′ chimeras were taken from ref 10. [b]k_a values for PC4−PC7 were determined from k_{cat}/K_d ratios as described in Materials and Methods. The reactions with furin were monophasic; therefore, the effects of K_d and k_{cat} on reactivity were not separated. [c]Unstable covalent complexes prevented the SI from being determined, so the rate constant values are larger than those reported here.

Bank entry 5JXG) and the ligand-bound form (Protein Data Bank entry 5JXH) of human furin as templates.

RESULTS

Furin Hydrolyzes Two Small Peptide Substrates at a Chemical Conversion Rate That Is Faster Than Those of PC4, PC5, PACE4, and PC7. Recombinant furin, PC4, PC5, PACE4, and PC7, consisting of only their catalytic and P domains, were produced in a fully active and highly purified form.[10] To determine the relative specificity and selectivity of these PCs for two of the most commonly used PC substrates, we measured the Michaelis−Menten kinetic parameters for the PC-catalyzed hydrolysis of the substrates (Table 1). This comparative study showed that furin is 2−20-fold more reactive than PC4−PC7 primarily because of the faster chemical conversion step (k_{cat}).

Serpin B8 Is a Specific and Selective Furin Inhibitor. We have previously determined that serpin B8 inhibits furin at a physiologically relevant rate.[10] If serpin B8 is a specific and selective natural furin inhibitor, then it should react much more rapidly with furin than with PC4−PC7. To test this hypothesis, the rate of inhibition of PC4, PC5, PACE4, and PC7 by serpin B8 was measured using our stabilized recombinant form of serpin B8 that we previously described,[10] in which five external or internal cysteine residues were mutated to serine or alanine, respectively (Table 2). Serpin B8 reacted ∼20-fold slower with PC4−PC7 ($k_a = 1 \times 10^4$ M^{-1} s^{-1}) than with furin ($k_a = 2 \times 10^5$ M^{-1} s^{-1}). Serpin B8 is thus significantly more selective for inhibiting furin over PC4−PC7.

The Serpin B8 P6−P5′ RCL Segment Confers Greater Furin Selectivity in α1PDX Than in Serpin B8. We previously determined that the primed and nonprimed regions of the serpin B8 RCL, when grafted onto the RCL of the serpin α1PDX, play critical roles in influencing reactivity with furin.[10] The same analysis was applied here to investigate the role that these two serpin B8 RCL regions play in determining the differential reactivity between furin and PC4−PC7. Serpins share the same general structure and a suicide substrate mechanism of inhibition of proteases that results in the formation of a conformationally trapped serpin−protease covalent complex (Figure S1).[17] α1PDX is a derivative of the serpin α1-antitrypsin that was developed as a specific furin inhibitor by grafting the P4Arg-X-X-P1Arg PC recognition sequence onto the RCL.[18] We found that α1PDX is equally reactive with furin, PC4, PC5, PACE4, and PC7, all of the PCs being inhibited efficiently by α1PDX at similar rates (10^6 M^{-1} s^{-1}) and with stoichiometries of inhibition of 1:1 (Table 2). A previous report[16] found differences in α1PDX reactivity with some of these PCs based on an erroneous characterization of serpin reactivity by K_i values instead of k_a values.[19] The serpin B8 RCL P6−P5′ segment (Figure 1), when placed at its homologous location in the RCL of α1PDX, resulted in a chimera that reacted with furin 10-fold slower (10^5 M^{-1} s^{-1}) than α1PDX, similar to serpin B8 (Table 3). However, the P6−P5′ chimera reacted with PC4−PC7 much slower than serpin B8 and in a biphasic manner distinct from the monophasic reaction with furin (Figure 2A). The P6−P5′ chimera thus caused an immediate inhibition of a fraction of the protease activity followed by a slower exponential inhibition of the remaining activity (Figure 2C). This behavior suggested that an initial rapid equilibrium binding of the serpin and protease to form a Michaelis complex was kinetically separated from the slower acylation of the Michaelis complex to form the conformationally trapped serpin−protease covalent complex. Indeed, the serpin concentration dependence of the initial rapid inhibition phase was consistent with K_d values of ∼1 μM for formation of the Michaelis complex (Figure 2B and Table 4), whereas the subsequent exponential reaction phase indicated first-order rates of acylation of the Michaelis complex ($k_{obs} \sim 10^{-4}$ s^{-1}) that were ∼100-fold slower than k_{cat} values measured for the hydrolysis of the tetrapeptide fluorogenic substrates by PC4−PC7 (Table 5). Because of the kinetic separation, the contributions to overall reactivity ($k_a = k_{cat}/K_m$) by the binding (K_m) and chemical (k_{cat}) steps can be calculated separately. The K_m equals the K_d for the rapid equilibrium formation of the Michaelis complex, and the k_{cat} can be calculated by dividing k_{obs} for formation of the covalent complex by the fractional saturation of the Michaelis complex (Figure 2C and Table 5). Values of k_a calculated from k_{cat}/K_d ratios (10^2 M^{-1} s^{-1}) were several thousand-fold lower than k_a values for reactions of α1PDX with PC4−PC7 (Table 3). The serpin B8 P6−P5′ segment when grafted onto α1PDX thus amplified the differences in reactivity observed for serpin B8 with furin and PC4−PC7.

The Serpin B8 P6−P1 RCL Segment Determines PC Selectivity. To define the origin of the large difference in

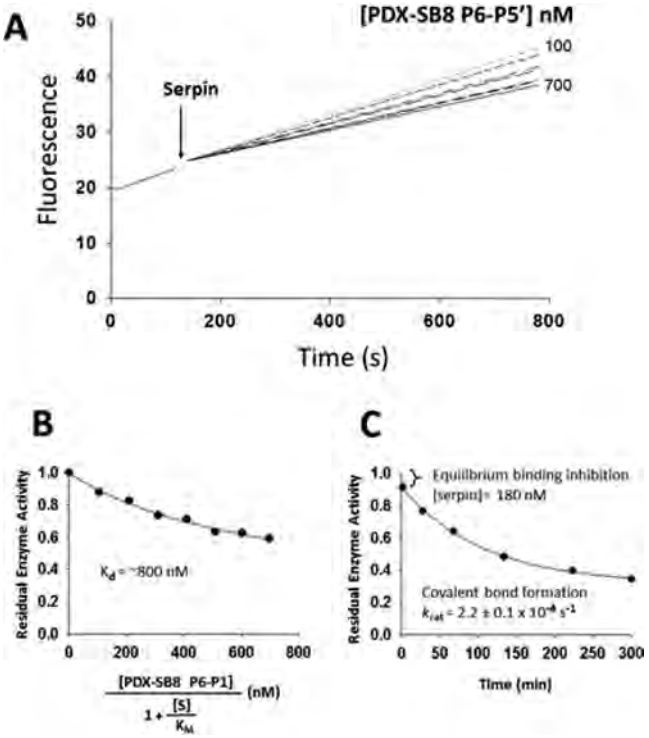

Figure 2. Reaction of the α1PDX−serpin B8 P6−P5′ chimera with PACE4. (A) Plots of PACE4 residual activity at increasing concentrations of the α1PDX−serpin B8 P6−P5′ chimera. Progressive reactions of 2 nM PACE4 activity with 10 μM fluorogenic substrate pyr-Arg-Thr-Lys-Arg-amido-methylcoumarin under protease activity assay conditions were performed as described in Materials and Methods. (B) Fitted plot of the dependence of residual PACE4 activity on increasing concentrations of the serpin chimera that were corrected for the fluorogenic substrate concentration [S]. The plot was fitted to the quadratic tight binding equation of Morrison.[21] Similar results were obtained with PC4, PC5, and PC7, and K_d values are listed in Table 4. (C) Plot of residual PACE4 activity for the inhibition of 50 nM PACE4 by 1.4 μM serpin chimera. The initial decrease in activity reflects the fast equilibrium binding for the formation of the Michaelis complex that precedes slow covalent complex formation.

reactivity between furin and PC4−PC7 observed with the P6−P5′ chimera, the serpin B8 P6−P1 segment was alone grafted onto the RCL of α1PDX. In contrast to the P6−P5′ segment, the P6−P1 segment resulted in a 2-fold increase in reactivity with furin (2×10^6 M^{-1} s^{-1}) (Table 3). However, the P6−P1 chimera reacted with PC4−PC7 like the P6−P5′ chimera did, i.e., with a greatly reduced overall reactivity relative to α1PDX and biphasic kinetics of inhibition (Figure 3A). Surprisingly, the chimera formed Michaelis complexes in an initial rapid equilibrium binding step that exhibited affinities ∼100-fold stronger than those of the P6−P5′ chimera (K_d values of 7−15 nM) (Figure 3B and Table 4). Moreover, the subsequent slower exponential phase reflecting conversion of the noncovalent Michaelis complex to the covalent inhibitory complex (Figure 3C) exhibited k_{cat} values minimally 10-fold slower than those observed with the P6−P5′ chimera ($\leq 10^{-5}$ s^{-1}) (Table 5). This slow reactivity was confirmed by electrophoresis analysis of the serpin chimera−PC reaction that showed minimal reaction of the serpin to form a covalent complex or to be cleaved as a substrate over the time frame in which covalent complexes formed with the P6−P5′ chimera. Calculated k_a values for PACE4 and PC7, for which k_{cat} values were measurable, were determined from the k_{cat}/K_d ratios (10^3 M^{-1} s^{-1}) to be 100−1000-fold lower than those for the reaction of α1PDX with PC4−PC7 (Table 3).

Further reducing the size of the grafted serpin B8 RCL to only the P6−P5 segment produced a chimera with PC reactivity that resembled that of the P6−P1 chimera. This chimera thus increased the reactivity with furin 2-fold and reduced the reactivity with PC4−PC7 relative to α1PDX (Figure 4A). Moreover, the kinetics of PC inhibition was monophasic for furin and biphasic for PC4−PC7. However, unlike the immediate equilibrium formation of the Michaelis complex observed for the P6−P1 chimera reaction, the P6−P5 chimera showed a slower approach to the Michaelis complex binding equilibrium (Figure 4A). Notably, Michaelis complex affinities for the interaction of the P6−P5 chimera with PC4−PC7 were 10−30-fold greater than those for the P6−P1 chimera (K_d values of 0.4−1 nM) (Figure 4B and Table 4). Moreover, the conversion of the Michaelis complex to the covalent complex in the subsequent slow exponential phase indicated that k_{cat} values were 3−12-fold faster for the P6−P5 chimera than for the P6−P1 chimera ($1-3 \times 10^{-4}$ s^{-1}) (Figure 4C and Table 5). As a result, k_a values calculated from k_{cat}/K_d ratios were larger for the P6−P5 chimera than for the P6−P1 chimera (10^5-10^6 M^{-1} s^{-1}) and approached those for the reactions of α1PDX with PC4−PC7 (Table 3). Like the P6−P5′ and P6−P1 chimeras, the serpin B8 P6−P5 substitution in α1PDX thus resulted in the formation of stable high-affinity Michaelis complexes with PC4−PC7 that were poorly reactive in forming a conformationally trapped covalent complex.

The grafting of the serpin B8 RCL P3−P2 segment led to losses of α1PDX reactivity of ∼10-fold with furin (10^5 M^{-1} s^{-1}) and ∼1000-fold with PC4−PC7 (∼10^3 M^{-1} s^{-1}) (Table 3). In contrast to the reaction of the P6−P5 chimera, the reaction of the P3−P2 chimera with PC4−PC7 showed an initial equilibrium binding of low affinity that was not measurable at the inhibitor concentrations used. The serpin B8 P3−P2 segment thus decreased the reactivity of α1PDX with all PCs, but especially with PC4−PC7.

Together, these results suggest that the RCL P6−P1 segment contributes to the enhanced substrate selectivity

Table 4. Dissociation Constant Values for the Binding of PCs to α1PDX−Serpin B8 RCL Chimeras[a]

	equilibrium binding dissociation constant, K_d (nM)				
α1PDX−serpin B8 chimera	furin	PC4	PC5	PACE4	PC7
P6−P5′	–	∼1400	∼1000	∼800	∼1500
P6−P1	–	13 ± 1	7.8 ± 0.8	9.1 ± 0.7	15 ± 0.9
P6−P5	–	0.52 ± 0.01	0.62 ± 0.01	1.0 ± 0.1	0.41 ± 0.06

[a]Equilibrium binding dissociation constant (K_d) values were determined from the fittings of plots of the dependence of residual PC activity on inhibitor concentration described in panels B of Figures 2−4. Errors represent the standard error from linear regression fits of data.

[a]Comparison of k_{cat} values for the catalyzed hydrolysis of two tetrapeptide fluorogenic substrates by PCs (taken from Table 1) against the k_{cat} values obtained from the reaction of PCs with three α1PDX−serpin B8 RCL chimeras. These reactions, which are described in Figures 2−4, occur on the basis of initial rapid formation of high-affinity Michaelis complexes followed by slower chemical step reactivity leading to covalent complex formation. The k_{cat} values for the chemical step were obtained from the equation $k_{obs} = k_{cat} \times$ fractional occupation. The reactions of furin with serpins were monophasic; therefore, the value of k_{cat} could not be determined.

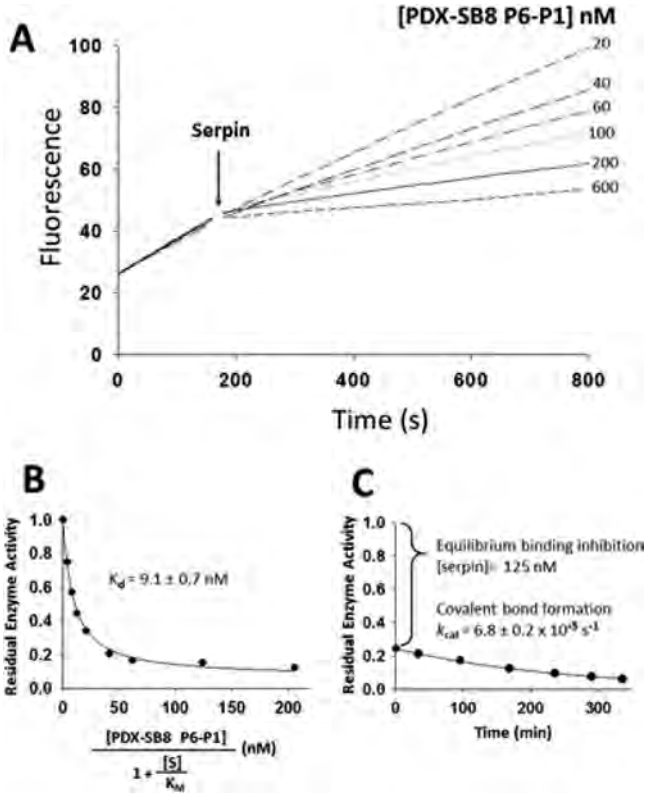

Figure 3. Reaction of the α1PDX−serpin B8 P6−P1 chimera with PACE4. (A) Plots of PACE4 residual activity at increasing concentrations of the α1PDX−serpin B8 P6−P1 chimera. Progressive reactions of 5 nM PACE4 were performed as described in the legend of Figure 2. (B) Fitted plot of the dependence of residual PACE4 activity on increasing concentrations of the serpin chimera as described in the legend of Figure 2. Similar results were obtained with PC4, PC5, and PC7, and K_d values are listed in Table 4. (C) Plot of residual PACE4 activity for the time course of inhibition of 50 nM PACE4 by 1.0 μM chimera. The large initial decrease in activity reflects the fast equilibrium binding for the formation of the Michaelis complex that precedes slow covalent complex formation.

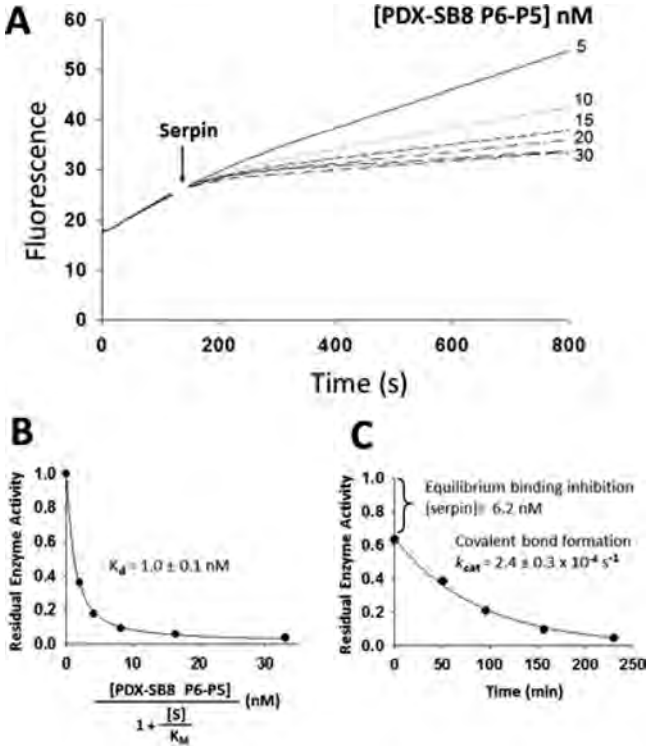

Figure 4. Reaction of the α1PDX−serpin B8 P6−P5 chimera with PACE4. (A) Plots of PACE4 residual activity at increasing concentrations of the α1PDX−serpin B8 P6−P5 chimera. Progressive reactions of 3 nM PACE4 were performed as described in the legend to Figure 2. (B) Fitted plot of the dependence of residual PACE4 activity on increasing concentrations of the serpin chimera as described in the legend of Figure 2. Similar results were obtained with PC4, PC5, and PC7, and K_d values are listed in Table 4. (C) Plot of residual PACE4 activity for the time course of inhibition of 2 nM PACE4 by 50 nM chimera. The large initial decrease in activity reflects the fast equilibrium binding for the formation of the Michaelis complex that precedes slow covalent complex formation.

between furin and PC4−PC7 observed with the P6−P5′ chimera.

The P2′ Residue Determines PC Reaction Specificity. In contrast to the effect of the P6−P1 segment, the serpin B8 RCL P1′−P5′ segment decreased α1PDX reactivity with furin, 20-fold, and PC4−PC7, 40−80 fold (10^4 M^{-1} s^{-1}) (Table 3). No kinetic separation of the formation of the Michaelis and covalent complexes was observed for this chimera. Single-residue substitutions within the P2′−P4′ region identified the P2′ substitution as the most detrimental to reactivity as it reduced α1PDX reactivity 17-fold with furin and 60−120-fold with PC4−PC7 (10^4 M^{-1} s^{-1}), similar to the effect produced by substituting the full P1′−P5′ region (Table 3). The effect of the P3′ and P4′ serpin B8 residue substitutions on α1PDX reactivity with all PCs was comparatively modest (10^5−10^6 M^{-1} s^{-1}). The lack of importance of the P1′ residue in terms of PC substrate specificity and selectivity was shown by a serine

[a]The tyrosine (Y) and glutamic acid (E) exosite residues were grafted at their homologous location in strand 3 of sheet C of α1PDX and the P6−P5′ chimera. Serpin B8 has the conserved residue phenylalanine at the position of the tyrosine residue. Second-order association rate constant (k_a) values for the reaction of PCs with the chimeras α1PDX+YE exosites and the α1PDX−serpin B8 RCL P6−P5′+YE exosites were determined as described in Table 3. Errors represent the standard error from linear regression fits of data. The k_a values for the reaction of furin with both chimeras were taken from ref 10. The k_a values for the reaction of α1PDX and the P6−P5′ chimera with all PCs were taken from Tables 2 and 3 and included for comparison.

to aspartic acid mutation that had a <10-fold detrimental effect on α1PDX reactivity with all PCs (Table 6).

Exosites Selectively Regulate Reactivity with PCs. We have previously shown that the homologous grafting of the serpin B8 strand 3C exosite residues onto α1PDX or the α1PDX−serpin B8 P6−P5′ chimera leads to losses of reactivity with furin of 5-fold (10^5 M^{-1} s^{-1}) or 70-fold (10^3 M^{-1} s^{-1}), respectively.[10] In stark contrast, the serpin B8 exosite residues increased α1PDX reactivity with PC4−PC7 by 3−9-fold (10^6−10^7 M^{-1} s^{-1}) but reduced reactivity of the α1PDX−serpin B8 P6−P5′ chimera with PC4−PC7 by 8−30-fold (10 M^{-1} s^{-1}) (Table 7).

The Catalytic-Site Conformations of Furin and PC4−PC7 Differ. Protein crystallography and MDS studies have shown that the catalytic site of furin adopts active and inactive conformations and have suggested that substrates preferentially bind to the active conformation through conformational selection or induced fit binding mechanisms.[7,8] The kinetic studies described above show that unlike furin, the catalytic site of PC4−PC7 may adopt inactive conformations that preferentially bind substrate nonproductively. To investigate the basis for such differences, we compared the catalytic-site conformations of furin and PC4−PC7 by MDS. Homology models of the whole catalytic domain for PC4−PC7 were built on the basis of the X-ray crystal structures of the ligand-free and ligand-bound forms of furin. Although the amino acid sequence is 50−65% conserved between furin and PC4−PC7, the structures are expected to be highly conserved.[8] MDS were performed on 10 simulated systems of five proteins and two different conditions: (1) ligand-free form associated with active and inactive configurations and (2) ligand-bound form associated with only active configurations. A principal component analysis (PCA), constructed on a common structural core of 313 Cα atoms in the catalytic domain, was performed employing MDS trajectories for a global evaluation of the structures (Figure 5A). The analysis showed well-resolved and distinct active and inactive furin conformations in agreement with previous studies.[7] PC4−PC7 showed the most pronounced differences in PACE4 and, especially, in PC7 for the ligand-free forms. The ligand-bound forms were more consistent with furin, except for PC7. A second PCA was performed on five Cα atoms located in the catalytic site. Again, furin produced two clearly distinguishable sets of conformations corresponding to active and inactive states (Figure 5B). In agreement, PC4−PC7 also produced clearly differentiated active and inactive conformations. Only the ligand-free conformations of PC4−PC7 showed more variability compared to furin, especially that of PC7.

DISCUSSION

Despite the large body of information regarding how PCs regulate the growth, proliferation, and differentiation of cells in numerous physiological and pathological processes, a molecular understanding of how PCs perform their specific regulatory functions has remained elusive.[22] Because PCs are co-expressed and overlap at their cellular location, significant cross-reactivity seems to be unavoidable, and the significance of the redundant targeting of substrates by PCs is unclear. However, examples of PCs with opposite regulatory effects imply that PCs should be able to target their substrates selectively.[23] A recurrent theme is that of furin and PC4−PC7 playing opposite roles by targeting the same protein but in a selective manner involving different recognition sites.[24,25] The basis for this PC selectivity has not been well characterized. In this study, serpin B8 was demonstrated to react with furin selectively on the basis of a 20-fold faster reactivity with furin than with PC4, PC5, PACE4, and PC7 (Table 2). In addition, it was shown that furin catalyzes the hydrolysis of two

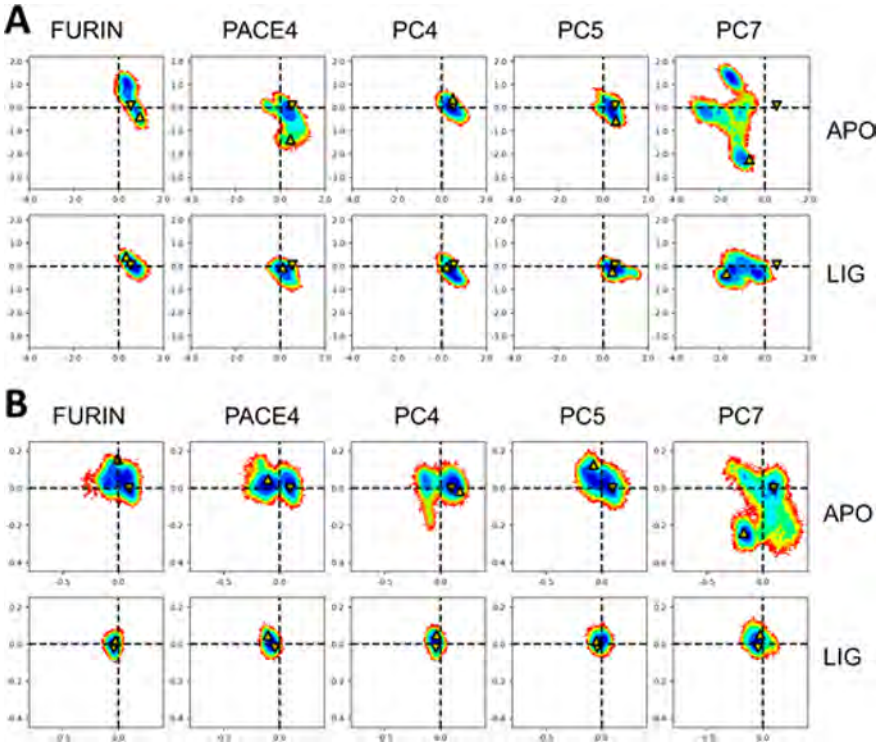

Figure 5. Molecular dynamics simulation analysis of the structure of PCs. The configuration of amino acid residues in the catalytic domain of furin, PC4, PC5, PACE4, and PC7 was simulated employing furin crystal structures and molecular models of the catalytic domain of PC4−PC7 based on the X-ray crystal structure of the ligand-free and ligand-bound furin, as described in Materials and Methods. Two different starting structure conditions were employed: (i) ligand-free form, which is associated with active and inactive configurations, and (ii) ligand-bound form, which is associated with only active configurations. Shown are molecular dynamics trajectories from the simulated systems projected on the first two principal components (nanometers). These projections are presented as heat maps where blue represents highly populated states. The maps derived from scenario i are labeled as APO, and the ones from scenario ii as LIG. The arrows pointing down correspond to the starting frame, which is the furin crystal structure. The arrows pointing upward correspond to the last frame of the analysis. (A) Comparative MDS analysis of the PC catalytic domain. PCA performed over 313 Cα atoms of amino acid residues. (B) Comparative MDS analysis of the PC catalytic site. PCA performed over five Cα atoms of catalytic-site amino acid residues (Asp153, His194, Gly255, Asn295, and Ser368).

tetrapeptide substrates at a faster catalytic rate, especially with the substrate Boc-Arg-Val-Arg-Arg-AMC (20-fold), than PC4−PC7 (Table 1). These observations suggested that furin and PC4−PC7 differ in substrate specificity and selectivity. Following the same rationale that we used to study the reactive-site and exosite elements of serpin B8 that determine reactivity with furin,[10] we used α1PDX as a model substrate to determine the basis for the differences in serpin B8 reactivity between furin and PC4−PC7 by the homologous transferring of RCL and exosite amino acid residues from serpin B8 to α1PDX.

Notably, the serpin B8 P6−P5′ RCL segment induced a difference in reactivity between furin and PC4−PC7 that was significantly larger within α1PDX (140−400-fold) than within serpin B8 (20-fold) (Tables 2 and 3). This disparity argues that the conformation that the serpin B8 RCL P6−P5′ segment adopts in the α1PDX context accentuates the difference in reactivity between furin and PC4−PC7. Unexpectedly, the α1PDX−serpin B8 P6−P5′ chimera reacted with furin with monophasic kinetics but reacted with PC4−PC7 with biphasic kinetics. The serpin thus bound rapidly to PC4−PC7 to form a Michaelis complex in the first kinetic phase, and this complex then slowly underwent acylation to form the trapped covalent serpin−enzyme complex in the second phase. The marked reduction in the rate of the second catalytic step therefore accounted for the biphasic kinetics and large reduction in overall reactivity of the chimera with PC4−PC7. The chimera thus by binding to the more variable catalytic site of PC4−PC7 than furin, as shown by the MDS experiments (Figure 5), may be favoring nonproductive conformations of the catalytic site.

The grafting of smaller segments of the RCL showed the P6−P1 segment and, in particular, the P6−P5 residues were responsible for the marked difference in reactivity between furin and PC4−PC7. By contrast, the serpin B8 P3−P2 residues did not produce biphasic reaction kinetics with PC4−PC7 but did result in marked reductions in reactivity with both furin (10-fold) and PC4−PC7 (1000-fold). The effects of other mutations of the P3 and P2 residues in α1PDX are also consistent with such mutations affecting reactivity more with PC4−PC7 than with furin (Table 6).

The major effects of the P6−P5 and P3−P2 residues, which flank the P4 Arg residue, on the reactivity of the P6−P1 chimera with PC4−PC7 suggest that the conformation of the P6−P1 segment plays a key role in regulating the productive insertion of the P4 arginine side chain into the S4 pocket of the enzyme catalytic site. Consistent with this idea, the level of PC reactivity of the P6−P1 chimera ($10-10^2$ M^{-1} s^{-1}) is comparable to that of α1-antitrypsin Pittsburgh (10 M^{-1} s^{-1}) (Table 6), a natural mutant of α1-antitrypsin,[20] which has an arginine for methionine substitution at the P1 position but lacks the P4 arginine (Figure 1).

The P1′−P5′ chimera led to significant losses of reactivity with all PCs (Table 3). The finding that the P2′ chimera

DOI: 10.1021/acs.biochem.8b01295
Biochemistry 2019, 58, 1679−1688

largely accounted for the losses in reactivity indicated that the P2′ residue was principally responsible for the detrimental effect of the serpin B8 primed region on α1PDX reactivity. Like α1PDX, the P1′−P5′ and P2′ α1PDX chimeras showed little selectivity in their reaction with furin and PC4−PC7. This region thus contributes to general PC specificity but not to selectivity.

The contribution of the primed region of the RCL to PC reactivity was also shown to be influenced by exosite interactions. In our previous study of furin reactivity, we showed that of the four furin active-site loops, only the 298−300 loop is involved in the exosite regulation of furin reactivity.[10] We also demonstrated that the 298−300 furin loop, of which Arg298 forms part of the S2′ pocket in the catalytic site,[8] mediates the interactions of the exosite residues in strand 3C of the serpin with the primed region of the RCL (Figure S2). In this study, we further advanced this notion by establishing that the exosite residues selectively affected PC reactivity depending on the RCL primed region amino acid sequence. While the serpin B8 exosite residues were detrimental to reactivity with all of the PCs in the presence of the serpin B8 primed region, they negatively affected furin reactivity but promoted reactivity with PC4−PC7 in the context of the α1PDX primed region (Table 7). These observations strongly suggest that the exosite residues modulate the insertion of the P2′ residue into the S2′ pocket and can regulate substrate selectivity between furin and PC4−PC7. Thus, the P1′−P5′ segment serves as a determinant of general PC substrate specificity that can be modulated by exosites.[10,25]

Our demonstration of differences in substrate specificity and selectivity between furin and PC4−PC7 significantly advances our understanding of the molecular determinants of specificity and selectivity in the PC family of proteases. Our findings thus clearly establish the ability of PCs to differentiate target substrates on the basis of the recognition of different preferred substrate cleavage sequences. Moreover, our findings underscore the importance of the structural context of such recognition sequences and the ability of exosites to influence this context.[26] Finally, they establish that substrate recognition can be favored or disfavored by differential abilities of furin and PC4−PC7 to bind their substrates productively versus nonproductively, due to differences in catalytic-site conformational states of PCs. Interestingly, such differences may be exploited to engineer selective inhibitors of PC4−PC7 as shown by the nanomolar Michaelis complex affinities observed for P6−P1 and P6−P5 chimera interactions with these PCs (Table 4).

Serpins are the only known natural PC inhibitors.[10−14] Protein-based inhibitors have an advantage over small molecule inhibitors in that they can be expressed by the targeted cell and directed to specific subcellular locations.[18,27] We have demonstrated that serpin B8 is a specific and selective furin inhibitor and shown that introducing serpin B8 reactivity determinants into the engineered general PC inhibitor, α1PDX, results in added selectivity for furin or for PC4−PC7 (Figure 1). The P6−P5′ chimera (now named α1ORD) achieves a 140−400-fold higher reactivity with furin than with PC4−PC7 (Table 3). Although this chimera forms inhibitory Michaelis complexes with PC4−PC7, the binding affinity is weak (K_d = 1 μM) and minimal inhibition is expected at concentrations of <1 μM. The α1PDX+YE derivative (now named α1MDW) is selective for PC4−PC7 with 20−60-fold higher reactivity with these PCs than with furin (Table 7). These inhibitors, and their future improved derivatives, should become useful tools in efforts to understand the regulatory role of PCs and to discover new therapeutic drugs.

Abstract

For more than three decades it has been known, that striatal neurons become hyperactive after the loss of dopamine input, but the involvement of dopamine (DA) D1- or D2-receptor-expressing neurons has only been demonstrated indirectly. By recording neuronal activity using fluorescent calcium indicators in D1 or D2 eGFP-expressing mice, we showed that following dopamine depletion, both types of striatal output neurons are involved in the large increase in neuronal activity generating a characteristic cell assembly of particular neurons that dominate the pattern. When we expressed channelrhodopsin in all the output neurons, light activation in freely moving animals, caused turning like that following dopamine loss. However, if the light stimulation was patterned in pulses the animals circled in the other direction. To explore the neuronal participation during this stimulation we infected normal mice with channelrhodopsin and calcium indicator in striatal output neurons. In slices made from these animals, continuous light stimulation for 15 s induced many cells to be active together and a particular dominant group of neurons, whereas light in patterned pulses activated fewer cells in more variable groups. These results suggest that the simultaneous activity of a large dominant group of striatal output neurons is intimately associated with parkinsonian symptoms.

INFORME DE LABORES 2019

1 | INTRODUCTION

Since pioneering work in the 1970s we know that unilateral destruction of dopamine (DA) neurons in the rodent mesencephalon induces unilateral hypokinesia, deviated posture, and spontaneous circling or turning behavior toward the lesion side (Ungerstedt & Arbuthnott, 1970). This experimental model of Parkinson's disease (PD) was initially useful in pharmacological studies and it is still useful in the characterization of function of basal ganglia outputs (Greco et al., 2008). However, one of the most striking initial findings using this model is that unilateral destruction of striatal DA input is accompanied by an increase in activity of striatal neuronal activity on the ipsilateral side (Arbuthnott, 1974; Hull, Levine, Buchwald, Heller, & Browning, 1974; Ohye, Bouchard, Boucher, & Poirier, 1970; Schultz, 1982; Schultz & Ungerstedt, 1978).

It is characteristic of striatal projection neurons (SPNs), in anaesthetized animals, that in spite of a correlation between cortical rhythmic activity and membrane potential fluctuations (up and down states) they do not fire rhythmically or synchronously in the presence of DA. However, in the absence of DA, the cortically induced rhythmicity is dramatically increased from less than 1 burst/min to more than 2.5 bursts/min as seen in anesthetized (Arbuthnott, 1974; Nisenbaum, Stricker, Zigmond, & Berger, 1986; Schultz & Ungerstedt, 1978) and awake animals (Chen, Morales, Woodward, Hoffer, & Janak, 2001; Kish, Palmer, & Gerhardt, 1999; Ohye et al., 1970) as well as in vitro (Calabresi, Mercuri, Sancesario, & Bernardi, 1993; Galarraga, Bargas, Martinez-Fong, & Aceves, 1987). Rhythmic bursting of SPN output targets in the absence DA is a consistent finding (Bergman, Wichmann, Karmon, & DeLong, 1994; MacLeod, Ryman, & Arbuthnott, 1990; Murer, Riquelme, Tseng, & Pazo, 1997; Murer, Tseng, Kasanetz, Belluscio, & Riquelme, 2002; Ni, Bouali-Benazzouz, Gao, Benabid, & Benazzouz, 2000; Nini, Feingold, Slovin, & Bergman, 1995; Pan & Walters, 1988; Rohlfs et al., 1997; Sanderson, Mavoungou, & Albe-Fessard, 1986; Wichmann et al., 1999).

Concurrent pharmacological blockade of DA receptor 1 (D1) and DA receptor 2 (D2) SPNs produces an akinesia (often mischaracterized as catalepsy) similar to a DA lesion, but specific blockade of D1 or D2 SPNs indicates that synchronous activity is affected in greater extent by D1 compared to D2 receptor antagonists (Burkhardt, Jin, & Costa, 2009).

In order to understand the role of DA in specific subpopulations of SPNs we used calcium imaging of individual D1- or D2-expressing enhanced eGFP to visualize their activity and study their characteristic patterns of activation in cell assemblies. Moreover, we used calcium imaging and optogenetics to illustrate the specific contribution of both D1 and D2 microcircuits in the generation of the pathological circling behavior characteristic of the animal model of PD.

2 | MATERIAL AND METHODS

2.1 | Ethical standards

We used a total of 64 of 78 (14 discarded as failures in procedure or stereotaxic coordinates) Swiss Webster bacterial artificial chromosome (BAC) transgenic mice D1- enhanced fluorescent protein (eGFP) and D2-eGFP (postnatal 21–25 days, males) or C57BL/6J control mice were used. Animals were bred in the university's animal facilities. In general, we adjust the number of animals in our experiments according to the mortality rates after surgeries, the success rate of stereotaxic placement of viral injections and the general success of the experiments considering the expertise of trainees. Our experiments complied with the Guide for the care and use of laboratory animals of the US National Institutes of Health; the Society for Neuroscience Policy on the Use of Animals in Neuroscience Research and the Guiding Policies and Principles for Experimental Procedures endorsed by the government of Japan and supervised by the local Animal Care and Use Committee, approved protocol number 2018-212-2.

2.2 | Stereotaxic surgeries

Surgeries were performed under aseptic conditions in a small animal stereotaxic instrument (Leica Angle Two, Leica Biosystems, Wetzlar, Germany). Isoflorane inhalation (IsoFlo, Abbot, 1.0%–1.5% in medical O_2) was used as anesthetic and the respiratory rate, heart rate, and hindpaw withdrawal reflexes were monitored throughout the procedure to maintain an adequate anesthetic level as stably as possible. Animals were fixed with atraumatic earbars, the cornea protected with mycochlorin ointment 2% and the skin rubbed with anesthetic gel (10% ketoprofen and lidocaine). Post-operative care measures to control hypothermia, dehydration and pain included keeping mice warm until they came out of anesthesia (<15 min) by placing them on a disposable heating pad, administering sterile saline (0.5 ml, s.c.) immediately after surgery and leaving available, during the first 72 hr after surgery, a can of diet gel with carprofen (e.g., MediGel CPF, Portland, ME, USA). One-to-two weeks after surgery, animals were tested or the brain extracted.

For the intracerebral unilateral administration of the neurotoxin 6-hydroxydopamine (6-OHDA, Sigma), mice were premedicated 1 hr before surgery with desipramine HCl (25 mg/kg base, in 0.9% sterile saline, subcutaneous). The 6-OHDA (0.5 µl of 4 mg/ml in 0.9% NaCl and 0.5% ascorbate)

INFORME DE LABORES 2019

was slowly injected (0.01 µl/min) at stereotaxic coordinates (Franklin & Paxinos, 2008) aimed to the left substantia nigra pars compacta (bregma: AP, −2.3 mm; L, 0.7 mm and from dura: V, −4.3 mm). These animals were challenged with apomorphine (Sigma, 0.01 mg/kg, subcutaneous) 1 week after surgery and turning behavior was automatically evaluated by protocols written under Ethovision XT 11 animal tracking system (Noldus, Wageningen, The Netherlands). Behavioral measurements were counted for 5 min after being placed in the recording environment. Only animals showing robust turning (>5 turns/min) were considered to have adequate DA depletion.

To induce viral infection in SPNs, adeno-associated viruses (AAV) were intracerebrally delivered D1-eGFP and D2-eGFP BAC mice. The AAV10 under the human origin elongation factor-1 alpha (EF1a) promoter was used to drive expression of channelrhodopsin variant 2 (ChR2) and the fluorescent protein 2mCherry. The AAV1 under the human promoter of synapsin 1 (hSyn) was used for the expression of the genetically engineered red calcium indicator (RCaMP1h, Penn Vector Core, AV-1-PV3010). Either a single AAV (0.3 µl) or a combination of both (0.15 µl each) was unilaterally injected in the left dorsal striatum of D1-eGFP and D2-eGFP BAC mice (AP, 0.98 mm; L, 1.89 mm; V −3.45 mm) (Franklin & Paxinos, 2008).

Animals that received AAV1 RCaMP1h were left for at least 2 weeks to recover and allow viral expression before in vitro recording experiments. Animals that received AAV-10 ChR2-2mCherry injection had a longer surgery since a 3 mm stainless steel guide cannula (25 gauge) was inserted above the injection site and fixed to the skull with a small amount of dental cement (Super-Bond C&B, Sun Medical) followed by a 5-mm-long optic fiber (diameter: 260 µm, length 5.45 mm, Teleopto, Nagoya, Japan) placement into the injection site. A device containing the optic fiber, the high-intensity light-emitting diode (LED; 470 nm) and a connector to plug the wireless receiver was also fixed to the skull with more dental cement.

2.3 | Behavioral observations

To allow viral expression, animals were housed for at least 2 weeks before any recording or behavioral observation was performed. A couple of days before the experiments, animals were first trained for 20 min to carry a mock receiver (12 × 18 × 7 mm, 2 g) plugged to the wireless stimulation system in their home cage. On the experiment day, the infrared receiver (Teleopto, Nagoya, Japan) with the same dimensions and weight, replaced the mock receiver and animals were placed in a rectangular (45 × 20 × 15 cm) or circular (15 cm diameter × 20 cm high) testing chamber.

The stimulation device (Teleopto, Nagoya, Japan) triggered a LED of 470 nm (blue light) with intensity at the tip of 1.0 mW. Behavioral procedures consisted of a period of habituation (≈5 min) followed by a sequence of three periods repeated 10 times: 20 s pre-stimulation, 15 s of light stimulation either delivered continuously or in patterned pulses (6 ms pulses at 14 Hz) and a 30–60 s post-stimulation period. Turning behavior was measured and evaluated automatically by protocols written under Ethovision XT 11 animal tracking system (Noldus, Wageningen, The Netherlands).

2.4 | Corticostriatal slice preparation

Mice were anesthetized with isoflorane inhalation and perfused transcardially using cold saline containing (in mM): 124 choline chloride, 2.5 KCL, 1.3 $MgCl_2$, 26 $NaHCO_3$, 1.2 NaH_2PO_4–H_2O, 1 $CaCl_2$ and 10 glucose saturated with 95% O_2 and 5% CO_2, pH = 7.4, 298 mOsm/L. Sagittal corticostriatal slices (200–250 µm) were cut (Leica VT1200S, Nussloch, Germany) and transferred to regular artificial cerebral spinal fluid containing the following in mM: 123 NaCl, 3.5 KCl, 1 $MgCl_2$, 1 $CaCl_2$, 26 $NaHCO_3$, and 11 glucose, saturated with 95% O_2 and 5% CO_2, where they remained at room temperature (21–25°C) for at least 1 hr before recording.

2.5 | In vitro recordings of neuronal activity

For recordings of neuronal calcium activity Fluo-4 or RCaMP1h, corticostriatal slices (210–250 µm) of D1-eGFP or D2-eGFP BAC mice were visualized using an upright microscope (Olympus BX51W1F, Japan, 100W halogen lamp) fitted with brightfield (UM Plan FL 10×) and water immersion (10× Olympus) objective. The microscope was also equipped with a cooled charge-coupled device (CCD) camera (PCO.EDGE, Kelheim, Germany) with a field view of 800 × 600 µm; acquisition of images was set to 5–6 images/s. At the beginning of each experiment coordinates and landmarks of the displayed image were stored for reference and subsequent analysis. Experimental data were recorded using the CCD camera with acquisition protocols written in camware software. Short movies (180 s, 50–100 ms exposure, 250–500 ms/frames) were taken at time intervals of 5–20 min during 1–2 hr). At the end of the experiment potassium depolarization (mM): 50 KCl, 120 NaCl, 10 HEPES-Na, and 2 $CaCl_2$ pH7.4, was applied for 5 s to validate slice integrity, slices with small numbers of responsive cells (<10) were discarded from the analysis.

When a cell-permeant calcium indicator was used, slices were incubated in the dark at 38°C for 20–30 min with Fluo-4 (Fluo-5AM in few occasions) in 0.1% dimethyl sulfoxide diluted to a final concentration of 10 µM, pH 7.4 (95%O_2 and 5%CO_2). Once loaded with the calcium indicator, slices were transferred back to the microscope's recording chamber perfused with artificial cerebrospinal fluid.

The pair ChR2 and RCaMP provided independent addressable spectral channels. For neuronal activation with

INFORME DE LABORES 2019

ChR2 and imaging via the genetically encoded red calcium indicator RCaMP1h and RCaMP1 h activation was achieved using excitation pulses at 580 nm delivered by a xenon-arc lamp of (Lambda LS Sutter Instruments) and a bandpass filter (FB580-10, ThorLabs, Newton, NJ, USA). A combined non-overlapping calcium imaging/optogenetics was possible since light of 580 nm—the peak activation for RCaMP1h—does not activate ChR2 (Glock, Nagpal, & Gottschalk, 2015). The emitted RCaMP1h fluorescence was passed through a long pass filter (550 nm, FEL0550, ThorLabs, Newton, NJ, USA) (Akerboom et al., 2013). Optogenetic stimulation (488 nm) was achieved using a fiber-coupled LED light source (DC2100, OGKR2 Thorlabs. Newton, NJ, USA). The same optogenetic stimulation parameters (continuous or in 14 Hz pulses) were used in slices and behaving animals.

For depolarization block assessment electrical neuronal activity of ChR2-/RCaMp1h- expressing neurons was recorded during 30 s of continuous light stimulation emitted from the fiber-coupled LED with the same intensity at the tip than the in vivo configuration (1 mW). Electrical neuronal activity was recorded using borosilicate glass micropipettes (Harvard Apparatus 30-0057, Holliston, MA, USA) heat polished to obtain direct current resistances of ~4–6 MΩ. Micropipettes were filled with an internal solution containing in mM: 115 KH_2PO_4, 2 $MgCl_2$, 10 HEPES, 0.5 EGTA, 0.2 Na_2ATP, and 0.2 Na_3GTP. The recordings were made with a microelectrode amplifier with bridge and voltage clamp modes of operation (BVC-700A, Dagan Co, Minneapolis, MN, USA). Conventional characterization of neurons was made in voltage and current clamp configurations. Access resistances were continuously monitored to be less than 20 MΩ, experiments with changes over 20% were interrupted and terminated. Software designed in LabVIEW environment (National Instruments, Austin, Texas, USA) was used for data acquisition and we performed analysis with Origin (version 8.6, Microcal, Northampton, MA, USA).

During recordings of calcium or electrical activity, slices received a constant flow of artificial cerebral spinal fluid of 2.5 ml/min.

2.6 | Processing of neuronal calcium images

For this processing we used the methods previously described (Carrillo-Reid et al., 2008; Jaidar et al., 2010). Briefly, Image J (v.1.45s, National Institutes of Health, WA), MATLAB (Math-Works, Inc., Natick, MA, USA) and programs written in IDL (Exelis-Harris software version 8.2) (Cossart, Aronov, & Yuste, 2003; Mao, Hamzei-Sichani, Aronov, Froemke, & Yuste, 2001; Schwartz et al., 1998) were used to analyze the movies acquired during the recordings (see above). For each movie frame neurons were identified, their contours defined and the mean fluorescence measured as a function of time. Changes in fluorescence were computed as (Fi–Fo)/Fo, where Fi = fluorescence intensity and Fo = resting fluorescence, that is, median fluorescence of the first four frames of the movie. The calcium signals elicited by action potentials were detected based on a threshold value given by their first derivative over time (2.5× standard deviation of the noise). Images were inspected one by one to remove artifacts and slow calcium transients, most likely from glial cells (Carrillo-Reid et al., 2008; Cossart et al., 2003; Jaidar et al., 2010; Sasaki, Matsuki, & Ikegaya, 2007). As previously described (Miller, Ayzenshtat, Carrillo-Reid, & Yuste, 2014) to determine whether peaks of synchrony were significant (number of coactive neurons per peak), binary activity from recorded calcium imaging (calcium spikes) were shuffled 1,000 times by randomly transposing intervals of activity within each cell. We then set a threshold corresponding to a significance level of $p < 0.05$ for peak detection.

2.7 | Visualization of network states

The vectorization of all recorded activity was performed to express network activity as a function of time. Active and inactive elements were therefore represented within a 250 ms time bin. With this analysis, association of bursting activity of synchronized cells occurring at a particular time can be easily identified (Carrillo-Reid et al., 2008, 2009; Sasaki, Kimura, Tsukamoto, Matsuki, & Ikegaya, 2006; Sasaki et al., 2007). The inner product of all possible vector pairs (equivalent to the cosine of the angle between the vectors) was used to construct a similarity matrix of all neurons firing in synchrony. This process graphically reveals whether vectors have same or similar components (Sasaki et al., 2006, 2007). To follow network dynamics within the neuronal microcircuits and determine how neuronal activity travels among the different network states in the field of observation, we analyzed the data using multidimensional reduction techniques previously described (Carrillo-Reid et al., 2008, 2009; Jaidar et al., 2010). Briefly, (a) To reduce the dimensionality of population vectors representing network states, we applied locally linear embedding (LLE), a technique that preserves the structure of nonlinear multidimensional data (Brown, Joseph, & Stopfer, 2005; Carrillo-Reid et al., 2008; Roweis & Saul, 2000). (b) To choose the optimal number of network states, we used hard and fuzzy clustering algorithms and the Dunn's index as a validity function (Bezdek & Pal, 1998; Carrillo-Reid et al., 2008, 2009; Sasaki et al., 2007). (c) To visualize clusters of data points representing similar population vectors (i.e., network states) following activity sequences or closed cycles we projected vectors into a two-dimensional space (Jaidar et al., 2010; Liu, Khalil, & Oweiss, 2011; Sasaki et al., 2007; Schreiber, Fellous, Whitmer, Tiesinga, & Sejnowski,

2003). (d) The position of all cells involved in each state was plotted onto the original image of the slice containing the defined neuronal contours (see previous paragraph).

2.8 | Statistical analyses

Experimental and control sample size was chosen based on previous literature (Lee et al., 2016). The Shapiro–Wilk test was applied to all original data to assess normality in data distribution. Data withdrawn from a normal distribution were analyzed with the parametric statistical significance test one-way ANOVA followed by post hoc Tukey honestly significant difference (HSD). When necessary, a paired-*t* test was also used. Results were expressed as M = mean, SD = standard deviation and n = number of cases; statistical probability values were expressed in the results and figure legends. A simple randomization (i.e., heads-continuous; tail-pulses) was applied when the same slices were activated with pulsed or continuous light.

2.9 | Histology

Following a brief rinse in phosphate buffer 0.01 M, mice were perfused with 4% paraformaldehyde and 14% picric acid; brains were post-fixed for at least 2 hr and then cryoprotected in a 50/50 mixture of fixative and 20% sucrose in 0.01 M phosphate-buffered saline (PBS) for at least 24 hr. Sections were cut at 60 μm on a sledge microtome with a freezing stage (Yamato REM-710 electrofreeze MC-802A), washed in PBS and incubated in 20% normal goat serum. Primary antibodies to tyrosine hydroxylase (rabbit polyclonal 1:5,000, Enzo Life Sciences) or glial fibrillary acid protein (GFAP, rabbit polyclonal, Dako; 1:500) were incubated overnight at 4°C and stained with secondary goat antirabbit antibodies (Life Technologies; 1:200). At least 2 hr were allowed for binding before rinsing in PBS. Sections were mounted on slides; Vectamount AQ (Vector) or occasionally Santa Cruz mountant with DAPI was used to fix the coverslips. A spinning disk confocal microscope (Olympus BX-DSU) was used and pictures were taken using Neurolucida software and a Hammatsu (EM-CCD C91) camera.

3 | RESULTS

3.1 | Spontaneous calcium activity in corticostriatal slices of intact or DA-depleted mice

The proposed involvement of DA in the generation of striatal neuronal assemblies (Burke, Rotstein, & Alvarez, 2017; Nicola, Surmeier, & Malenka, 2000; O'Donnell, 2003) became testable through calcium imaging that allows simultaneous measurement of many individual neurons (Carrillo-Reid et al., 2008; Jaidar et al., 2010). With the use of population calcium imaging that allows the indirect measurement of neuronal spiking in striatal networks in vitro (Carrillo-Reid et al., 2008; Jaidar et al., 2010; Lopez-Huerta et al., 2013) we characterized the population activity of SPNs in slices obtained from naïve controls and mice depleted of DA for at least 9 days. Examples of simultaneous recordings of fluo-4 calcium signals and analysis of large numbers of D1eGFP$^+$ and D2eGFP$^+$ SPNs are shown for naïve and DA-depleted mice in Figure 1 and Supporting Information Video S1. Spontaneous activity of both D1 and D2 SPNs from non-lesioned mice slices is characterized by sparse events without significant coactivity episodes (Figure 1a), and following DA depletion, a significant increase in the number of D1 and D2 active SPNs relative to controls is observed (one-way ANOVA $(3,28) = 27.12$, $p < 0.0001$), accompanied by the presence of significant coactivity peaks absent in non-lesioned controls (Figure 1b). As indicated in the graphs of coactive cells (Figure 1c), we counted calcium fluorescent signals not only on eGFP-positive neurons (D1-green dots- or D2-red dots-) but also in SPNs with negative eGFP expression (black dots) that represent the other half of SPNs (D1 or D2) and the interneurons. Group analyses of the number of active SPNs and the number of calcium events of DA-depleted and control slices revealed as that slices from DA-depleted slices showed increases of active SPNs for D1eGFP$^+$- and D2eGFP$^+$-expressing groups, D1 (green): $M = 37.7$, $SD = 5.33$, $n = 11$ mice, and D2 (red): $M = 30.18$, $SD = 7.01$, $n = 11$ mice, whereas control animals exhibited very few active D1 or D2 neurons for the duration of the measurements (3 min), D1: $M = 4.8$, $SD = 1.3$, $n = 5$ mice and D2: $M = 4.4$, $SD = 1.94$, $n = 5$ mice. The coactivity histograms (Figure 1d) are consistent with an increase in activity in both populations (green and red boxes), and also with significant increases in cell activity and peaks of coactivity in the eGFP-negative neurons (gray boxes). This is a corroboration that most SPNs and possibly interneurons become active in the absence of DA.

Similar results were obtained from neurons with negative eGFP expression (black dots) (Figure 1b1): a low number of active neurons in the control group (Figure 1a) (D1: $M = 11.8$, $SD = 4.96$, $n = 5$ mice and D2: $M = 9.6$, $SD = 4.03$, $n = 5$ mice) and high number of active neurons in the DA-depleted slices (Figure 1b) (D1: $M = 59.6$, $SD = 5.33$, $n = 11$ mice and D2: $M = 30.18$, $SD = 7.01$, $n = 11$ mice). The increase in the number of active neurons was statistically significant when compared to controls (Figure 1d). DA depletion was corroborated with immunohistochemistry (Figure 2) and turning behavior (see Section 3). Animals depleted of DA displayed spontaneous turning toward the side of the lesion ($M = 1.77$ turns/15 s, $SD = 1.35$, $n = 11$ mice) (Figure 1d).

To continue with the analysis of cell activity and peaks of coactivity as illustrated in Figure 1c, we compared network

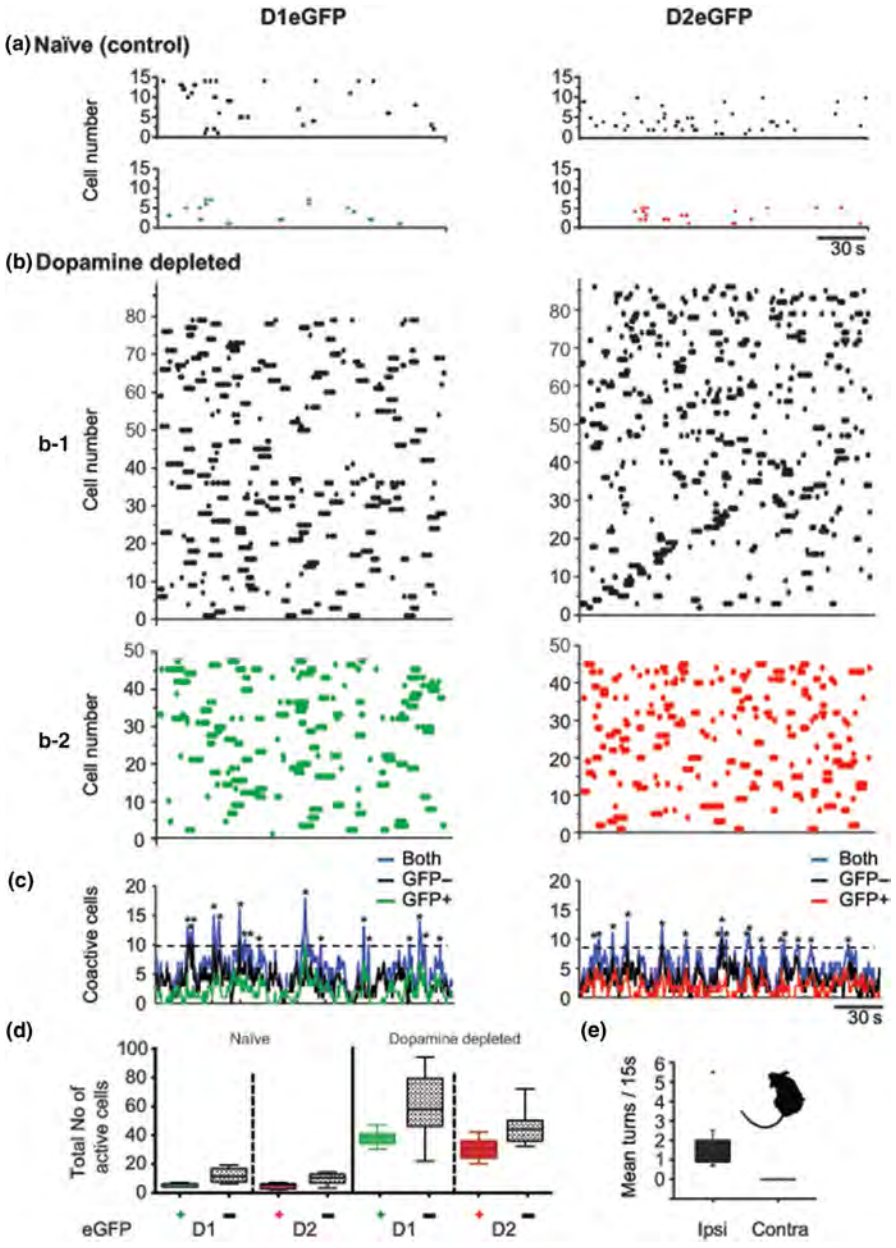

FIGURE 1 SPNs of the direct or indirect output pathways (D1-dSPN or D2-iSPN) contribute to the synchronized network activity after DA depletion. Data are displayed in raster plots where every dot at any given time along the *x* axis represents an active neuron identified by its unique number in the *Y* axis. (a) Representative raster plots of spontaneous striatal activity from D1eGFP (left) and D2 eGFP (right) unlesioned mice. (b) Representative raster plots (top) of D1eGFP (left) and D2eGFP (right) from DA-depleted animals. (b1) Raster plots of eGPP-negative neurons, that is, interneurons and the unlabeled SPNs (black dots), (b2) Raster plots of eGPP-positive neurons of D1 (green) and D2 (red) mice. The increment of neuronal activity after DA depletion compared to controls was statistically significant (one-way ANOVA (3,28) = 27.12, $p < 0.0001$). (c) Plots of coincidently firing cells (identified by colors: black: eGFP$^-$ negative; green: D1eGFP positive; red: D2eGFPpositive; blue: all recorded neurons, that is, eGFP positive and eGFP negative$^-$ together). (d) Box plots of total number of spontaneous active neurons recorded in periods of 180s. (e) Box plot of spontaneous mean rotations recorded on separate experiments. Rotation was toward the side depleted of DA ($M = 1.77$ turns/15 s, SD 1.35, $n = 10$ mice). For later comparisons with turns obtained with optogenetic stimulation, turns in DA-depleted mice were also recorded for 15 s after a 5–10 min period. A contour detection snapshot of a recorded mouse illustrates the deviated posture typical of an ipsilateral DA depletion

responses induced by DA depletion (Figure 3) using multi-dimensional reduction techniques as described (see Section 2.7). A previous description of the striatal microcircuit of un-identified SPNs of rats deprived of DA, was characterized by a dominant network state (Jaidar et al., 2010). Similarly, as previously observed in rats (Jaidar et al., 2010) we observed that D1- or D2-eGFP-expressing neurons formed three sets that generated sequential activity states. Moreover, as

INFORME DE LABORES 2019

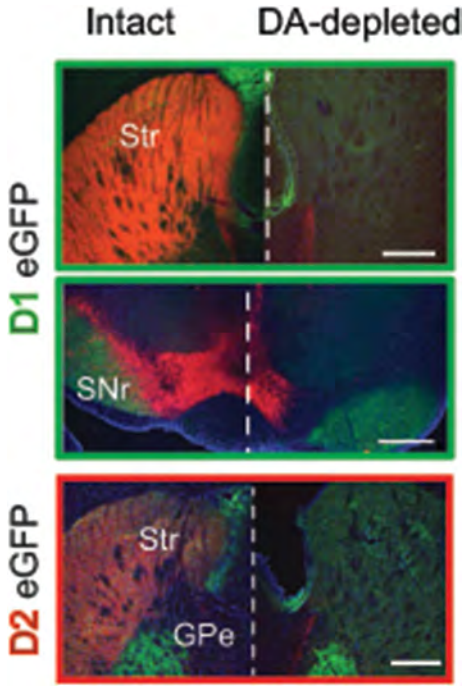

FIGURE 2 Immunohistochemistry of control and dopamine-depleted brains. Coronal brain slices of intact and DA-depleted D1eGFP+ and D2eGFP+ mice illustrate DA neurons and axons by tyrosine hydroxylase (TH) staining (red); positive expression of fluorescent protein (green) and the presence of cell bodies stained with 4,6-diamidino-2phenylindole, dihydrochloride (DAPI) (blue). GPe: external globus pallidus; Scale bars: 1 mm; Str: striatum; SNr: substantia nigra pars reticulata

observed in rats (Jaidar et al., 2010), one state that comprised the largest number of active neurons became dominant (refer to Figure 3a,b,d,e orange dots). Importantly, the dominant state was formed by SPNs belonging to both striatal output pathways as illustrated by the presence and absence of the plus sign in active neurons (Figure 3c,f).

3.2 | Simultaneous photoactivation of direct and indirect pathway SPNs

Consistent with the coordinated synchronous activation of indirect and direct SPNs necessary for the selection, initiation and performance of a particular movement, it has been reported that when the animal is not moving, SPNs remain inactive, but become coactive during movement initiation (Cui et al., 2013; Klaus et al., 2017). With the increase in the number of active cells and peaks of synchrony observed in DA-depleted tissue, we hypothesized that in the absence of DA, the observed increase in synchronous activation of large sets of striatal neurons could be responsible for the animal's motor impairments, such as deviated posture and persistent spontaneous turning (Costall, Marsden, Naylor, & Pycock, 1976; Dunnett & Iversen, 1982), Figure 1e.

To examine the relationship between the increment of neuronal activity and behavior, animals expressing AAV10 ChR2-mCherry (EF-1promoter) were used for the unilateral optogenetic activation through an optic probe implanted into the dorsolateral striatum (Figure 4a). We delivered to our behaving animals stimulation at the same intensity (470 nm; 1.0 mW at the tip) for 15 s in two modes as reported by others, for example, a single continuous 15 s pulse (Kravitz et al., 2010) or patterned pulses at 14 Hz (210 pulses of 6 ms each: (Jin, Tecuapetla, & Costa, 2014). When stimulation was delivered in pulses (14 Hz, 6 ms) it induced turning toward the opposite side characteristic of the activation of striatal cell assemblies (Ossowska & Wolfarth, 1995) (M 1.73 turns, SD 0.99, $n = 7$ mice) (Figure 4b right panel and Supporting Information Video S3). Interestingly, when light was delivered continuously in control animals, behavior changed drastically, mice turned toward the stimulated side (M 1.92 turns, SD 0.35, $n = 9$; Figure 4b, left panel). This turning behavior is compelling since it is similar to the one observed in DA-depleted animals ($M = 1.77$ turns, $SD = 1.35$, $n = 11$; Figure 1e). Optogenetically induced turning to the two types of stimulation was statistically significantly different (one-tail ANOVA $F(3,28) = 97.14$, $p < 0.001$, $n = 9$, 7 continuous vs. patterned pulses), Figure 4b.

Our results demonstrate that in the absence of DA, spontaneous synchronous patterns of SPN activation are observed in both D1 and D2 SPNs, and that when similar large synchronous patterns of activity are induced in both D1 or D2 SPNs by continuous optogenetic stimulation, normal mice turn in circles as do animals with a DA depletion.

3.3 | Visualization in vitro of striatal dynamics under optogenetic stimulation

To further visualize how the striatal network elements behaved under optogenetic stimulations we used electrophysiology, calcium imaging, and optogenetics (Figure 5). We combined AAV10 ChR2-mCherry (EF-1promoter) with genetically encoded calcium indicator RCaMP1h (hSyn promoter) delivered by AAV1 viral infection. It is relevant to mention that AAV10 ChR2-mCherry labels the majority of SPNs, but excludes the population of SPN contained in the striosomes (less than 20%) (Lopez-Huerta et al., 2016).

Neuronal calcium responses were recorded and their amplitude of the responsive cells was normalized by considering the brightest recorded neuronal fluorescence as 100% for each tissue slice. This analysis showed that the normalized calcium response amplitude elicited with continuous stimulation ($M = 0.77$, $\Delta F/F$, $SD = 0.1$, $n = 17$ slices) was significantly larger than the response observed with stimulation in patterned pulses ($M = 0.37$, $\Delta F/F$, $SD = 0.1$, $n = 17$ slices; paired t (16) = 16.22, $p = 2.33504^{-11}$; Figure 5 and Supporting Information Video S2).

INFORME DE LABORES 2019

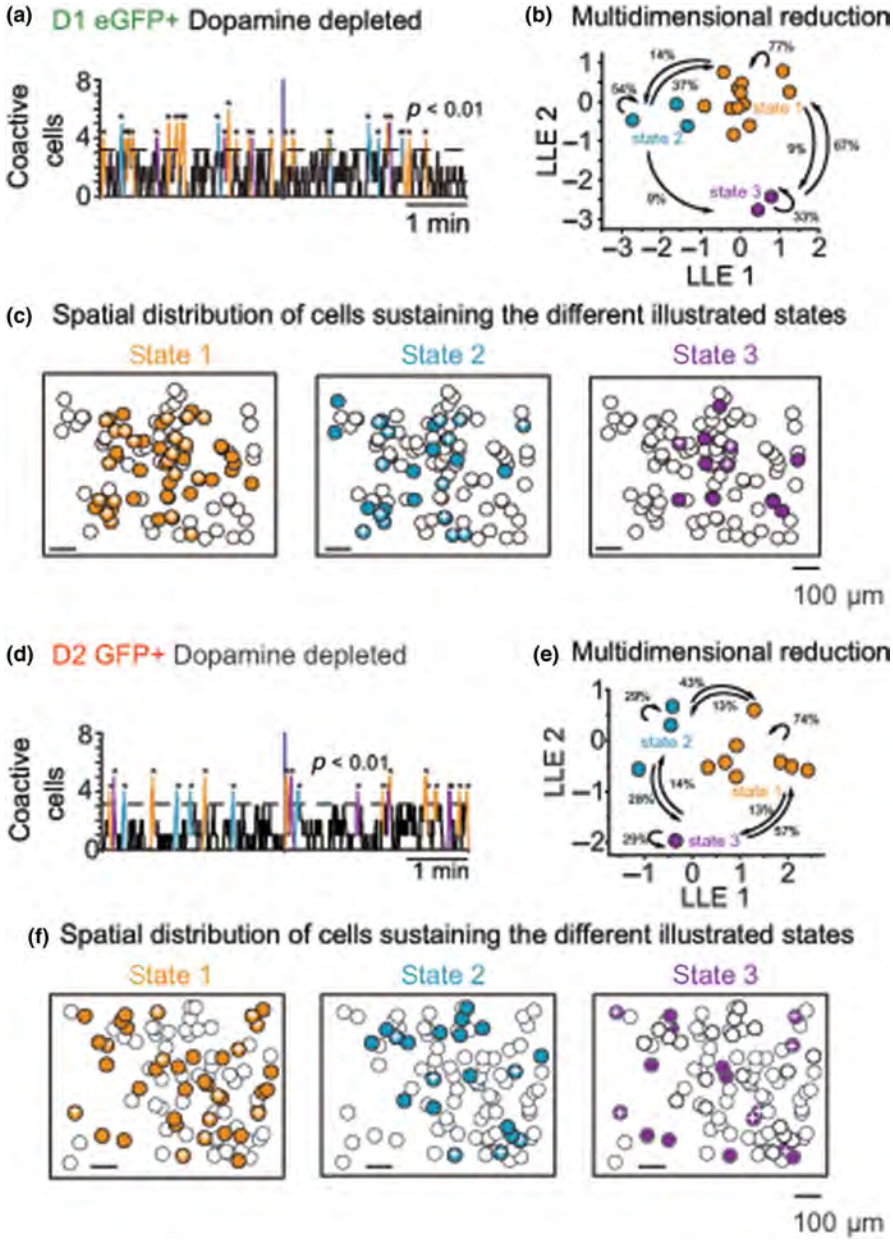

FIGURE 3 D1 or D2eGFP expressing neurons formed three sets that generated sequential activity states with one predominant set. (a and d) Analyses of coactive cells with significant peaks of synchrony (above the dotted line) also seen in Figure 1c were used for multidimensional reduction (see 2.7). (b and e). The network states reconstructed from the raster plots show that D1 or D2SPNs generate three sequential activity states (one color per state). The numbers indicate the percentage of transitions between states in the direction of the arrows. The "orange" state clearly dominates. (c and f). Superimposed onto the ROI or map of all observed active neurons, the spatial location of active SPNs can be observed for each one of the states. Colored circles represent active neurons that belong to the same state, circles with no color represent active neurons that do not belong to that particular state, and the plus sign inside the colored circles represents positive eGFPs, that is, represented as red green dots in the raster plots of Figure 1

Similarly, when the same tissue slices from 11 animals were activated with stimulation delivered at random either continuously or in patterned pulses, the total number of neurons activated by continuous stimulation was significantly larger ($M = 108$ active neurons, $SD = 32.63$, $n = 11$) than the number of neurons activated by patterned pulses ($M = 61.54$ active neurons, $SD = 29.65$, $n = 11$; paired t (20) $= 3.5$, $p = 0.005$, Figure 5d).

Since prolonged electrical stimulation often induces adaptation of SPN discharge (Kita, Kita, & Kitai, 1985) and strong (10–40 mW/mm^2) prolonged light activation of ChR-2 can silence instead of activating neurons by depolarization block, particularly interneurons (Herman, Huang, Murphey, Garcia, & Arenkiel, 2014), we first determined in vitro, the firing characteristics of our ChR2-RCaMP1h-expressing neurons by stimulating with 470 nm (blue light), 1.0 mW at the tip, for 30 s (see Section 3). A total of 14 SPNs ($n = 7$ for each D1 or D2 neurons) responded in similar proportions of activation/adaptation. During depolarization block assessment neurons were exposed to a continuous light pulse for 30 s, the duration of response of activated neurons before undergoing to depolarization block was: D1: $M = 17.5$ s, $SD = 6.38$, $n = 3$ and D2: $M = 18.25$s, $SD = 11.02$, $n = 4$. The other neurons continued firing for the whole exposure time. To our behaving animals stimulation at the same intensity (470 nm; 1.0 mW at the tip) for 15 s in two modes as reported by others, for example, (Jin et al., 2014; Kravitz et al., 2010): a single continuous 15s pulse or patterned pulses at 14 Hz (210 pulses of 6 ms each), all the experimental stimulations were therefore shorter than the average time to cease firing in both groups of

INFORME DE LABORES 2019

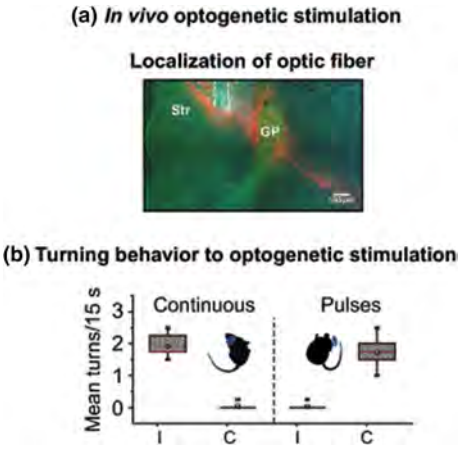

FIGURE 4 Photostimulation. (a) Photomicrograph illustrating the location of the stimulation optic fiber fixed in the dorsolateral striatum as delineated by dashed white line. (b) Box plots summarizing all behavioral sessions during optostimulation. With continuous light (15 s) (left) animals displayed turning behavior similar to 6-OHDA treated animals, that is, toward the side stimulated. With stimulation in patterned pulses (14 Hz) animals displayed turning behavior opposite to the stimulated side (right). Behavioral sessions lasted approximately 10–15 min divided as follows: a period of habituation (≈5 min) followed by three sequences repeated 10 times: 1–20 s pre-stimulation, 2–15 s of light stimulation either delivered continuously or in pulses and 3–30–60 s post-stimulation. As described in Section 2.3, a tracking system was used to automatically measure turning. A contour detection snapshot of a recorded mouse illustrates the deviated posture typical of an ipsilateral DA depletion, but in this case in an intact mouse during optogenetic stimulation

cells. Although depolarization block is likely induced in up to half the stimulated cells, the obtained pattern of activation of larger calcium transients was indication that most of the striatal cells were not blocked from firing impulses. The activation was clearly sufficient to induce behavioral changes, in vivo, suggesting that the cells excited did influence behavior and so a large recruitment of output neurons is the likeliest explanation of the outcome of the optogenetic stimulation.

We studied striatal responses from both direct and indirect pathway (D1eGFP and D2eGFP mice) from the same slices (Figure 6). Light stimulation induced synchronous activation in similar proportions, in both positive and negative eGFP neurons regardless of stimulation delivered continuously or in patterned pulses (D1–D2: range 47–54 synchronous neurons; one-way ANOVA $F(7,36) = 1.2$, $p = 0.32$, $n = 5,6$; Figure 5a–e), however, it is important to underline that continuous stimulation activated a larger number of both direct and indirect SPNs, whereas patterned pulsed stimulation recruited a smaller number of neurons (continuous D1–D2: $M = 54.0$, $SD = 27.8$, $n = 24$; $M = 82.6$, $SD = 28.47$, $n = 24$; patterned pulses D1–D2: $M = 19.79$, $SD = 10.13$, $n = 24$; $M = 26.3$, $SD = 11.43$, $n = 24$; one-way ANOVA $F(3,92) = 43.56$, $p \leq 0.0001$, $n = 24$; Figure 6a–d,f).

To visualize the differences in population activity evoked by continuous or patterned optogenetic stimulation we created similarity maps (Carrillo-Reid, Hernandez-Lopez, Tapia, Galarraga, & Bargas, 2011; Carrillo-Reid et al., 2008, 2009; Jaidar et al., 2010) (Figure 7a,b). We found that similarity index between synchronized neurons was significantly higher with continuous stimulation compared to responses following patterned pulses, in other words, continuous stimulation not only activates a larger population of neurons, but it has the tendency of recruit the same neurons across stimuli, whereas patterned pulses recruits fewer and more alternated neurons. Network dynamic between DA-depleted and pharmacological-activated striatal cell assemblies, were mimicked by the two forms of light stimulation. That is, pathologically engaged under continuous stimulation and flexible or alternating under patterned stimulation (continuous: $M = 0.52$, $SD = 0.19$ $n = 12$ mice; pulsed: $M = 0.4$, $SD = 0.23$ $n = 12$; paired $t(11) = 4.24$, $p < 0.001$; Figure 7c).

DA modulates short and long-term SPN function (Gerfen & Surmeier, 2011; Wickens, 2009), modulates its own release (Shen, Flajolet, Greengard, & Surmeier, 2008), presynaptically modulates GABA release at recurrent collateral synapses (Guzmaan et al., 2003; Tecuapetla, Carrillo-Reid, Bargas, & Galarraga, 2007; Tecuapetla, Koos, Tepper, Kabbani, & Yeckel, 2009), tonically inhibits D2-SPNs and possibly interneurons too all variables that affect SPN excitability. (Flores-Barrera, Vizcarra-Chacon, Tapia, Bargas, & Galarraga, 2010). However, in the unilateral absence of DA, striatal neurons increase their activity and animals display persistent spontaneous ipsilateral turning.

4 | DISCUSSION

Early studies of striatal cells after DA damage were unanimous in finding the striatal cells more active in anaesthetized animals for example (Arbuthnott, 1974; Hull et al., 1974; Ohye et al., 1970; Schultz, 1982; Schultz & Ungerstedt, 1978). Then came the formulation that made a clear prediction that in PD the direct pathway SPNs should be less active, whereas the indirect pathway SPNs were more active (Albin, Young, & Penney, 1989). This formulation had its origin in changes in genetic activity in the two groups of cells (Gerfen & Young, 1988; Gerfen et al., 1990). The idea was very powerful and led to new therapies including globus pallidus lesions (Laitinen, Bergenheim, & Hariz, 1992), then to subthalamic nucleus deep brain stimulation (Bergman, Wichmann, & DeLong, 1990) and thence to deep brain stimulation (Polack et al., 2007). However, there were difficulties in relating this success to the electrophysiology of individual cells of the two types once they became identifiable by transgenesis. Some laboratories did find differences in the expected direction (Flores-Barrera, Vizcarra-Chacon,

INFORME DE LABORES 2019

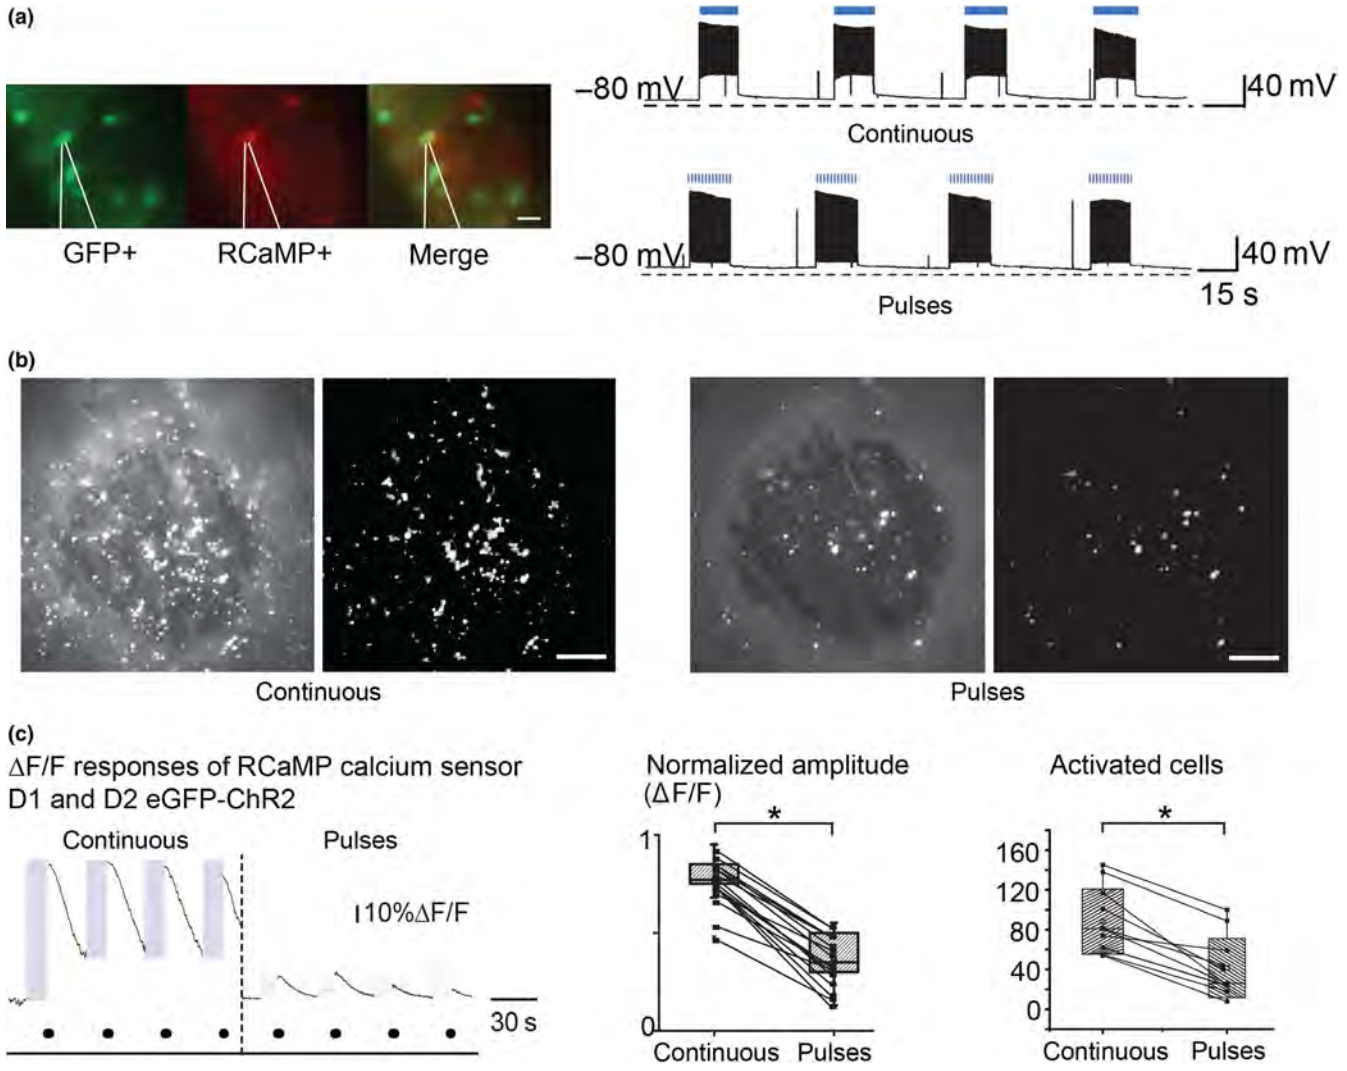

FIGURE 5 Comparison of responses to in vitro optogenetic stimulation delivered continuously or in patterned pulses. (a) Patch clamp recordings of SPNs expressing ChR2-RCaMP1 h show normal passive and active membrane properties to 15 s stimulation delivered continuously (top) or in pulses at 14 Hz (bottom). (b) Example of in vitro recorded neuronal response of calcium indicator (RCaMP1 hr) from ChR2-expressing SPNs with continuous (left) and pulsed (right) light stimulation. (c) Left and middle—Normalized amplitudes of calcium traces from cells activated by continuous stimulation were larger ($M = 0.77$, $SD = 0.12$, $n17$) than those produced by stimulation in patterned pulses ($M = 0.37$, $SD = 0.13$, $n = 17$); paired $t\,(16) = 16.22$, $p = 2.33504^{-11}$). Right— Total number of activated cells from same recorded fields during continuous ($M = 108$, $SD = 32.63$, $n = 11$) and stimulation in patterned pulses ($M = 61.54$, $SD = 29.65$, $n = 11$) paired $t\,(20) = 3.5$, $p = 0.00221$. Parameters of stimulation were: 15 s of LED of 470 nm blue light stimulation either delivered continuously or in patterned pulses (6 ms pulses at 14 Hz), with intensity at the tip of 1.0 mW

Bargas, Tapia, & Galarraga, 2011; Shen et al., 2008; Warre et al., 2011) but as the methodology became more sophisticated, the obvious interactions of both cell types with cortical activity and the beta power increase in the electrocorticogram, common in PD, has changed the emphasis from "faster or slower firing" to changes in the intrastriatal dynamics which result from the interactions of the many effects of DA removal on functional relationships within the striatal network (Cui et al., 2013; Klaus et al., 2017; Lindahl & Hellgren Kotaleski, 2016; Parker, Kim, Alberico, Emmons, & Narayanan, 2016; Parker et al., 2018; Perez-Ortega et al., 2016; da Silva, Tecuapetla, Paixao, & Costa, 2018).

Analyses of many cells at a time have revealed that such neuronal activation is characterized by an increased number of coactive neuronal discharges that involve both types of SPNs (Jaidar, Carrillo-Reid, & Bargas, 2012; Jaidar et al., 2010). Using calcium imaging in eGFP transgenic animals, we first confirmed the characteristics of SPN activity in the absence of DA, and revealed that both populations of SPNs equally participate in this abnormal microcircuit activity. In our in vitro recordings of spontaneous activity in DA deprived animals, both populations of D1 and D2 SPNs to some extent increased their activity. Therefore, although electrophysiological and anatomical evidence indicates that D2, but not

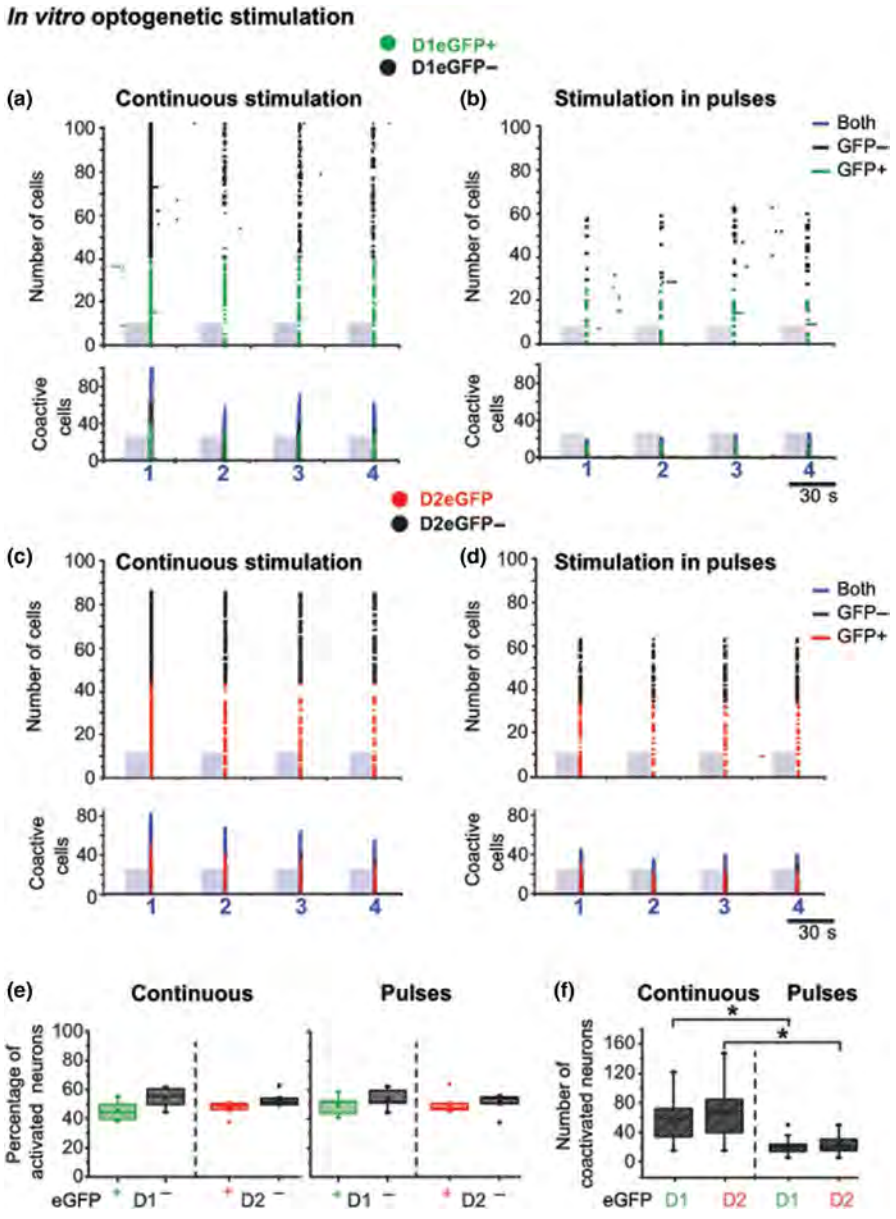

FIGURE 6 Comparison of SPN activity of synchronous striatal calcium signals induced by continuous and pulsed patterned optogenetic stimulation. Data are represented in sets of two graphs of striatal activity induced by a blue-light-emitting diode (470 nm;1.0 mW at the tip) delivered continuously for 15 s or in patterned pulses (14 Hz/15 s). Top traces: illustrate representative examples of raster plots of ChR2-induced SPN calcium activity reported by RCaMP1 hr. Bottom traces: illustrate histograms of number of coactivated neurons from continuous (a, c, and e left) or patterned pulsed stimulations (b, d, and e right). Blue rectangles represent the light stimulus artifact (see Figure 4a); colors representing individual active neurons and coactivity are, black: all eGFP negative; green: D1eGFP^{+}; red D2eGFP^{+}. (e) In spite of a differential neuronal activation induced by stimulation delivered continuously or in patterned pulses, the percentage of activated SPNs within groups of positive or negative D1 or D2eGFP neurons remains around 50%, as expected. No preferential neuronal activation was observed. (f) Total number of coactivated neurons from both D1 or D2 neurons with positive eGFP expression. Note that both cell types showed higher synchronization to optogenetic stimulation delivered continuously than in patterned pulses (one-way ANOVA $F(3,92) = 43.56$, $p \leq 0.0001$)

D1 neurons suffer a loss of dendritic spines (Day et al., 2006) but see (Suarez, Solis, Aguado, Lujan, & Moratalla, 2016) and an increase in excitability (Day, Wokosin, Plotkin, Tian, & Surmeier, 2008), in the absence of DA, perhaps the increase in excitability could somewhat compensate the loss of dendritic spines. A recent electrophysiological study in anesthetized rats by Sharott and collaborators claimed that only D2 cells were changed in firing rate but their laborious methodology meant a very small fraction of identified D1 cells in the lesioned animals ($n = 5$ in Figure 3 and $n = 8$ in figure 8) (Sharott, Vinciati, Nakamura, & Magill, 2017). Our method, although in vitro, samples at least 50 cells per slice of both genotypes, the calcium signals are not single action potentials like those of the electrophysiological studies but the likeliest

INFORME DE LABORES 2019

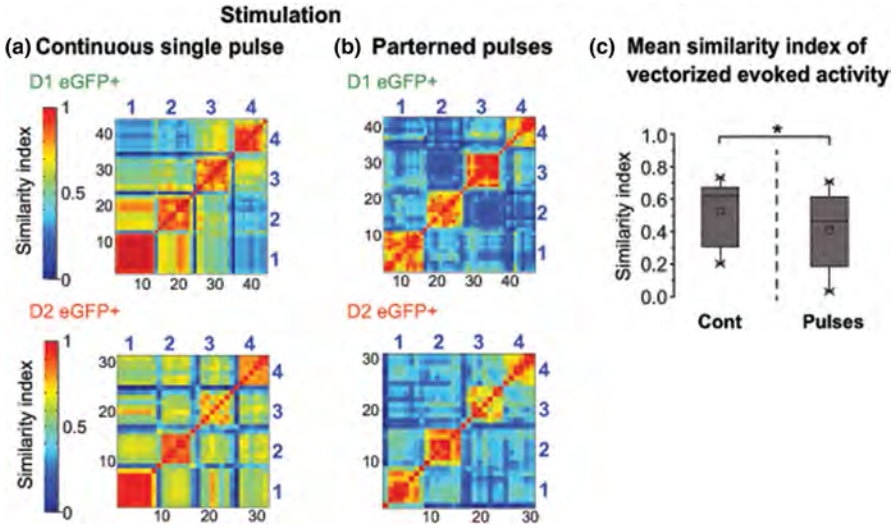

FIGURE 7 Analysis of network dynamics of D1 and D2 SPNs. The similarity index matrices of the stimulation induced by continuous (a) and stimulation in patterned pulses (b) show that continuous delivery of light activated sets of neurons with higher similarity index across stimulations, than stimulation delivered in patterned pulses. (c) Summary box plots to illustrate the significantly higher mean similarity index of vectorized activity observed with continuous versus patterned stimulation (paired $t\,(11) = 4.24$, $p < 0.001$, $n = 12$ mice). Black numbers: vector numbers; blue numbers: responses from one of the four stimulations

explanation for the transients we measure is a burst of at least three spikes (Carrillo-Reid et al., 2008). The synchronization of striatal cells is common to both studies, with the Sharott et al. (2017) having correlated the synchronous discharges of D2 cells with beta frequencies in the EEG in their anaesthetized animals; an effect we could not test in vitro. Parker et al. (2018) reported on calcium transients in freely moving animals with a miniature camera and implanted GRIN lens. Although they too see reductions in D1 cell activity, they also see a dislocation of the response of (particularly D2) cells to the initiation of movements after 6-OHDA injections. During normal movement both D1 and D2 cells are tuned to movements but the rate changes obliterate the movement relations in D2 cells. These different results reflect the within animal control that we lose in our ex vivo models, but we do find a similar disruption of patterned activity in "clusters" of cells that they report.

The effect of bilateral SPN activation using optogenetic techniques has been studied (Parker et al., 2016), but only a few have explored unilateral effects of SPN manipulations (Cui et al., 2013; Jin et al., 2014; Lee et al., 2016). We observed similar results following stimulation in patterned pulses. This suggests that stimulation in patterned pulses is sufficient to stimulate striatal SPNs of either type. Consistently, network analyses revealed that stimulation delivered in patterned pulses (14 Hz/15 s), compared to continuous stimulation, was less efficient in recruiting neurons, but obviously sufficient to induce contralateral turning. The smaller number of coactivated neurons by pulses (14 Hz) induced contralateral turning characteristic of tonic activation of striatal cell assemblies (Carrillo-Reid et al., 2008; Ossowska & Wolfarth, 1995). Reminiscent of the patterning of responses in striatal cells (independent of output class) observed in the awake mice (Parker et al., 2018). In contrast, from the analyses of network dynamics, it is clear that continuous stimulation induces a significantly higher similarity index compared to patterned stimulation, as also seen in dopamine-depleted rats (Jaidar et al., 2010).

Therefore, it seems plausible that continuous stimulation induces a dominant recurrent pattern of network activity sufficiently pronounced to induce ipsilateral turning like the spontaneous turning observed in DA-depleted animals. Such largely synchronous activity patterns would perhaps look "unstructured" if viewed with the small field of view in the in vivo camera, but in our study is obviously a very dispersed concurrent activation. *Pulsed* patterned stimulation could induce a restorative neuronal activity by recruiting fewer coactive neurons. This is a speculative functional relationship obtained from the observed in vitro neuronal network activation by the two stimulation parameters, that remains to be proven with in vivo recordings of neural networks, once technical advances allow such striatal recordings of hundreds of cells, without removal of the overlying cortical tissue.

The reasons for the differences in neuronal recruitment between patterned and continuous stimulation, although interesting, are not the focus of this paper; methodological aspects perhaps involving a ChR2-activated calcium conductance; reciprocal multisynaptic influences between direct and indirect SPNs and motor cortex (Burke et al., 2017; Freeze, Kravitz, Hammack, Berke, & Kreitzer, 2013; O'Hare et al., 2016; Oldenburg & Sabatini, 2015; Shipp, 2017), intrastriatal

INFORME DE LABORES 2019

influences on SPNs (Planert, Szydlowski, Hjorth, Grillner, & Silberberg, 2010; Taverna, Ilijic, & Surmeier, 2008) and or the participation of interneurons (Damodaran, Evans, & Blackwell, 2014; Dehorter et al., 2009) should be considered in further analyses. Modulation of neuronal assemblies by specific patterns of neuronal stimulation may represent a modified animal model to study the pathogenesis in basal ganglia.

Our purposes were to optogenetically activate selective groups containing both D1- and D2-eGFP-expressing neurons enough to induce the striatal network activity that presumably supports the spontaneous turning in dopamine-depleted animals. Therefore, it may be possible that the larger synchronization of the striatal circuit (via continuous stimulation) more closely reproduced the effects of DA depletion. Consequently, the abnormal turning observed in the 6-hydroxydopamine animal model of PD may result from the pathological striatal synchronous activity that follows DA depletion.

It may be meaningful that to reproduce the pathological state, strong neuronal activation is necessary. It is clear that the stronger continuous stimulation of both D1 and D2 SPNs was required to induce the ipsilateral turning, as it is also the case for the bilateral excitation of D2 SPNs to elicit parkinsonian bradykinesia (Kravitz et al., 2010). A robust inhibition and excitation of different subsets of substantia nigra reticulata neurons has been reported following bilateral striatal optogenetic stimulation of D1 or D2 SPNs, for 1,000 ms but not for 100 ms (Freeze et al., 2013).

Recently, in freely moving animals, it was reported that both SPN populations become active in localized compact groups of synchronized neurons, that alternate their activity over time (Barbera et al., 2016; Klaus et al., 2017; London et al., 2018), these results are similar to previous slice recordings treated with NMDA (Carrillo-Reid et al., 2008). In contrast, slices from DA-depleted animals report neuronal activity locked into a dominant network state with reduced alternations between the assemblies (Jaidar et al., 2010; Lopez-Huerta et al., 2013). Normal striatal motor control requires activation of both direct and indirect SPNs population in a "complementary" and "coordinate" network dynamic (Jin et al., 2014; Klaus et al., 2017; Tecuapetla, Jin, Lima, & Costa, 2016; Vicente, Galvao-Ferreira, Tecuapetla, & Costa, 2016). Very recent results from a modeling study suggest that for planned movements both output pathways need to be engaged (Bahuguna, Weidel, & Morrison, 2018).

We conclude that the concept of neural networks has provided neuroscientists with an important tool not only to study their properties and capabilities (Blaeser, Connors, & Nurmikko, 2017; Carrillo-Reid, Lopez-Huerta, Garcia-Munoz, Theiss, & Arbuthnott, 2015; Carrillo-Reid et al., 2009, 2011; Liu et al., 2011), but to activate different functional processes and the related behavior. Fear memories and freezing behavior have been induced by optically stimulating dentate gyrus neurons whose activity during passive avoidance was previously identified (Liu et al., 2012; Ramirez et al., 2013); for review see (Carrillo-Reid, Yang, Kang Miller, Peterka, & Yuste, 2017).

Here we have used neural network manipulation to demonstrate that: (a) DA depletion caused simultaneous activation of both types of identified D1 and D2 SPNs, (b) the contralateral turning behavior, characteristic of unilateral activated striatal neurons, was induced by patterned pulsed optogenetic stimulation of both types of SPNs, (c) ipsilateral turning behavior, as observed in DA-depleted animals, was induced in normal animals by continuous optogenetic stimulation that mimics the pathological microcircuit dynamics that accompany this animal model of PD. Our experiments confirm that large, unilateral and synchronous discharges of SPNs can simulate the ipsilateral turning model of PD in intact animals, and suggest that dopamine degeneration causes circling due to a similar large increase in unilateral SPNs discharge. The clinical relevance of this finding is supported by past studies using turning behavior as a model for PD. Resent results implicating glutamate receptors in the hyperexcitability of SPNs in monkeys (Singh et al., 2018) only add to the idea that this striatal pathological activity is close to the symptom development in PD.

ABSTRACT

Inter-cellular and inter-kingdom signaling systems of various levels of complexity regulate pathogenic and mutualistic interactions between bacteria, parasites, and fungi and animal and plant hosts. Inter-kingdom interactions between mutualistic bacteria such as rhizobia and legumes during nodulation and between fungi and plants during mycorrhizal associations, are characterized by the extensive exchange of molecular signals, which allow nitrogen and phosphate assimilation, respectively. A novel aspect of this signaling exchange is the existence of specific structures, the exosomes, that carry important molecules that shape the plant–pathogen interactions. Exosomes contain a wide array of molecules, such as lipids, proteins, messenger RNA, and microRNAs, that play important roles in cell-to-cell communication in animal and plant cells by affecting gene expression and other physiological activity in distant cells within the same organism (e.g., during cancer metastases and neuron injuries). In plant cells, it has been recently reported that exosomes go beyond organism boundaries and inhibit a pathogenic interaction in plants. Plant produce and send exosomes loaded with specific small miRNA which inhibit the pathogen infection, but the pathogen can also produce exosomes carrying pro-pathogenic proteins and microRNAs. Therefore, exosomes are the important bridge regulating the signal exchange. Exosomes are small membrane-bound vesicles derived from multivesicular bodies (MVBs), which carries selected cargos from the cytoplasm (protein, lipids, and microRNAs) and under certain circumstances, they fuse with the plasma membrane, releasing the small vesicles as cargo-carrying exosomes into the extracellular space during intercellular and inter-kingdom communication. Animal and plant proteomic studies have demonstrated that tetraspanin proteins are an integral part of exosome membranes, positioning tetraspanins as essential components for endosome organization, with key roles in membrane fusion, cell trafficking, and membrane recognition. We discuss the similarities and differences between animal tetraspanins and plant tetraspanins formed during plant–microbe interactions and their potential role in mutualistic communication.

Introduction

The multiple functions of tetraspanins

Tetraspanins constitute a diverse superfamily of transmembrane proteins, with 33 members identified in mammals and 17 in the model plant *Arabidopsis thaliana*. Although tetraspanin homologues have not yet been reported in yeast, bacteria, and archae, they are ubiquitous in eukaryotic cells and the first member of this family likely appeared around 570 million years ago.[1,2] Several tetraspanin isoforms exist in deuterostomata, including fruitfly (*Drosophila melanogaster*), zebrafish (*Danio rerio*), and humans.[3–5] Tetraspanins are involved in basic cell functions such as motility, fusion, and membrane and vesicular trafficking, and play key roles in diverse physiological processes including sperm–egg fusion, antigen presentation, and tissue differentiation.[2,6–8] While knockout of the tetraspanins CD9- and CD81 in mice (*Mus musculus*) results in a clear defect in egg–sperm fusion, other tetraspanins are involved in virus and parasite interactions.[2,6–10] More recently it has been reported that a single point mutation, L31S substitution in the third amino acid of TM1 has been associated with field-evolved resistance of cotton bollworm to transgenic Bt cotton.[11]Tetraspanins also regulate cellular invasiveness or metastases through associating with peptidases, matrix metalloproteinases, and urokinase plasminogen activator surface receptors in animal cells.[12] In animals and plants, some tetraspanins have a broad tissue distribution, while others show a restricted expression; for instance, in plant cells, different tetraspanins are expressed in specialized tissues such as the reproductive tissue and meristems, during embryo development, and in specific cell niches, such as the quiescent center or the early initial cells that give rise to lateral roots.[13–15]

Tetraspanins appear to act as molecular organizers by forming homo- or heterodimers that localize to microdomains known as tetraspanin-enriched microdomains (TEMs). As components of TEMs, both animal and plant tetraspanins maintain a network of interactions with other membrane proteins, such as integrins, and signaling molecules, such as receptors, allowing the assembly of multi-molecular signaling platforms.[12] Therefore, tetraspanins are dynamic master organizers within membranes that control the

distribution and clustering of associated partner-proteins and thereby regulate cellular functions, such as signaling and adhesion.[14,16] Their role in vesicular trafficking and as a component of exosomes, which mediate the transport of protein, lipids, and microRNAs during intercellular and interkingdom communication, open a new avenue of research in pathogenic and mutualistic interactions in plant and animal hosts.[17]

Tetraspanin structure

As its name implies, tetraspanins are proteins with four membrane-spanning domains. The amino- and carboxy-terminal tails and a small loop between transmembrane regions 2 (TM2) and 3 (TM3) are localized in the cytoplasmic compartment. Two loops, a small one (ECL1) located between TM1 and TM2, and a large one (ECL2) between TM3 and TM4, are extracellular (Figure 1).[6,18] ECL2 can be subdivided into a conserved and variable region. The conserved region mediates dimerization, whereas the variable region is required for interactions with non-tetraspanin partner molecules. The highly conserved cysteine residues in the large ECL2 are essential tetraspanin signatures, and the polar residues conserved in the TM regions stabilize the tertiary structure.[12]

Palmitoylation of intracellular and juxta-membrane cysteines might be required for initiating tetraspanin–tetraspanin web formation. This chemical modification also protects tetraspanins from lysosomal degradation, provides a link to cholesterol and gangliosides, and promotes cell–cell contact.[6,19] In animal cells, palmitoylation of specific integrins also contributes to tetraspanin complex formation.[20] Although *bona fide* integrins have not been identified in plant cells, other proteins such as NDR1 play similar functions.[21] In plant cells, some tetraspanins possess a tyrosine-based sorting motif (Yxxφ, with φ representing an amino acid with a bulky hydrophobic side chain) at the carboxyl end that delivers the tetraspanin to a specific intracellular compartment.[17,22] However, internalization can also proceed through association with proteins with a sorting motif or by additional, not yet defined domains.[12] The major extracellular loop ECL2 is a key region for tetraspanin function in animal and plant cells. Disulfide bonding between conserved cysteines in ECL2 produces a sub-loop structure in this region, which shows the greatest variability between tetraspanins.[15,23] Some tetraspanins have an additional two-to-four cysteines within this sub-loop, which may also participate in disulfide bonding. The remainder of the ECL2 region is highly conserved and contains three alpha helices.[2] The ECL2 loop appears to determine tetraspanin functional specificity and most specific monoclonal antibodies (mAb) bind to this region.[2]

Conservation of a single Cys residue at a specific point in the small loop is a unique feature of plant cell tetraspanins, suggesting that it plays a particular role that has not yet been determined. For instance, disulfide bonding between the big and small loops, which is important for tetraspanin–tetraspanin interactions, could stabilize the interaction in a redox-dependent fashion or affect the affinity for cholesterol or gangliosides present in the plasma membrane.[24] In contrast to animal tetraspanins, plant tetraspanins

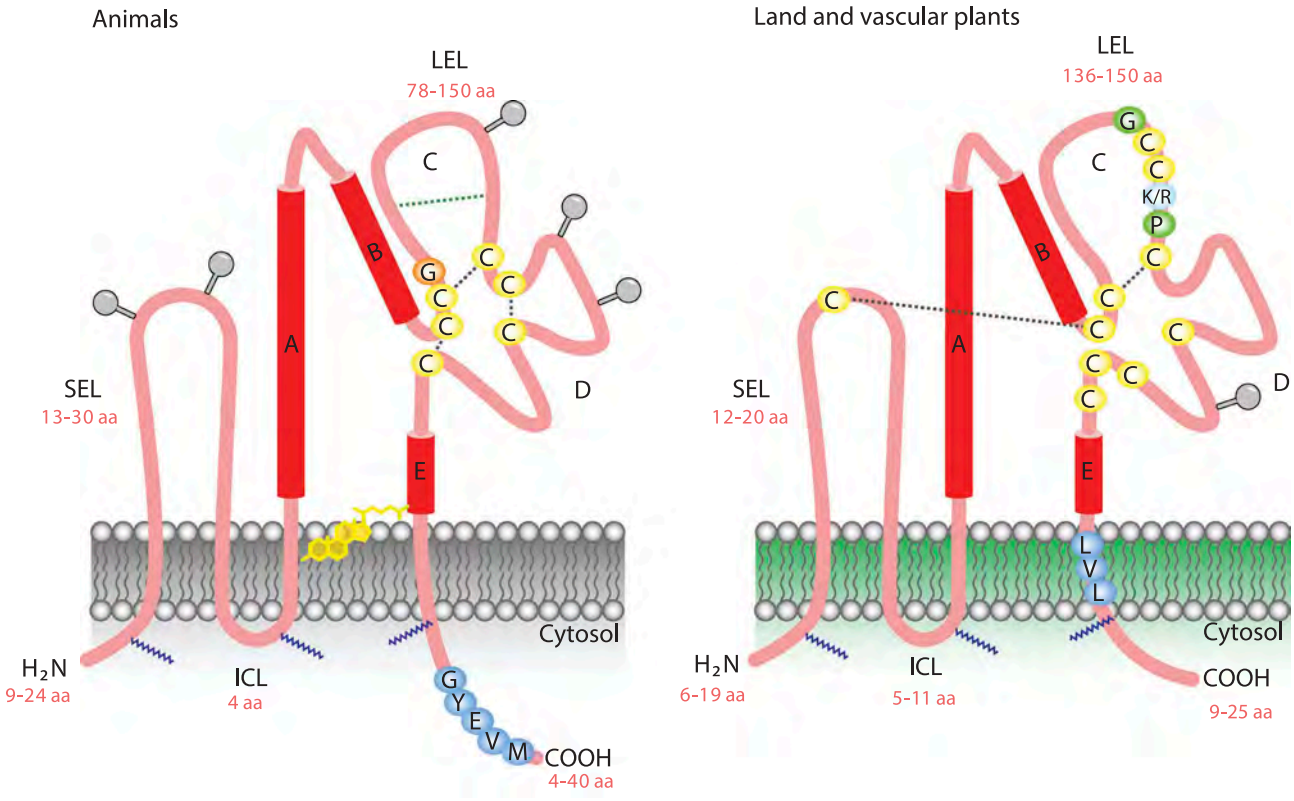

Figure 1. A general model describing the tetraspanin organization in the plasma membrane. Note the similarity and differences in the two extracellular loops. Plant tetraspanins contain a conserved cysteine that is not present in animal tetraspanin. (SEL) small extracellular loop, (LEL) large extracellular loop, (ICL) intracellular cytoplasmic loop, (GYEVM) endosome signal peptide, (GCCK/RPC) conserved sequence in plants, (LVL) putative plasmodesmata sorting.

have nine, rather than four, six, or eight, completely conserved Cys residues.[14] In plants, missense mutations in these Cys residues in *trn2–2* and *trn2–3* alleles, or the exchange of an uncharged amino acid (Pro-164 in *trn2–2* and Gly-177 in *trn2–3*) with a charged amino acid (Gluc) within the conserved EC2 region containing three Cys residues, could affect folding due a defect in disulfide bridges and thereby inhibit tetraspanin function.[25] This is intriguing, as crystallographic data and an analysis of the molecular dynamics of tetraspanin CD81 ECL2, showed the conformational plasticity of the EC2 region under different pH values and redox environments, suggesting that it acts as a molecular sensor of environmental change.[15,26] It is possible that plant tetraspanins could have a similar response under pH and redox changes. Little is known about the C-terminal tail of tetraspanins, a divergent and short region (4 to 40 amino acids) in animals and plants that is longer in fungi.[14,15,27] However, the C-terminal tail has been implicated in trafficking, as discussed below.[28–30]

Tetraspanin interactors: what we have learned from the animal field and how little is known in plant cells

In animal cells, the most prominent tetraspanin interactors are the integrins, growth factor receptors, G-protein-coupled receptors (GPCRs), several peptidases, transmembrane proteins associated with tumor progression (CD44), epithelial cell adhesion molecule (EPCAM), immunoglobulin (Ig), protein kinase C PKC), phosphatidylinositol 4-kinase (PI4KII), and phospholipase Cγ (PLCγ).[12] By contrast, the interactors of plant tetraspanins are unknown and the literature is limited to the expression and subcellular localization of plant tetraspanins in a few cell models,[4,14,15,31] and their role in recruiting ROS generating enzymes.[32–34]

In animal cells, TEM components have been dissociated using various detergents to examine interactions between tetraspanins and other molecules in the TEM. Different levels of interactions, ranging from strong associations to much weaker associations that are stable only in less hydrophobic detergents, such as Brij97, have been observed.[23] Three types of primary tetraspanin interactions, types I–III, exist. Type I interactions involve direct protein–protein interactions, such as those occurring in tetraspanin homodimers, homotrimers, homotetramers, and some heterointeractions.[23,35] Most tetraspanin–integrin and tetraspanin–tetraspanin interactions are type II interactions, which are less strong. Palmitoylation of tetraspanins, and possibly of their associating proteins, is essential for this type of interaction, which may be initiated in the Golgi apparatus.[36] Weak type III interactions, such as those occurring between tetraspanin and several kinases, are also stabilized by palmitoylation. In addition to primary interactions, the functional activity of tetraspanins also depends on cholesterol and gangliosides, which enable higher-order tetraspanin complexes to form, which constitute the TEM.[37] TEMs provide a signaling platform that recruits tetraspanin and its interactors. The palmitoylation of juxta-membrane cysteine residues of tetraspanins (Figure 1) is critical for the assembly of TEMs and is necessary for tetraspanin/tetraspanin interactions. Some integrins are also palmitoylated, and this modification appears to promote TEM formation. Cholesterol embedded in the membrane of the endosome is thought to stabilize TEMs.

Although TEMs share features with lipid rafts, they are independent and distinct from these structures. For instance, lipid rafts, but not TEMs, are disrupted by Triton X-100 at 4° C and the signature molecules of classical rafts, such as the glycosylphosphatidylinositol-anchored proteins and caveolin, do not associate with tetraspanins.[12] Furthermore, TEMs can be purified in low-density sucrose gradient fractions and are enriched in certain lipids (e.g., cholesterol and ganglioside GM3), while lipid rafts have different biophysical properties, are more sensitive to cholesterol depletion, and contain different arrays of membrane proteins.[6,7] Visualization of TEMs by fluorescence microscopy suggested that they are confined in discrete units at the nanometric scale for each class of tetraspanin. Recent single-molecule analyses of tetraspanin CD9 in animal cells shed light on tetraspanin dynamics in TEMs and the plasma membrane, redefining the tetraspanin web.[7,38,39] These studies indicate that tetraspanins form stable interaction platforms that are distinct from lipid rafts and in permanent exchange with the rest of the cell membrane. In addition, CD9 mobility and partitioning into these platforms depends on palmitoylation and cholesterol.[2]

Although no direct interaction partners of tetraspanins have been identified in plant cells, the cellular distribution of tetraspanin in reproductive tissues has been described.[15] Genetic data indicate that AtTET1 functions in a common pathway with TORNADO1 (TRN1), a leucine-rich-repeat protein that regulates patterning processes during *Arabidopsis thaliana* development, and double mutant analysis showed that these proteins are required for related, overlapping signaling events.[14] Furthermore, AtTET1 functions together with WINDHOSE1 and 2 (WIH1/WIH2), two small peptides, to promote megasporogenesis.[25,40,41] The short and divergent C-terminal tail of both animal and plant tetraspanins has been linked to targeting to intracellular locations and interaction with cytoskeletal or signaling molecules, including protein kinase C, integrins, and mu3A subunit AP-3.[14,15,19] The phenotype of the Arabidopsis mutant *trn2-4*, which lacks 10 of 14 amino acids of the tetraspanin C-terminal tail, is as dramatic as that of the other *trn2* alleles, suggesting that this region of plant tetraspanins is as critical as that described for animal tetraspanins.[25] The C-terminal tail of the fungal tetraspanin Tps3 is larger than that of plant and animal tetraspanins and its specific interactors are unknown.[27]

Tetraspanins are key players in cancer development, with multiple antagonistic effects.[42] For example, the tetraspanin CD82 is downregulated, while tetraspanins CD151 and tetraspanin 8 are induced during metastases and support tumor progression.[12] Not all activities of tetraspanin rely on primary interactions with associating molecules; some biological phenomena can only be explained by considering the higher organization of tetraspanin complexes, which can interfere with the capacity of tetraspanins to recruit other molecules that negatively regulate a cellular event, such as the activation of a tyrosine phosphatase.[43] However, recruitment of specific partner molecules in TEMs such as gangliosides could contribute to CD82-mediated metastasis-inhibiting activity.[12] Tetraspanin CD9 also hampers the migration of metastasizing cells by interacting with the cytoskeleton. Indeed, overexpression of CD9 downregulates WAVE2 by a yet unknown mechanism,[44] since WAVE is part of the ARP2 and ARP3

complex in actin polymerization, it links upstream signals to activation of the ARP2 and ARP3 complex (e.g., during lamellipodium and filipodium formation). Some tetraspanins have a Yxxφ sorting motif, located close to the transmembrane region, that can disrupt the binding of the μ subunit of the AP2 adaptor complex, resulting in another cytoskeleton key regulatory component.[12,17] Therefore, tetraspanins exert their function by modulating, stabilizing, or preventing the activities of their associated molecules, depending on the composition of the TEM.[12,44,45]

Role of tetraspanin in cell trafficking

Although tetraspanins were first identified as cell surface markers, it is now clear that some associate with the endosomal pathway, i.e., in early and late endosomes, multivesicular bodies [MVBs], clathrin-coated vesicles, lysosomes, and various types of secretory vesicles.[46] Tetraspanins on the plasma membrane can be internalized via endocytosis and traffic to intracellular vesicles.[47,48] Conversely, on cell stimulation, secretory vesicles containing tetraspanins fuse with the plasma membrane.[46] Late endosomes and MVBs also fuse with the plasma membrane and release vesicles containing microRNA, proteins, and lipids known as exosomes that are enriched in certain tetraspanin proteins.[49] Exosomes released from cells infected with intracellular pathogens, including mycobacteria, are potent stimulators of inflammation in uninfected cells.[50] Thirteen of the 33 mammalian tetraspanins contain potential tyrosine-based sorting motifs, which have also been described in plants. However, in plants, additional motifs have been identified in tetraspanins, and the coat protein clathrin is necessary and sufficient for the uptake of cargo into clathrin-coated vesicles (CCVs). These motifs in the tetraspanins are based on the sequences YXXØ [D/E]XXXL[L/I] and FXNPXY, which are recognized by a family of adaptor protein (AP) complexes that determine the cellular localization of interacting proteins.[2,17] The intracellular trafficking of tetraspanin CD63 has been well described.[17,22] CD63 has a conserved GYEVM motif at its C-terminus, which interacts primarily with AP-2 complexes, linking tetraspanins to clathrin-mediated endocytosis pathways, and with AP-3 complexes for trafficking from endosomes to lysosomes. Furthermore, CD63 is also targeted to lysosomes directly from the trans-Golgi network.[22] Tetraspanin CD63 interacts directly through its C-terminus with syntenin, which may compete with AP-2 and AP-3 to alter the trafficking of syntenin and therefore link its spatial localization with actual function.[17,22] It has also been recently suggested that CD63 in animal cells is internalized from the plasma membrane by endocytosis of a specialized type of lipid raft known as caveolae, linking tetraspanin to the regulation of endocytosis.[2,17,22]

Tetraspanins as key players in pathogenic interactions in animal and plant cells

Several infectious agents evolved mechanisms to exploit tetraspanins for pathogen entry, subsequent intracellular trafficking, replication, and even exit from the host cell. Tetraspanins have been associated with or shown to mediate infection by human hepatitis C (HCV), HIV, *Plasmodium* species that cause malaria, certain types of bacteria, and even prions.[2] Some viruses (e.g., HIV, human T-cell leukemia virus [HTLV]) induce cell–cell fusion in a tetraspanin-dependent manner, resulting in the formation of giant cells or viral syncytia that contribute to spread of infection.[2,51] In some cases, tetraspanins act as pathogen receptors; however, they can also work as 'molecular organizers', forming TEMs by the lateral association of tetraspanins with other tetraspanin and non-tetraspanin membrane proteins.[2]

In T cells themselves, tetraspanins in TEMs promote actin cytoskeleton associations that may lead to more efficient signaling or contribute to the formation of the immune synapse in T cells and it has been suggested that tetraspanins facilitate antigen presentation or antigen signaling.[2] The localization of tetraspanins in TEMs has made it challenging to define the functions of individual family members, mainly because the antibodies that cross-link specific tetraspanins also perturb the organization and functions of interacting molecules, giving misleading information.[23,43] However, the soluble recombinant EC2 domain is an alternative tool to investigate the role of specific tetraspanins.[52] Recombinant EC2s appear to fold correctly and have biological activity in a number of systems.[2,52] Nonetheless, knockouts clearly demonstrate that particular cellular functions (e.g., T-cell proliferation, sperm–egg fusion) can be affected by the modulation of a specific tetraspanin. Targeting of individual tetraspanins may provide a therapeutic means to modulate cellular processes without global detrimental effects on the organism, including plant cells.[2]

Plants have the capability to respond to abiotic and biotic stresses, including fungal pathogens. Fungi are responsible for major diseases of agriculturally important plants. For example, *Magnaporthe grisea* is the causative agent of the most devastating fungal disease (blast) of rice (*Oryza sativa*) worldwide, *Botrytis cinerea* is a necrotrophic pathogen affecting more than 200 different host plants, and *Colletotrichum lindemuthianum* is responsible for anthracnose diseases in a wide range of crops and ornamental plants. The ability of plant pathogenic fungi to infect their host plants depends on successful penetration into plant tissues. During the infection process, these fungi differentiate a specialized cell called the appressorium, in a process involving arrest of polarized growth, apex swelling, and cell wall reinforcement[27,53,54] (Figure 2). Appressorium-mediated penetration occurs through the formation of a penetration peg at the base of the appressorium lying against the plant substratum, a region called the 'appressorium pore'. The narrow penetration peg is able to perforate the host surface, which includes the plant cuticle and cell wall, allowing the fungus to penetrate into host tissues.[27,53,54] The penetration peg emerges at a certain point of the base of the appressorium and requires spatial and temporal coordination of cellular functions, including reorganization of cytoskeletal elements; vesicular trafficking; exocytosis, including membrane and synthesis; assembly and remodeling of the cell wall.[53,55,56] Fungal tetraspanins have emerged as key coordinators of the infection process in several pathogenic fungi (*M. grisea, B. cinerea*, and *C. lindemuthianum*).[32,54,57,58] In these phytopathogenic fungi, Pls1 is essential for appressorium-mediated penetration into the host plant, since Pls1 null mutations result in appressoria that are unable to form functional

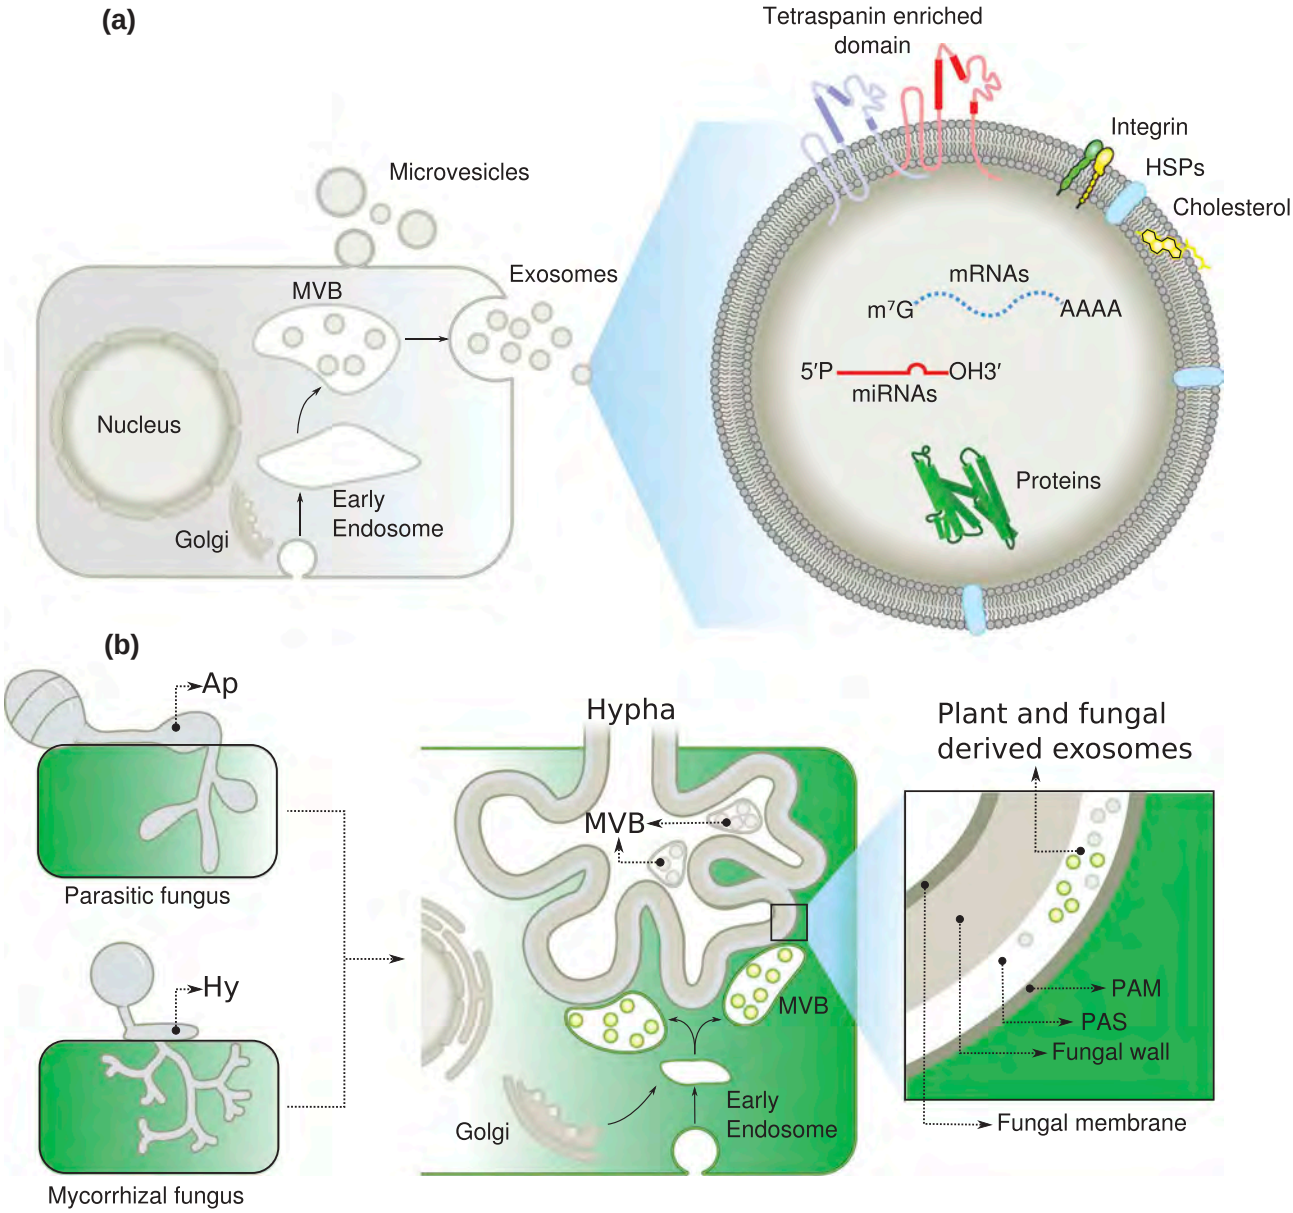

Figure 2. A model describing the role of exosomes in inter-kingdom communication. (a), Note the key role of exosomes in transporting molecules and tetraspanin in the exosome membranes as a marker. (b) Putative role of exosomes in mutualistic interactions. penetration pegs.[27,53,58] Using a transcriptional fusion between the *PLS1* promoter and an eGFP reporter gene, clear expression is observed during the penetration of *B. cinerea*.[54] These results suggest that processes involved in appressorium-mediated penetration are conserved among taxonomically unrelated fungal species.[27,54] Since peg formation and penetration require the re-establishment of cell polarity at a focal point localized at the base of the appressorium, Pls1 tetraspanins might be required for the correct localization of the emergence site of the penetration peg. The finding that penetration peg was aborted or mislocalized in *C. lindemuthianum clpls1* null mutants supports this interpretation.[58] Therefore, functional studies of Pls1 tetraspanins in pathogenic fungi may reveal more general functions such as the generation of positional information during specific stages of fungal morphogenesis.

Tetraspanins as regulators of localized ROS generation by NADPH oxidases (NOX)

The wide distribution of tetraspanins in eukaryotes and their notable absence in unicellular fungi suggest that tetraspanins co-emerged with multi-cellular organisms during evolution, and are thus associated with multicellularity.[4] It is largely unknown how tetraspanins engage in multi-faceted functions at the cellular level. However, there is an emerging co-occurrence between tetraspanins and the mechanisms of ROS generation.[33] In the nematode *C. elegans*, the rigid and flexible cuticular exoskeleton, which is composed of collagen, protects the internal tissues. Once secreted, this collagen is tyrosine cross-linked in a ROS-dependent manner, in a process assisted by BLI-3, a DUOX NADPH oxidase.[59] This process also requires the participation

of tetraspanin TSP-15, which recruits the NADPH oxidase.[33,34,60] Inactivation of this tetraspanin or of BLI-3 produces similar phenotypes. This finding suggests a connection between the mechanism generating ROS and the tetraspanins. In fungi, tetraspanins have been related to NOX function based on the fact that mutants lacking either of these proteins show the same phenotypes. Furthermore, during plant infection with the pathogenic fungus *M. grisea* or *B. cinerea*, the tetraspanin PLS1 specify the infection sites, and the tetraspanin and ROS generated by NADPH oxidase coordinate ROS production at the infection site. Furthermore, in the pathogenic *C. lindemuthianum*, a tetraspanin is required in the appressorium, which is a swollen not growing structure, but in order to progress the fungal infection a re-initiation of the polarity is required.[32–34,58,61] Furthermore, in *Claviceps purpurea*, Nox2 and Pls1 are also important for host–pathogen interaction.[62]

These data point to a strong connection between tetraspanins and the ROS generating machinery, both in animal and plant cells, suggesting that tetraspanins regulate localized ROS production.[33,34,60,63] Localized ROS production is also required during Casparian strip lignification in plants, where CASP, a protein that recruits NADPH oxidase, plays a role similar to tetraspanin, by bringing together NADPH oxidase and peroxidase and ensuring the localized activation of the oxidase.[64] Tetraspanins have also been found at the tip of growing pollen tubes, a region that requires NADPH oxidase activity for the generation of ROS, key players in the regulation of polar growth.[65,66] Moreover, tetraspanins accumulate at the site of female gametophyte differentiation, suggesting an active role during pollen fertilization, a well-described ROS-dependent process that regulates programmed cell death.[15] It is tempting to speculate that tetraspanins recruit the ROS-generating machinery in a site-localized manner.

Exosomes as signaling shuttles, from inter-cellular communication to inter-kingdom communication

Inter-cellular and inter-kingdom signaling require specific molecules that can diffuse and be recognized by a different cell. Exosomes have emerged as a ubiquitous mechanism for transferring information between cells and organisms across all three kingdoms of life.[67,68] Initially described in animal cells as a general signaling pathway that allows communication between tumor and distal tissue during metastases, exosomes have also been shown to function in immune surveillance in plant cells during host–pathogen interactions,[69–72] and we propose that exosomes could also contribute to the regulation of mutualistic interactions.

Exosomes containing proteins, lipids, and RNAs produced by fungal pathogens can promote plant infection by transmitting pathogen-related molecules that could escape the host immune system or inhibit immune responses by favoring immune cell apoptosis. Furthermore, exosomes secreted by the plant host can have anti-infection roles by inducing immune responses that inhibit pathogen proliferation or infection. Therefore, exosomes might act as regulatory "bridges" during plant–pathogen interactions.[70]

How are exosomes produced and how are they related to tetraspanins? The general view is that exosomes are derived from multivesicular bodies (MVBs), which form when the endosomal membrane undergoes invagination, taking up proteins, lipids, inhibitors of apoptosis, and microRNAs from the cytosol.[73,74] The resulting vesicles inside the endosomes are termed MVBs. MVB either fuse with lysosomes or the plasma membrane, releasing their intraluminal vesicles as exosomes. There are other similar structures such as the ectosomes and microvesicles, which are assembled and released directly from the plasma membrane and therefore represent a different size and origin. The molecular composition of exosomes reflects their origin from intraluminal vesicles and includes several tetraspanins both in animals and plants.[71] It is important to note that exosomal proteins maintain their activity. Another notable feature is phosphatidylserine content on the outer membrane leaflet of the exosome in animal cells, which facilitates or triggers exosome uptake by phosphatidylserine-binding proteins (such as scavenger receptors, integrins, and complement receptors). The finding that exosomes can contain mRNAs and microRNAs that can be transferred to target cells where they can be translated or mediate RNA silencing, is a critical aspect of intercellular communication during the immune response, cell-to-cell spread of infectious agents, and tumor progression.[75–79] This process is specific to the target cell, such that RNA is transcribed in one cell, but travels long distances to affect another cell. Notably, the relative abundance of proteins, mRNA, and microRNA differs between exosomes and the cytoplasm of donor cells, suggesting a certain degree of specificity in the segregation of these components and therefore in the specificity of this type of communication. This implies that cargo is actively sorted into multivesicular bodies, through mechanisms such as monoubiquitylation, localization in cholesterol-rich membrane microdomains, or higher-order oligomerization. Although the contribution of tetraspanins to the composition of exosomes is well established, their impact on the functions of exosomes is unknown. However, it seems likely that tetraspanins are involved in the cross-talk between distant cells.[12] Specific tetraspanins and their interacting proteins, might contribute to exosome function and define the target cell.[80] Future studies providing the molecular mechanism to select the cargo and target cells by the exosomes will provide important information to manipulate the formation and targeting of exosomes.[2,81,82]

Exosomes in inter-kingdom communication during plant–pathogen interactions and future directions in mutualistic interactions

Eukaryotic regulatory small RNAs (sRNAs) that induce RNA interference (RNAi) are involved in a plethora of biological processes, including host immunity and pathogen virulence for successful infection.[83–85] In plants, diverse classes of sRNAs contribute to the regulation of host innate immunity. These immune-regulatory sRNAs operate through distinct RNAi pathways that trigger transcriptional or post-transcriptional gene silencing. Remarkably, the influence of regulatory sRNAs is not limited to the individual organism in which they are generated and it can sometimes extend to interacting species from different kingdoms.[71,86] Similarly, many pathogen-derived sRNAs regulate pathogen virulence, where they trigger gene silencing in the interacting organism, a phenomenon called cross-kingdom RNAi.[85,86] Aggressive

fungal pathogens such as *Botrytis* and *Verticillium* spp. that cause severe crop losses worldwide secrete effector proteins that suppress host immune responses.[86] Notably, the plant fungal pathogen *Botrytis cinerea* delivers and translocates small RNA effectors into host cells, where they hijack the plant RNAi machinery and suppress host immunity.[85,86] Upon *B. cinerea* infection, expression of the microRNA Bc-siR37 is specifically induced in the fungus, downregulating at least eight predicted Arabidopsis target genes and thereby enhancing disease susceptibility to *B. cinerea*.[86] Furthermore, knockout of the target genes of Bc-siR37 enhances disease susceptibility, further indicating that these genes promote plant defense against *B. cinerea*.[86] In summary, by regulating the expression of specific target genes in the plant host, it is possible to control multiple fungal diseases simultaneously. Therefore, cross-kingdom RNAi opens up a vastly unexplored area of research on mobile sRNAs in the host–pathogen interactions.[71,78,85] The big question is how is cross-kingdom communication carried out? Exosomes are produced in all domains of life, but little is known about exosomes in plants despite their implication in plant defense.[71,87–89] This work lays the foundation for the concept of cell-to-cell communication through exosomes in plants.[79] This idea is also supported in sunflower (*Helianthus annuus*), where exosomes in extracellular fluids of seedlings are enriched in cell wall remodeling enzymes and defense proteins which can be taken up by the phytopathogenic fungus *Sclerotinia sclerotiorum*, and affect fungal growth and even killing fungal cells.[88]

In animal cells, sRNAs can be transported by extracellular vesicles, specific transmembrane proteins, high-density lipoprotein complexes, or gap junctions.[90] The gastrointestinal parasite *Heligmosomoides polygyrus* also secretes exosomes, thereby transporting microRNAs (miRNAs) into mammalian cells and suppressing host immunity.[76] By contrast, the mechanism by which sRNAs are transported from hosts to interacting pathogens is unknown. In plant cells, it is well known that sRNAs travel through plasmodesmata, and thus systemically through the vasculature; however, cross-kingdom/organism RNA interference (RNAi) mediated by exosomes opens up a new area of research.[71] Because exosomes transfer miRNAs between animal cells as part of a long-distance signaling system and also in parasites interacting with mammalian host cells, the recent finding that plants and pathogenic fungi employ a similar mechanism involving exosome-mediated sRNA transfer indicates that exosomes constitute a general mechanism for intercellular and inter-kingdom signaling. This is a bi-directional communication with exosomes generated in the host to control the pathogen, but also with exosomes generated in the pathogen to promote the infection. Thus, studies should examine how exosomes travel across the boundaries between organisms of different taxonomic kingdoms.[71] In Arabidopsis, the cuticle is an important barrier against pathogens. However, in cuticle mutants, higher ROS production is able to sustain constitutive resistance against *B. cinerea* due to an increase in the cuticle permeability, which facilitates the diffusion and recognition of the cuticle monomers that induce the innate response. However, increased cuticle permeability could also facilitate exosome transport and diffusion in the permeable cuticle, allowing for neutralization of the pathogen through the exchange of miRNAs.[91–93]

Mammalian tetraspanins, such as CD63, are specific exosome markers.[77] Arabidopsis has 17 *TETRASPANIN* (*TET*)-like genes, but only closely related *TET8* and *TET9*, which are structurally similar to mammalian CD63, are induced by *B. cinerea* infection, at the fungal infection sites and as part of the exosomes.[15,94] Since mammalian exosomes are derived from MVBs, it is not surprising that the *Arabidopsis thaliana* MVB marker Rab5-like GTPase ARA6[95] is also enriched at infection sites, and is partially co-localized with TET8, suggesting that TET8-associated vesicles are likely derived from MVBs. Electron microscopy studies revealed in Arabidopsis that MVBs fuse with the plasma membrane and release extracellular vesicles at infection sites. Furthermore, TET8-associated vesicles have been visualized with*TET8-GFP*, but not ARA6, because ARA6 localizes to MVB outer membranes that fused to and remained on plasma membranes.[71] Thus, TET8-labeled extracellular vesicles can be considered as a specific marker for plant exosomes. The observations that TET8-GFP-labeled exosomes can be taken up by fungal cells under *in vitro* conditions[71] and that exosome-carried sRNAs can be translocated to fungal cells supports the involvement of a shuttle mechanism in inter-kingdom communication.

Animal tetraspanin proteins can induce the formation of specific TEMs; therefore, the finding that TET8-CFP and TET9-YFP are co-localized at fungal infection sites suggests that a particular TEM exists in those regions where hetero-tetraspanin organization is required. Such a TEM could play a key role in exosome biogenesis and translocation since the *tet8* T-DNA knock-out mutant and two independent *tet9* CRISPR frame-shift lines resulted in a weak, but consistently enhanced susceptibility to *B. cinerea*, as compared to the wild type.[71] Moreover, *tet8tet9* double mutants showed pronounced enhanced susceptibility, suggesting that TET8 and TET9 have partially redundant functions, and supporting the idea that TET8- and TET9-associated exosomes contribute to plant immunity against fungal infection by transferring host sRNAs into fungal cells.[71] The transferred sRNAs are thought to suppress fungal pathogenicity by targeting fungal virulence genes. Most Arabidopsis sRNAs transferred to *B. cinerea* have predicted target genes, such as those involved in trafficking pathways, that are downregulated after infection. When such target genes were mutated in *B. cinerea*, the resulting strains showed reduced virulence on Arabidopsis, supporting the idea that vesicle trafficking pathways are important for fungal virulence.[71,86] Furthermore, transgenic Arabidopsis lines overexpressing those sRNAs displayed a reduced susceptibility to *B. cinerea* and the pathogen showed reduced expression of the target genes.[71] Therefore, exosomes play an essential role in cross-kingdom sRNA trafficking between Arabidopsis and the fungal pathogen *B. cinerea*.

An interesting parallel has been reported in humans: cross-kingdom trafficking of human miRNAs into the parasite *Plasmodium falciparum* inhibits expression of its pathogenicity genes, which explains why sickle cell anemia patients, who have elevated levels of these transferred miRNAs, are more resistant to malaria.[71,96] It is unclear whether human exosomes are also responsible for sRNA delivery, and how ubiquitous such sRNA trafficking-mediated defense mechanisms are in animals and plants. Functional studies of host-transferred sRNAs may reveal

INFORME DE LABORES 2019

important virulence genes in pathogens and pests. Knowledge of tetraspanin activity during exosome biogenesis, cargo loading, and cross-kingdom RNAi may suggest a strategy to develop effective delivery methods of pathogen-targeting artificial RNAs with the goal of controlling plant diseases during pre- and post-harvesting of crops.

MVBs proliferate in susceptible and resistant barley (*Hordeum vulgare*) leaves in response to infection by the biotrophic powdery mildew fungus *Blumeria graminis* f. sp. *hordei*, and this response is associated with the cell wall defense response.[97,98] This response is also exacerbated in the cytoplasm of haustorium-containing epidermal cells, where MVBs proliferate in the vicinity of the cell wall-associated oxidative microburst.[99] Since MVBs are related to exosome biogenesis, this could explain the exosome production observed at infection sites.

The successful establishment of the arbuscular mycorrhizal (AM) symbiosis relies on the formation of arbuscules in the inner cortex of the root, which mediates a nutrient exchange between the plant and fungus (Figure 2). A variety of transporter proteins on the peri-arbuscular membrane facilitate nutrient exchange and communication. Arbuscule formation depends on fungal recognition by the host plant, which requires the tight coordination of several cellular processes ranging from the formation of the pre-penetration apparatus to initial fungal colonization and development of arbuscules. During the early stages of infection, mycorrhizal associations also require cross-talk between the host and the beneficial fungus, and this signaling can occur before the hyphae have come into contact with the host. Plants secrete strigolactones, which induce hyphal branching, and stimulate the production and secretion of Myc factors, which allow the colonization process.[100,101] It would be interesting to determine if MVBs proliferate at the arbuscule region and to determine at which stages of the mutualistic interaction exosomes are produced. So far, there is clear evidence that the secretory pathway of the plant host plays a critical role in the arbuscule formation, but it is unclear how this pathway is redirected during arbuscule development. It is attractive to speculate that exosomes coordinate the exchange of proteins, lipids, and sRNA during the establishment of AM symbiosis. Transcription factors are known to function in the transcriptional reprogramming of cortical cells during arbuscule development, and it is possible that they are modulated by exosomes released from fungi and the plant host. Studies involving the silencing and overexpression of key proteins involved in exosome biogenesis and function, such as the tetraspanins, will provide further insight into exosome biogenesis and the possible reprogramming of hyphal polarity in the hyphopodium structure which requires a further re-initiation of polarity to infect the host cells and generates the arbuscule formation.

Proteomic analyses of exosome cargo components formed during the AM symbiosis will be instrumental in determining their composition relative to those reported in pathogenic interactions.[71,102] Recently, H_2O_2 has been described as an important component of axonal regeneration after acute injury.[103] However, the injured neurons do not express the NADPH oxidase required for ROS generation. Instead, macrophages recruited to the vicinity secrete exosomes carrying NOX enzymes, which are taken up by the injured neuron via endocytosis and promote axonal growth in a ROS-dependent manner.[103–105] This is the first report describing the role of exosomes in NADPH oxidase translocation in injured neurons. This is an interesting finding since NOX enzymes also function in the injury response of the fungus *Trichoderma atroviride*.[106] It remains to be determined whether an exosome shuttle system carrying ROS generating enzymes contributes to localized ROS production in mutualistic and pathogenic interactions, at the infection thread or during arbuscule formation. Since the arbuscules and the infected cells require an intense vesicular trafficking, it will be important to decipher the role of tetraspanins and the exosomes in the exchange of key proteins, miRNA and mRNA, required for the mutualistic interaction (Figure 2). It could be involved in hyphal colonization during mycorrhizal association and arbuscular formation. During the legume–rhizobia interaction, the infection thread allows migration of the rhizobium through the root hairs until they reach the cortical cells. It is not clear how root hairs are inverted during infection thread formation, but this process clearly involves a complete change in root hair polarity. Given the involvement of tetraspanins in membrane fusion and endocytosis, we anticipate that tetraspanins might be key players in the regulation of root hair or fungal hypha polarity and in the exocytosis and endocytosis occurring at the tip of migrating infection threads. It is clear that the exosome role is just emerging in the plant biology field, but the parallelism between the pathogenesis and mutualism, and the different strategies used by the host, pathogen or symbiont to modulate the interaction, point out to the exosomes as a key player for tuning the interaction by exchanging important components required for a successful interaction. In this scenery, specific tetraspanin such as AtTET8, which are specific markers for exosomes, will open the door for the manipulating the number of exosomes and understand the role of exosomes in pathogenic and mutualistic interaction.

Abstract

Arbuscular mycorrhizal fungi and rhizobia association with plants are two of the most successful plant-microbe associations that allow the assimilation of P and N by plants, respectively. These mutualistic interactions require a molecular dialogue, i.e., legume roots exude flavonoids or strigolactones which induce the Nod factors or Myc factors synthesis and secretion from the rhizobia or fungi, respectively. These Nod or Myc factors trigger several responses in the plant root, including calcium oscillations, and reactive oxygen species (ROS). Furthermore, superoxide and H_2O_2 have emerged as key components that regulate the transitions from proliferation to differentiation in the plant meristems. Similar to the root meristem, the nodule meristem accumulates superoxide and H_2O_2. Tetraspanins are transmembrane proteins that organize into tetraspanin web regions, where they recruit specific proteins into platforms required for signal transduction, membrane fusion, cell trafficking and ROS generation. Plant tetraspanins are scaffolding proteins associated with root radial patterning, biotic and abiotic stress responses, cell fate determination, and hormonal regulation and recently have been reported as a specific marker of exosomes in animal and plant cells and key players at the site of plant fungal infection. In this study, we conducted transcriptional profiling of the tetraspanin family in common bean (*Phaseolus vulgaris L*. var. Negro Jamapa) to determine the specific expression patterns and subcellular localization of tetraspanins during nodulation or under mycorrhizal association. Our results demonstrate that the tetraspanins are transcriptionally modulated during the mycorrhizal association, but are also expressed in the infection thread and nodule meristem development. Subcellular localization indicates that tetraspanins have a key role in vesicular trafficking, cell division, and root hair polar growth.

role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Introduction

The symbiotic interaction between rhizobia and legumes requires a molecular dialogue that involves the exchange of specific signaling molecules. Legumes secrete particular flavonoids or strigolactones that are specifically recognized by rhizobia or mycorrhizal fungi [1]. These compounds induce the expression of specific genes, which encode proteins involved in the synthesis and secretion of Nod factors (NFs) from rhizobia, which are lipochitin-oligosaccharides or the Myc factor from the mycorrhizal fungi [2, 3]. Thereafter, NFs or Myc factors are specifically recognized by the plant root and induce several responses, including ionic changes, membrane depolarization, cytoskeleton rearrangements, reactive oxygen species (ROS) generation, and gene expression [4–7]. Soon after the rhizobia reach the root hair, microfilament structures and Ca^{2+} gradients undergo dramatic changes in the tip region of root hair cells in response to NFs [8–11]. In *Arabidopsis thaliana* root hairs, ROS-mediated Ca^{2+} channel activity supports polar growth [12–14]. Therefore, ionic responses, ROS production, and cytoskeletal rearrangements have been suggested as key players in reprogramming root hair growth, which allows the root hair tip curling response during the establishment of symbiotic interactions in legume plants. Then, a tunnel-like infection thread (IT) forms through invagination of the plasma membrane and the cell wall [2]. While the bacteria travel inside the IT through the root hair, the cortical cells divide in a NF-dependent manner to form the nodule primordia that the rhizobia colonize in structures named symbiosome. Once mature, the nodule is able to fix atmospheric nitrogen [15]. On the other hand, the arbuscular mycorrhizal association induces the hypopodium and the further invasion of the cortical cells, which end up with the arbuscule formation. Both processes, the bacterial colonization trough the infection thread and arbuscule formation, require an active vesicular trafficking, endocytosis and exocytosis in order to increase the membranal surface required for symbiosome and arbuscule formation [16, 17].

Given their wide distribution in mammals, insects, fungi, mosses, and plants, tetraspanins likely coemerged in multicellular organisms during evolution [18]. In animal cells, tetraspanins are typically localized at the cell–cell interface in tetraspanin-enriched microdomains (TEMs), where they associate with each other and with other membrane-bound molecules and build important molecular platforms or cell–cell interactions [19, 20]. Tetraspanins get their name from their four transmembrane domains. The N and C tails of tetraspanins are localized on the cytoplasmic side of the membrane, and four transmembrane domains allow for the formation of two extracellular loops, one small and one large. The large loop has highly conserved cysteine residues, which could act as redox and pH sensors or promote protein–protein interactions. The small loop in plant tetraspanins contains a cysteine residue that is absent in animal tetraspanins [21]. Although tetraspanins in animal cells have been involved in various biological functions, such as cell motility, morphology, signaling, plasma membrane dynamics, and protein trafficking, how tetraspanins engage in plant cells functions at the cellular level is largely unknown [18]. Furthermore, tetraspanin have been described in animal and recently in plant cells as key components and specific markers of the exosomes, which are vesicles derived from the exocytic multivesicular bodies (MVB) that carry important molecules such as lipids, proteins, messenger RNA, and microRNAs, that play important roles in cell-to-cell communication in animal [22]. In plant cells it has been recently reported that exosomes go beyond organism boundaries and inhibit a pathogenic interaction in plants [23]. There is also an emerging idea that tetraspanins are part of a mechanism that generates ROS [24, 25]. In animal cells, H_2O_2 has been described as an important component of axonal regeneration after acute injury [26]. However, the injured neurons do not express the NADPH oxidase required for ROS generation. Instead, macrophages recruited to the vicinity secrete exosomes carrying NOX enzymes, which are taken up by the injured neuron via endocytosis and promote axonal

growth in a ROS-dependent manner with a key participation of exosomes [26–28]. On the other hand, the cuticle exoskeleton of the nematode *Caenorhabditis elegans*, in a similar way to the cell wall in plant cells, requires the ROS-dependent cross-linking of tyrosine residues, in a process assisted by BLI-3, which is a DUOX NADPH oxidase, and tetraspanin TSP-15 [24, 25, 29, 30]. When plants are infected with the pathogenic fungus *Magnaporthe grisea*, the fungal tetraspanin Pls1 and an NADPH oxidase are localized at the infection sites or appressorium structure to generate a ROS accumulation response that is required to reestablish the appressorium polarity [24, 25, 31–33]. Therefore, accumulating evidence links tetraspanin with ROS and polarity. Furthermore, tetraspanins have been identified at the tip of growing pollen tubes, a region that requires NADPH oxidase activity for the generation of ROS, a key player regulating polar growth [34]. However, we do not know if tetraspanins also function in pollen tube or even root hair polar growth [35].

Tetraspanins also accumulate in the female gametophyte, suggesting that they have an active role during gametophyte development or fertilization, a well-described ROS-dependent process. Furthermore, tetraspanins function during the transition from the floral meristem to the gynoecium as well as during the somatic-to-reproductive cell fate transition during megasporogenesis, suggesting that these proteins are regulators of cell fate determination [35–37]. As tetraspanins are also expressed in specialized tissues, such as the the quiescent center or the early initial cells that give rise to lateral roots meristems, these proteins may function in specific tissues or contribute to cell fate determination [18, 35, 38]. The meristematic distribution of some tetraspanins suggests that these proteins might be involved in regulating meristematic activity, which is highly dependent on ROS accumulation generated by NADPH oxidase activity, with superoxide-promoting meristematic activity and H_2O_2-promoting cell differentiation [39, 40].

On the other hand, NADPH-oxidase-derived ROS is a key component during nodule development and mycorhizal formation [41–43]. Since superoxide and H_2O_2 are produced during nodulation [43], it is possible that the molecular mechanism that maintains meristematic activity in the root is conserved during nodule meristem development [38]. Therefore, it is plausible that the ROS requirement for meristematic activity in the plant root is conserved during primordium development during nodule organogenesis and that tetraspanins have similar functions during the early stages of nodule development, as described in lateral root formation in *Arabidopsis* [38].

Here, we report the differential expression profile of the tetraspanin family in *P. vulgaris* in response to rhizobia or NF inoculation in several specific plant cells, such as root primordia, root hairs, and nodules at several developmental stages. *PvTET8*, *PvTET4* and *PvTET3* were highly expressed in the root meristematic region and during the early stages of primordium nodule development. Since PvTET8 was highly induced during nodulation, but not during mycorrhizal association, we suggest that this tetraspanin plays a particular role during nodulation, including the infection thread formation. Furthermore, the subcellular localization of some tetraspanins at the apical plasma membrane of *P. vulgaris* root hairs and in cytoplasmic vesicles suggests that these proteins function in polar growth, a central process during infection thread formation and migration. Our findings suggest that tetraspanins may also contribute to the vesicular trafficking required for localized exocytosis during the infection process or contribute to the exosome biogenesis as described during the pathogenic responses.

Materials and methods

Phylogenetic analysis

Using the methodology described by Huang et al. (2010), tetraspanin sequences containing four transmembrane domains were database screened, including a small and large extracellular loop,

using bioinformatics tools. The sequences were aligned in ClustalW. To avoid subjective bias, manual alignment editing was minimized. A phylogenetic tree was built using MEGA version 6.0.6 with 1000 bootstrap tests and pairwise deletion.

Vector construction for analyzing the activity promoter and subcellular localization

To evaluate promoter activity, the *pPvTET1A*::*GFP-GUS*, *pPvTET8*::*GFP-GUS and pPvTET3*::*GFP-GUS* construct, which includes the 1000-bp fragment upstream of the initiation codon of TET1A, TET8 and TET3 respectively, was created by PCR using *P. vulgaris* cv *Negro Jamapa* genomic DNA as template and gene-specific primers (S1 Fig). Each product of PCR was cloned into the pENTR/D-TOPO vector (Invitrogen) and recombined into the destination binary vector pBGWFS7.0 using Gateway LR Clonase II Enzyme Mix (Invitrogen) [44]. In each step, the presence of the insert was confirmed by Sanger sequencing and PCR. All constructed plasmids were introduced by electroporation into *Agrobacterium rhizogenes* strain K599. To design constructs for overexpressing *PvTET10*, *PvTET6* and *PvTET3*, the open reading frame of each gene was isolated from *P. vulgaris* cDNA and inserted into the pH7WG2D.1 binary vector under the control of the constitutive 35S promoter [45]. Empty pH7WG2D.1 vector, which constitutively expresses GFP, was used as the control in the overexpression system. All constructed plasmids were introduced by electroporation into *A. rhizogenes* strain K599 and used for further generation of transgenic roots or *Agrobacterium tumefaciens* strain AGL1 for transient expression in *N. benthamiana* leaves.

Bean hairy root transformation

Common bean seeds (*Phaseolus vulgaris cv* Negro Jamapa) were used for *A. rhizogenes* K599-mediated transformation to generate hairy roots harboring a construct of interest in composite plants using a previously described method [46].

Treatment with Nod factors by nebulization

Common bean seedlings were incubated with Nod factors at 48 h post germination (hpg) by nebulization with the Omron ComAir Nebulizer System Model NE-C801 according to the manufacturer's instructions. The Nod factors were purified according to our reported method [47]. A kinetic of transcript accumulation was conducted in roots incubated with Nod factors at 12, 24, and 36 h post inoculation for each tetraspanin. Nebulization with 1% CHAPS (w/v) was used as a control.

Nodulation assays

Rhizobium tropici CIAT899 bacteria were grown in 250-mL flasks containing 100 mL of PY broth supplemented with 7 mM $CaCl_2$, 50 μg/mL rifampicin, and 20 μg/mL nalidixic acid, in a shaking incubator (250 rpm) at 30˚C until the suspension reached an OD_{600} of 0.8. For nodulation assays, transgenic composite plants were transplanted under hydroponic conditions in glass tubes containing Fahreus medium and inoculated with 1 mL of a *R. tropici* CIAT899 suspension diluted to an OD_{600} of 0.05 in 10 mM $MgSO_4$ and grown in a controlled environment chamber (16 h light/8 h darkness, at 26˚C). At the indicated time points after inoculation, inoculated roots were frozen in liquid nitrogen and stored at −80˚C. At 5 and 7 days post infection (dpi), the root region close to the tail that is most susceptible to nodule formation was selected, and at 10, 14, and 18 dpi, only nodules were selected. In all cases, the equivalent root region of uninoculated roots was collected as a control.

Mycorrhizal spore inoculation and mycorrhization

Common bean seedlings at 48 hpg were transferred into pots (20-cm diameter) with vermiculite that was previously well inoculated in the pot with 1 gr of *Rhizophagus irregularis* substrate containing on average 800 spores homogeneously distributed. Inoculated plants were irrigated twice weekly with half-strength B&D solution containing a low concentration of potassium phosphate (50 μM; a 95% reduction compared with the control (500μM) to potentiate AM colonization [48]). As controls, two conditions without spores of *R. irregularis* were used: one set of plants were irrigated with 50 μM potassium phosphate (scarcity phosphate) and the other with 500 μM potassium phosphate (standard condition). AM fungal colonization status was determined by light and confocal microscopy, as indicated. Root samples were collected at 1, 2, 3, and 6 wpi and frozen in liquid nitrogen. All samples were stored at −80˚C.

Quantification of transcript levels by RT-qPCR analysis

Total RNA was extracted from frozen tissues using TRIzol reagent (Life Technologies) according to the manufacturer's instructions. To eliminate contaminating genomic DNA, total RNA samples (1 μg in 20 μL) were treated with 1 unit of DNaseI (RNase-free; Invitrogen) at 37˚C for 30 min and then at 65˚C for 10 min. Two-step RT-qPCR was performed using Maxima SYBR Green qPCR Master Mix (2X; Thermo Fisher Scientific), following the manufacturer's instructions. Each reaction was set up using 100 ng of cDNA as template in a 20-μL final volume. Gene-specific primers used in RT-qPCR reactions are listed in S1 Fig. qPCRs were performed in a LightCycler 480 real-time PCR system (Roche). Relative transcript abundance was calculated using the formulae reported by Schmitteng et al. [49]. *P. vulgaris* Elongation Factor 1α (Pv-EF1α) was used as a reference gene, as previously described. RT-qPCR data are averages of three independent experiments or biological replicates with two technical replicates.

Root hair and root isolation

The roots of *P. vulgaris* seedlings were divided and separated at 48 hpg. First, the region of the primary root that contained root hairs was cut into three equal segments named zones I, II, and III. Zone I contained the tip of the root that contained the initial or bulging out root hairs, zone II contained the rapidly growing root hairs, and zone III contained the mature or full-grown root hairs. Each fraction was collected in different containers in liquid nitrogen. Samples were stirred vigorously to separate the root hairs from the roots. Root hairs were isolated by pouring the liquid nitrogen mixture through a metal strainer. At the end, the root hairs were separated from the root (now shaved root) using a strainer. The shaved roots corresponding to regions I, II, and III were collected for tetraspanin transcript analysis. Fractions were stored at −80˚C until use. In each biological replicate, in order to confirm the different developmental stage of root hairs, the level of *RabA2* transcript was measured to assess the differential expression of this gene in each enriched tissue fraction.

Subcellular localization of common bean tetraspanins

Transient expression assays were conducted in *Nicotiana benthamiana* leaves to determine the subcellular localization of PvTET3 and PvTET6 proteins. The molecular construction carrying 35S:PvTET3-GFP and 35S:PvTET6-GFP was transferred to *A. tumefaciens* AGL1. For transient assays, leaves from 4- to 6-week-old wild-type *N. benthamiana* plants were coinfiltrated with the agrobacterium suspension harboring 35S:PvTETx-GFP. The infiltrated plants were marked and kept in a growth room at 16 h light/8 h darkness at 25 ± 2˚C. Plasmolysis was

INFORME DE LABORES 2019

induced using a 1M NaCl hypertonic solution. Fluorescence was visualized 48–72 h after infiltration using a spinning disk confocal microscope (Yokogawa, Japan) as described below.

Microscopy imaging and analysis

Transgenic roots were mounted in chambers adapted from large Petri dishes with a hole in the center. The hole was covered with a large glass coverslip. The chamber contained a layer of solid Fahreus medium (with Phytagel at 0.8%) and cellophane paper to prevent root movement. Roots were visualized under the inverted microscope (Nikon Eclipse Ti-E, Japan) with a 40x/1.25 NA water immersion lens (Nikon). For confocal images, we used a spinning disk confocal system (Intelligent Imaging Innovations /3i, USA) consisting of a CSU-W1 confocal head (Yokogawa, Japan) and a modular solid-state laser stack; Slidebook software was used to control the system and capture images (Intelligent Imaging Innovations /3i, USA). Images were recorded with a digital camera (Andor-IXON 3; Andor^{TM} Technology) for 1–2 min at 512-nm resolution and with frame rates of 100–300 ms. GFP fluorescence was obtained by exciting with an argon/2 ion laser (488 nm), and emitted fluorescence was collected using an emission filter (500 to 530 nm).

Statistical analysis

Data processing and statistical analysis were performed using GraphPad Prism version 6.00 for Windows (GraphPad Software). An unpaired two-tailed Student's *t*-test was used to determine whether data from two different groups were significantly different, Double, or triple asterisks above the columns indicate differences that are statistically significant (p-value < 0.05).

Results

Plant tetraspanins have a unique cysteine residue in the small extracellular loop

To determine the number of tetraspanin members in common bean (*Phaseolus vulgaris L*. var. Negro Jamapa), we searched the database of nonredundant protein sequences in NCBI using BLASTP (Protein-protein BLAST) using AtTET10 as query. AtTET10 and OsTET14 from *O. sativa* can be considered the founders of the tetraspanin family in their respective species [35, 50]. We identified 13 putative tetraspanin sequences in *P. vulgaris*, 25 in *Glycine max*, 9 in *Medicago truncatula*, and 5 in *Lotus japonicus* (Fig 1 and S2 Fig). Seventeen tetraspanins have been described in the model plant *Arabidopsis* and 15 in *Oryza sativa* [35, 50]. PvTET10, and other orthologs of AtTET10 and OsTET14, have between 10 and 12 introns in all reported genomes, including *Marchantia polymorpha* and *Physcomitrella patens*.

The amino acid sequences and functional motifs previously described in *Arabidopsis* allowed us to select tetraspanin members in *P. vulgaris* and compare them to other tetraspanins in the legume genome database reported in Phytozome (https://phytozome.jgi.doe.gov/pz/portal.html). Next, we conducted a bioinformatic screen based on several sequences, including the transmembrane domains, the cysteine pattern in the large extracellular loop (LEL), the single cysteine residue located exclusively in plant tetraspanins in the small extracellular loop (SEL), and the GCC(K/R)P signature in the large extracellular loop. Multiple sequence alignment and motif analyses revealed that common bean tetraspanins maintain the general features described for plant tetraspanins, with high conservation in specific motifs. For instance, in *P. vulgaris*, these proteins share an average of 38% identity and 42% similarity, which is comparable to that observed for *O. sativa* and *Arabidopsis*.

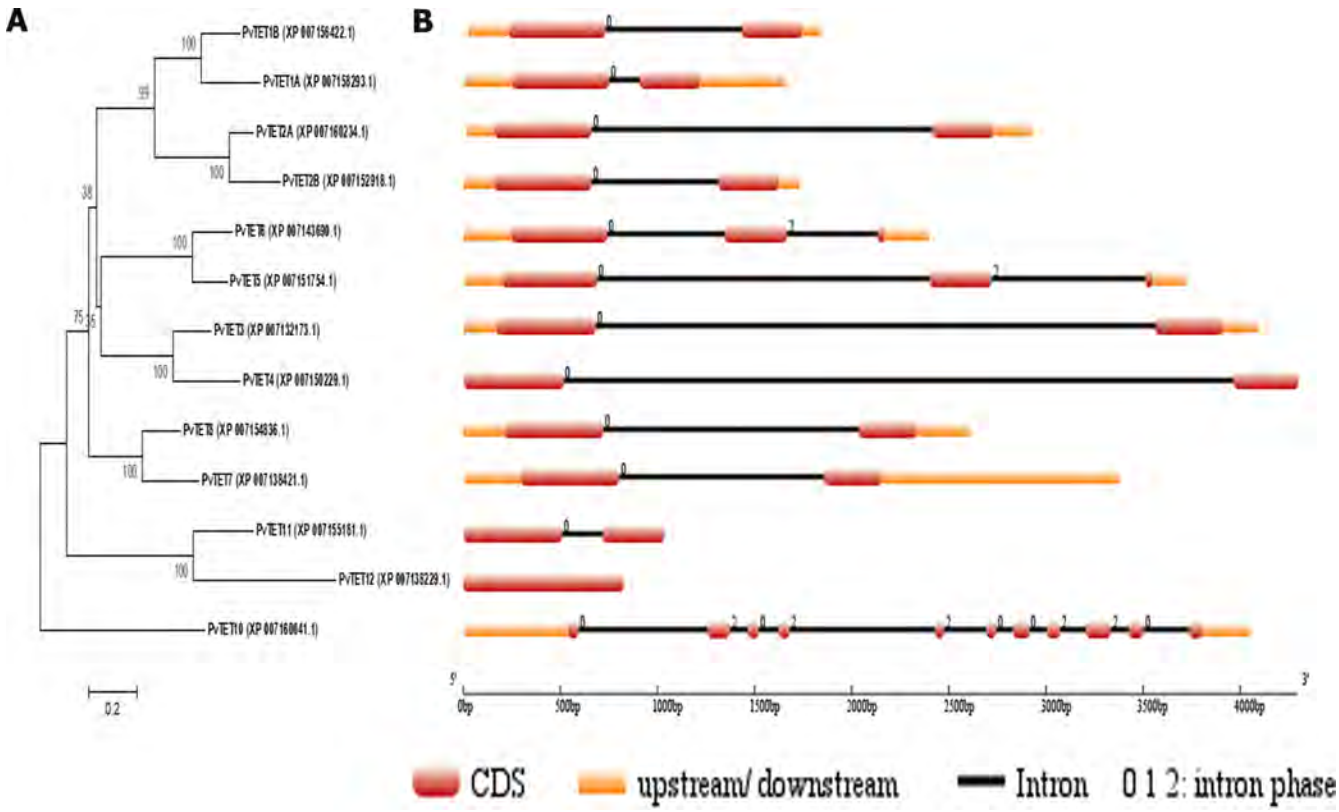

Fig 1. A rooted neighbor-joining phylogenetic tree of common bean tetraspanin. (A) On the left shown is the phylogenetic tree constructed using MEGA6.06, with amino acidic sequences from phytozome.org. Numbers above branches indicate bootstrap percentage values. PvTET proteins were clustered based on a significant bootstrap value of ≥50%. (B) On the right using an online tool, Gene Structure Display Server (GSDS; http://gsds.cbi.pku.edu.cn/), was used to draw the tetraspanin gene structure. Red boxes indicate exons, black lines depict introns, upstream/downstream sequences are shown as oranges boxes. Intron phases are indicated at exon–intron junctions.

https://doi.org/10.1371/journal.pone.0219765.g001

Based on these data, we generated an unrooted phylogenetic three using PvTET10 as a query from *Arabidopsis* (S2 Fig and S3 Fig). In our analysis, PvTET10 clustered with AtTET10 and OsTET14, whereas PvTET1A and PvTET1B clustered with AtTET1 (TORNADO) and AtTET2, and PvTET8 clustered with OsTET7-9 and AtTET8-9. We did not find a homolog of AtTET13 in the *P. vulgaris* genome or in any other legume genome. This could suggest the presence of a particular clade in *Arabidopsis* or in the Brassicaceae that does not exist in other plants, at least not in *P. vulgaris* or in legumes. In our molecular tree, we identified 7 groups, each of which contained at least two members, except the group that contained PvTET10 alone. Sequence identity and similarity analysis coupled with the number of introns supported the idea that PvTET10 is a common ancestor of tetraspanin in common bean, as described for its homologs in *Arabidopsis* (Fig 1). By contrast, PvTET12, which has no introns, is the most recent tetraspanin member and arose by functional divergence and loss of introns [51, 52].

GmTET12A (accession number XP_003551251.1) and GmTET12B (accession number XP_003547633.1) are homologs of PvTET12 (accession number XM_007138229.1). In *M. truncatula*, we identified one homologue of TET12 (accession number XP_013463988.1); however, we did not find a corresponding homolog in *L. japonicus*. The cytoplasmic N and C termini of plant tetraspanins each have 6–10 aa, making them shorter than animal tetraspanins, which contain between 9 and 40 aa, and even shorter than fungal ones, which contain between 4 and 100 aa.

In addition, we conducted an exhaustive *in silico* characterization of tetraspanins in common bean to predict disulfide bond formation. We used a bioinformatic tool for disulfide connectivity prediction named DiANNA (clavius.bc.edu/~clotelab/DiANNA/) and found that disulfide bonds form between the single cysteine located in the SEL and the cysteine residues found in the LEL of all common bean tetraspanins, as previously suggested for tetraspanins in *Arabidopsis* [35].

Tetraspanins PvTET3 and PvTET1A are highly expressed in root and root hair cells

To establish the transcript accumulation for the different tetraspanin genes in *P. vulgaris* roots, we selected root tissues and sectioned different regions with different developmental stages according to the experimental requirements (described in Materials and methods). In our experiments with *P. vulgaris*, we considered the three developmental root hair zones, which were evident by 48 h post germination (hpg). As depicted in Fig 2C we sectioned the three different root zones and separated the root hair cells from the root tissue, generating the enriched root hair fraction from the three developmental stages (zones I, II, and III) and the corresponding shaved root (Fig 2C). Transcript accumulation for all tetraspanin genes, except *PvTET2B* due to the lack of specific regions for primers design for amplification (accession number XP 007152918.1), was determined in each one of the generated samples (root hairs and shaved root); this analysis was conducted by selecting each tetraspanin family member and determining its accumulation in root hairs at different developmental stages (Fig 2B).

The monomeric GTPase PvRabA2 is a good marker of the different developmental stages of root hairs due to its key role in root hair tip growth (S4 Fig), although it is also expressed in root tissue [53, 54]. We observed that RabA2 transcript accumulated in root hairs; as expected, the transcript accumulation was higher in zones II and III, where the cells are rapidly expanding or reaching full length, compared with zone I, where root hairs are just bulging out (S4 Fig). As expected, the shaved root section that lacked root hairs also had increased *PvRabA2* transcript accumulation in zones I, II, and III, again with higher accumulation in zones II and III (S4 Fig). Therefore, these root sections were used to determine the transcript accumulation for selected tetraspanin members in *P. vulgaris*. We found that *PvTET3* and *PvTET1A* are more abundant in shaved roots or root hairs from zones II and III than from zone I (Fig 2A and 2B). However, *PvTET1A* present a very low expression in root hairs from zone II, but it is expressed in those from zone III (Fig 2B). This differential expression contrasts with shaved roots, where *PvTET1A* transcript accumulation increases gradually beginning from zone I to zone II and from zone II to zone III (Fig 2A). Furthermore, an analysis of the reported expression atlas of *P. vulgaris* [55] indicates that *PvTET3* is ubiquitously expressed during the different root developmental stages, while *PvTET1A* is constitutively expressed in all root tissue, but with higher expression in some stages of root development (S5 Fig).

PvTET1A, *PvTET8*, *PvTET3* and *PvTET4* are induced in response to NFs or rhizobia inoculation

We then evaluated the transcript accumulation of some tetraspanin genes in response to nanomolar concentration of NFs (10^{-9} M), which can reprogram polar growth and nodule primordia development [6]. In agreement with previous observations [6], treatment with 10^{-9} M NFs caused root hairs to swell and undergo morphological changes (S6B Fig). As expected, no morphological responses were observed when chitosan was used as a negative control (S6A Fig).

We initially considered to evaluate the transcript accumulation in response to NFs or rhizobia for *PvTET1A and PvTET3* since these genes were the most highly expressed in shaved root

INFORME DE LABORES 2019

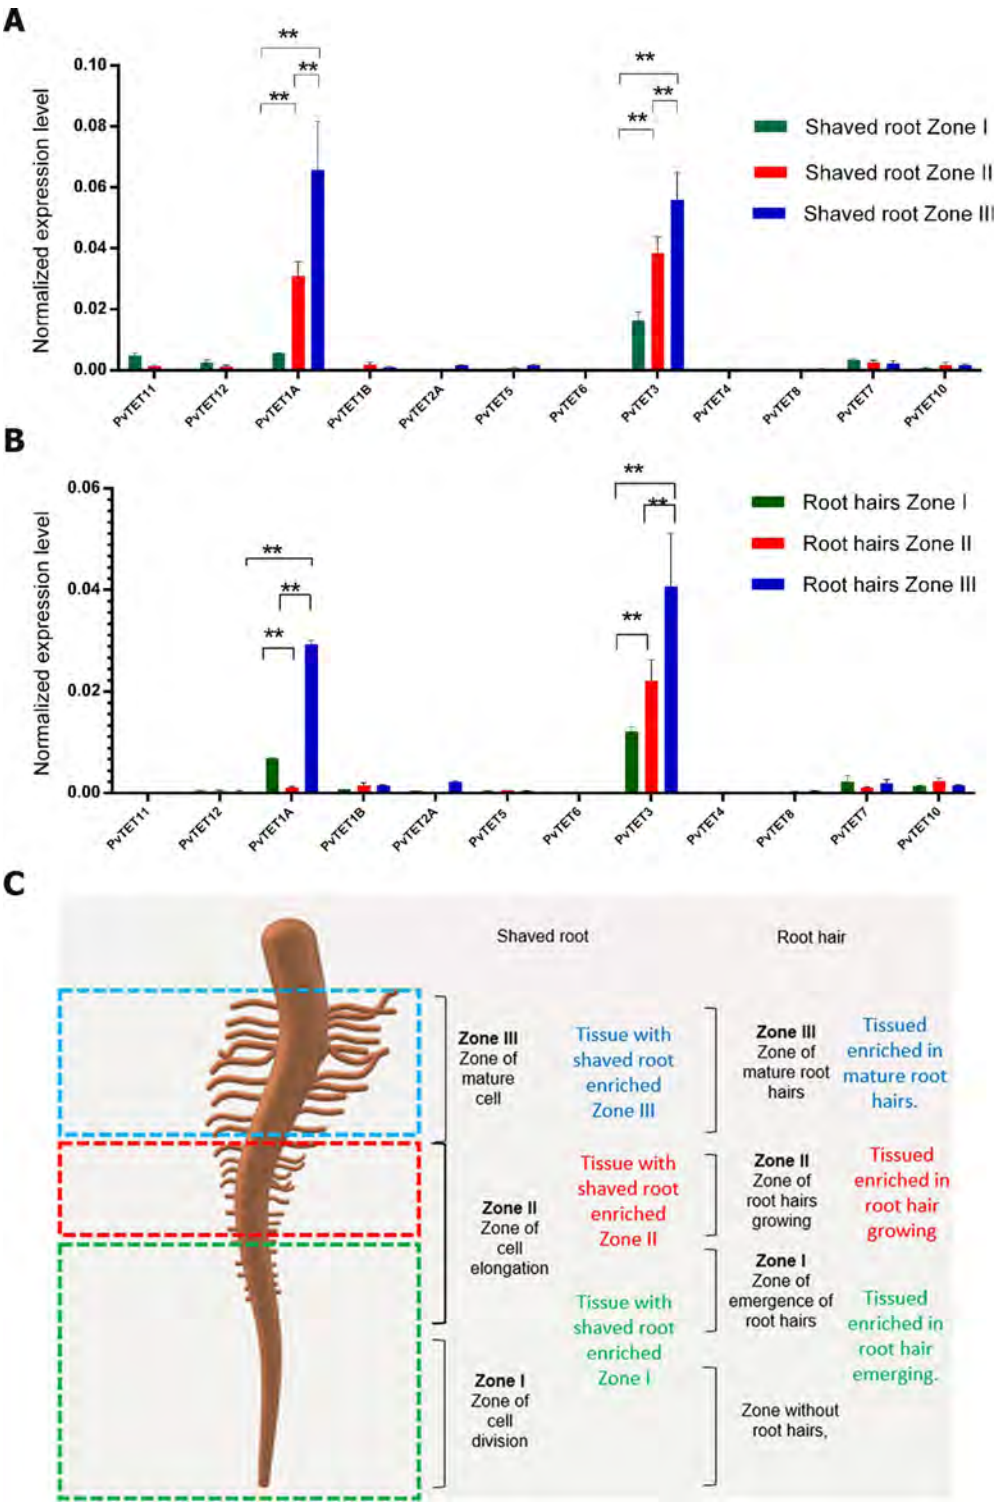

Fig 2. Tetraspanin gene expression profile in *P. vulgaris* root or root hairs from different developmental stages. The relative expression of each *PvTET* gene was evaluated by qRT–PCR in three different sections of root at 48 h post germination (hpg). Mature zone or Zone III (blue), elongation zone or Zone II (red), and meristematic, elongating and differentiating region or Zone I (green). Transcript accumulation was normalized to the expression of *EF1a*, which was used as a reference gene. Bars represent means ± SEM from at least three independent biological replicates with three technical repeats. (A) Tetraspanin (TET) gene expression in shaved root and (B) root hairs at different development stages at 48 hpg. Tissues enriched with emerging or bulging root hairs from Zone I (green bar), tissues enriched with

growing root hairs (red bar) and tissues enriched with mature root hairs (blue bar). Transcript accumulation was normalized to the expression of *EF1a*, which was used as a reference gene. Bars represent means ± SEM from at least three independent biological replicates with three technical repeats. P-values <0.05 are marked with two asterisks (Student's t-test). (C) Cartoon depicting the different root and root hairs zones analyzed.

https://doi.org/10.1371/journal.pone.0219765.g002

and root hairs under normal conditions, other tetraspanin genes were also tested, under NFs or Rhizobia inoculation, but the one that did not respond were not considered for further analysis (S7 Fig). *PvTET1A* was downregulated in *P. vulgaris* roots in the first 36 h days after inoculation with NFs, but we detected a response at 5–10 days post inoculation with rhizobia (Fig 3A). By contrast, *PvTET3* expression did not change within the first 24 h following inoculation with NFs, but a significative decrease was observed at 36 h after treatment. On the other hand, when inoculated with *R. tropici*, a further decrease was observed at 5 and 14–18 dpi (Fig 3B). Thus, some tetraspanin transcript levels respond to NF treatment or bacterial inoculation depending of the developmental stage, i.e at 5 dai, *PvTET1A* increases while *PvTET3* decreases. To confirm that *P. vulgaris* roots respond to rhizobia inoculation, we assessed the transcript accumulation of *PvENOD40*, an early nodulin gene induced during nodule development. *PvENOD40* is clearly induced after rhizobia inoculation, indicating that the nodule program is induced under our experimental conditions (Fig 3C).

We then further analyzed the transcript accumulation of *PvTET4* and *PvTET8* in roots treated with NFs and rhizobia. *PvTET4* was upregulated after *R. tropici* inoculation (Fig 3D), whereas *PvTET8* did not increase in response to NFs within the first 6 days, but it was specifically induced in response to rhizobia inoculation after 7 days (Fig 3E). Therefore, we selected *PvTET8* to examine whether transcript accumulation was correlated with promoter activity. We cloned the promoter and generated the *pPvTET8*::*GUS-GFP* construct, which revealed that *pPvTET8* was induced during nodule primordium development as well as in the meristematic region of the apical root, including the lateral root primordium (Fig 3F and 3G). We also observed clear promoter activity during the emergence of lateral root primordium, which originates from the pericycle (Fig 4B–4E), and this promoter activity remained in the root primordium (Fig 4F). Whereas the nodule primordium arises in the outer cells of the cortex (Figs 3G and 5D), the lateral root originates from the internal pericycle cells (Fig 3F). We examined promoter activity by assessing GUS activity (Fig 4B–4E) and fluorescence from the pPvTET8::GUS-GFP fusion. Both approaches yielded the same results (Fig 4G) including the pPvTET10::GUS-GFP (Fig 4I).

Next, we assessed *PvTET8* promoter activity during nodule development, from infection thread formation to fully grown nodules, and we found that the *pPvTET8*::*GUS-GFP* promoter is highly active during the early stages of nodule development, which includes infection thread formation in the root hairs (Fig 5A and 5B). Thereafter, when the cortical cells started to divide, forming cells that will give rise to the nodule primordium, clear promoter activity was observed in the outer cells that form the primordium (Fig 5C–5E). The fully developed nodule also depicts a clear and specific promoter activity in the infected zone of the nodule (Fig 5E). We also evaluated the promotor activity for *pPvTET1A*::*GUS-GFP* (Fig 5F and 5G) and *pPvTET3*::*GUS-GFP* (Fig 5H) the two most highly expressed gene in *P. vulgaris* root. Although these genes do not seem to have a strong increase during nodulation, when the promotor activity was assayed, there is a clear evidence that apart from the vascular bundle, the expression in the nodule is very clear.

Since *pPvTET8* was specifically induced in response to rhizobia inoculation, we analyzed the promoter sequence from *PvTET8* up to 1.0 kb upstream of the translation start site of *PvTET8* using PlantCARE (database) to identify putative *cis*-acting regulatory elements. In

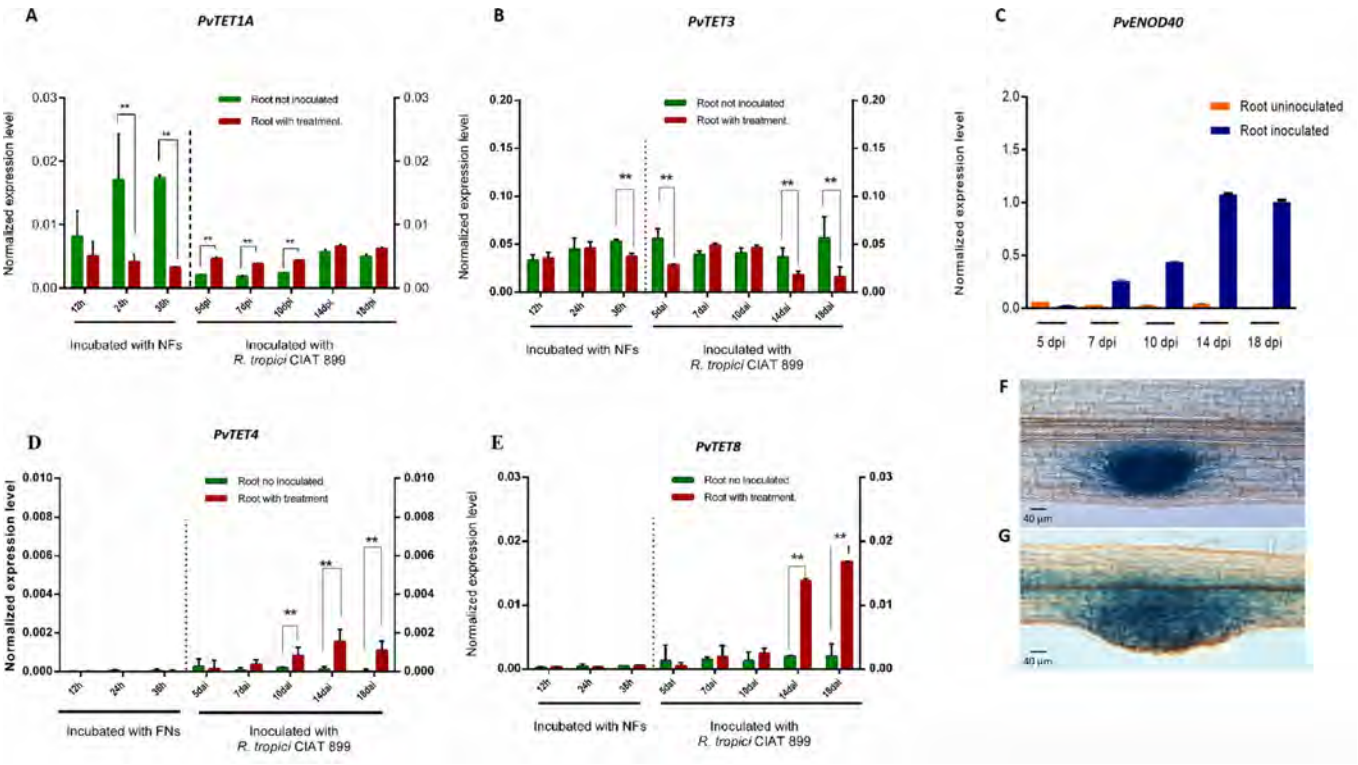

Fig 3. Expression of *PvTET1A*, *PvTET3*, *PvTET4*, and *PvTET8* in *P. vulgaris* during nodule development. Transcript accumulation is observed during nodule development under rhizobia colonization. (A) *PvTET1A*, (B) *PvTET3* and (C) *PvENOD40* transcript accumulation after Nod factor (NF) treatment or inoculation with *R. Tropici* CIAT 899 are depicted. *PvTET4* (D) and *PvTET8* (E) specifically respond to rhizobia inoculation. These results are compared with uninoculated roots harvested at the same time (green bars). Expression values were normalized with those of *EF1a*. Bars represent means ± SEM of at least three independent biological replicates with three technical repeats. P-values <0.05 are marked with two asterisks (Student's t-test). Promotor activity of *PvTET8* in lateral root primordia (F) and nodule primordia development (G).

https://doi.org/10.1371/journal.pone.0219765.g003

this analysis, we identified at least 14 different regulatory elements with a length of between 4 and 11 bp. Some *cis*-elements are represented in Fig 4A. The *cis*-regulatory elements TATA and CAAT were highly repeated in the promoter sequences. In addition, several putative *cis*-elements involved in the light, heat, and drought stress response, circadian control, defense, and anaerobic induction were present, as was one box associated with the YABBY transcription factor. Thus, *cis*-elements associated with defense and stress responsiveness and cell fate were well represented in this promoter region, as represented in Fig 4A.

Since *pPvTET3*::*GUS-GFP* was highly expressed in the root (Fig 5H), we prompted to explore if there is promotor activity during different stages of nodule development. We found that pPvTET3::*GUS-GFP* is expressed in the root meristematic region and vascular bundles (Fig 6A and 6B), including a low promotor activity during the early cell divisions in the nodule primordium (Fig 6C and 6D) and during the early nodule development (Fig 6E), again with higher activity in the vascular bundles, however, a clear localization in the nodule was found, although at latter stages of development in fully developed nodules (Fig 6F and 6G). Furthermore, the *pPvTET3* seems to be more localized in the cortex of the nodule, as compared to the *pPvTET8*, which seems more localized in the central region (Fig 5E) and most related to the infected region. These results suggest that both, *pPvTET8* and *pPvTET3* could be differentially expressed in the same organ, but in different region.

https://doi.org/10.1371/journal.pone.0219765.g004

Mycorrhizal association downregulates *PvTET3*, while phosphate scarcity upregulates *PvTET12* and downregulates *PvTET3*

Since the nodulation process recruited many genes from the mycorrhizal association, we also explored if the tetraspanin genes could be modulated in response and mycorrhizal association and low phosphate. Therefore, we determined the effect of mycorrhizal interaction with *P. vulgaris* on the accumulation of different TET transcripts. We inoculated *P. vulgaris* seedlings with *R. irregularis* and included two controls, one in which plants were uninoculated and

irrigated with a standard concentration of phosphate (500 µM) and another in which plants were uninoculated and irrigated with medium deficient in phosphate (phosphate scarcity at 50 µM), which is expected to induce the plant root response to phosphate scarcity, such as lateral root formation and root hair proliferation. Both controls were included to show the specific effect of mycorrhization on different tetraspanin transcript accumulation as a result of root hair proliferation and lateral root formation. While *PvTET8*, *PvTET4*, and *PvTET3* expression was modulated during nodule formation (Fig 3A and 3B and Fig 4A), inoculation

with *R. irregularis* only affected *PvTET3* expression during the mycorrhizal association (see Fig 7A). As expected, the expression of the phosphate transporter PT4 which is induced during the mycorrhizal association, was found to be induced under our experimental condition (Fig 7C).

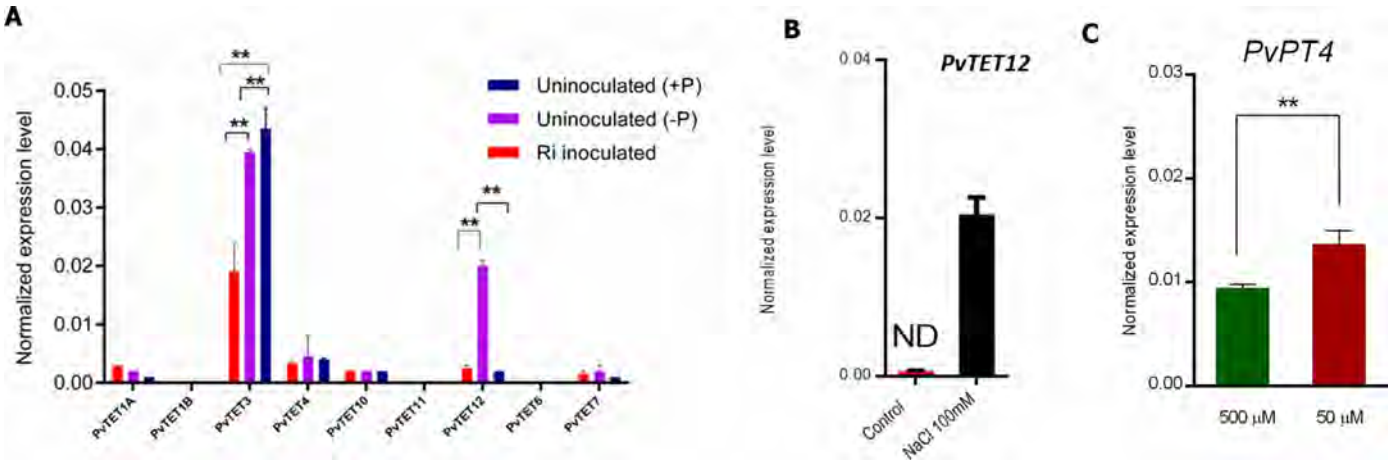

Fig 7. Tetraspanin transcript accumulation profile in *P. vulgaris* under *R. irregularis* colonization. A temporal analysis of *PvTET3* transcript accumulation under mycorrhization confirmed that *PvTET3* transcript levels were lower at 2, 3, and 6 weeks after mycorrhization compared with the control (Fig 8A). This suggests that *PvTET3* was downregulated during mycorrhization (Fig 7A and Fig 8A). It has been reported that transcript accumulation of *PvRbOHB* decreases during mycorrhizal association [56]. Therefore, we evaluated the accumulation of *PvRbOHB* transcript at 1, 2, 3, and 6 weeks post inoculation (wpi) to define its temporal response and correlate it with that of *PvTET3* (Fig 8B). *PvRbOHB* was not induced during the first week post inoculation, during which its expression was comparable to that of the control condition (Fig 8B). However, after 2–3 weeks, a clear increase in *PvRbOHB* transcript accumulation was observed, but a decreased *PvTET3* expression was found. However, at 6 weeks, a clear decrease in both *PvRbOHB* and *PvTET3* was observed, and thus confirming the previously reported data for *PvRbOHB* under mycorrhizal association [56].

We found no significant differences at the transcriptional level for the other tetraspanins under our experimental conditions (S7 Fig). However, we identified a clear *PvTET12* upregulation under phosphate scarcity (Fig 7A). It is interesting that under normal growth conditions, we did not observe significant *PvTET12* expression in root hairs at different developmental stages or even in the shaved roots (Fig 2A and 2B), even though its homolog, *AtTET12*, has been identified as a transcriptional signature in root hairs and pollen tubes [57]. To determine if another different stress, such as osmotic or saline treatment, could modify the *PvTET12* transcript level, we treated the *P. vulgaris* root with 100 mM NaCl; which is known to induce a saline response [58–60]. Under saline stress conditions, we found that *PvTET12* expression was also upregulated (Fig 7B).

P. vulgaris tetraspanins localize to the apical plasma membrane, intracellular vesicles, and meristematic regions

Tetraspanin proteins in general have been described to be plasma membrane proteins and component of cytoplasmic vesicles. However, TET3 in Arabidopsis has been found in

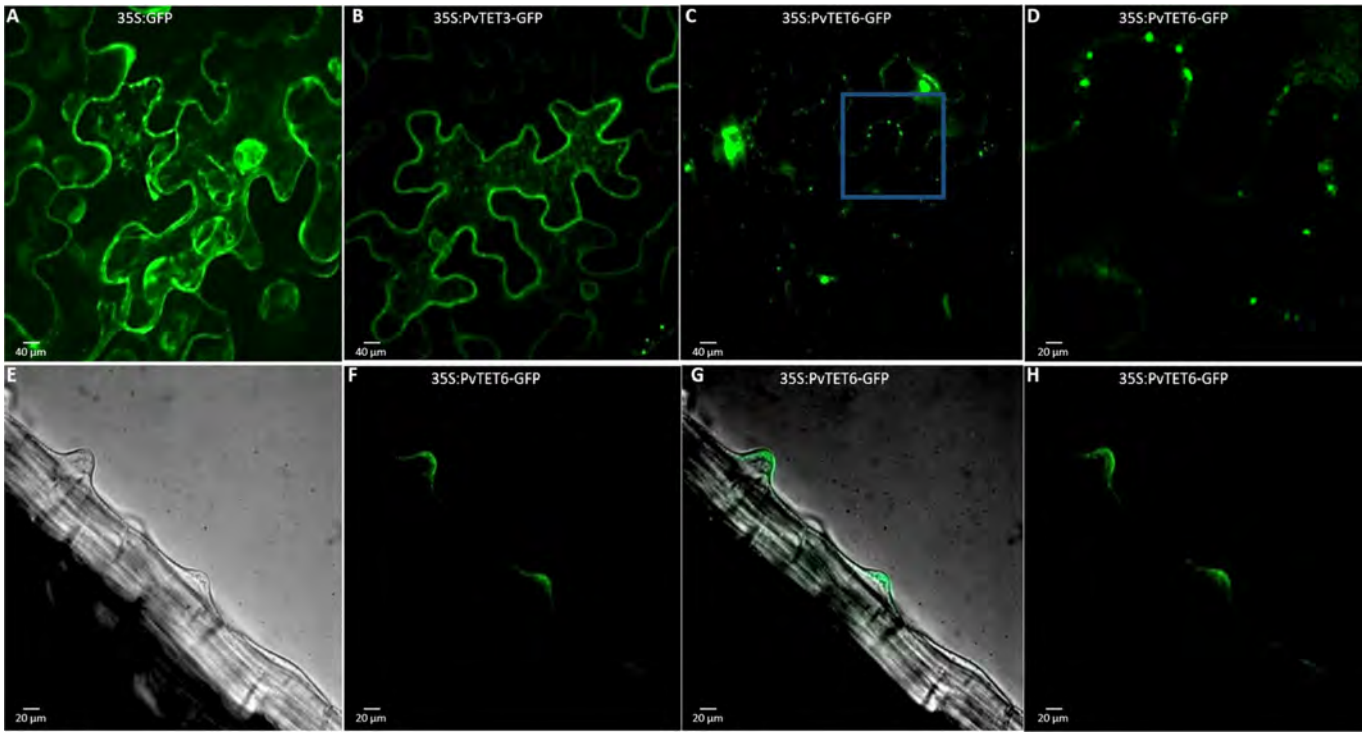

Fig 9. Subcellular localization of PvTET6 and PvTET3 in *Nicotiana benthamiana* leaves and growing root hairs of *P. vulgaris*. https://doi.org/10.1371/journal.pone.0219765.g009

proteomic analysis of plasmodesmata. Therefore, we determined the subcellular localization of *PvTET3* and *PvTET6* by generating GFP fusions of their encoding genes and transiently expressing these constructs in *N. benthamiana* leaves (Fig 9A–9D). An analysis of leaves expressing the 35S:PvTET3-GFP and 35S:PvTET6-GFP constructs under the control of a constitutive promoter (CaMV35S) showed that these proteins examined in this study accumulated at the periphery of *N. benthamiana* epidermal cells, indicating a membrane localization (Fig 9B and S8 Fig), and clearly differentiated from the cytoplasmic localization of GFP in control agroinfiltrated cells (Fig 9A). Furthermore, some of the tetraspanins localized to fluorescent spots in the plasma membrane, suggesting plasmodesmata localization (Fig 9C, inset). We also generated transgenic *P. vulgaris* composite plants expressing 35S:PvTET6-GFP using *A. rhizogenes* and found that some tetraspanins are expressed in vesicular structures that are swept along by cytoplasmic flux in growing root hairs, but are also localized in the apical plasma membrane of these cells (Fig 9E–9H, S1 Movie and S2 Movie). In order to determine the plasma membrane localization, we generated agroinfiltrated *N. benthamiana* epidermal cells expressing the tetraspanin and subjected to NaCl treatment for plasmolysis. These results suggest that the signal remains associated to the plasma membrane (S8 Fig).

We then evaluated 35S:PvTET10-GFP expression in composite plants. TET10 exhibited similar localization to TET6, namely, apical localization in the plasma membrane and dynamic vesicles in the cytoplasm of growing root hair cells in a pattern that sometimes follows the cytoplasmic streaming with higher ambulation at the tip dome (Fig 10A–10C). Furthermore, in *P. vulgaris* composite plants expressing 35S:PvTET10-GFP under nodulation conditions, the cortical cells that enter the division process that will generate the nodule primordium are

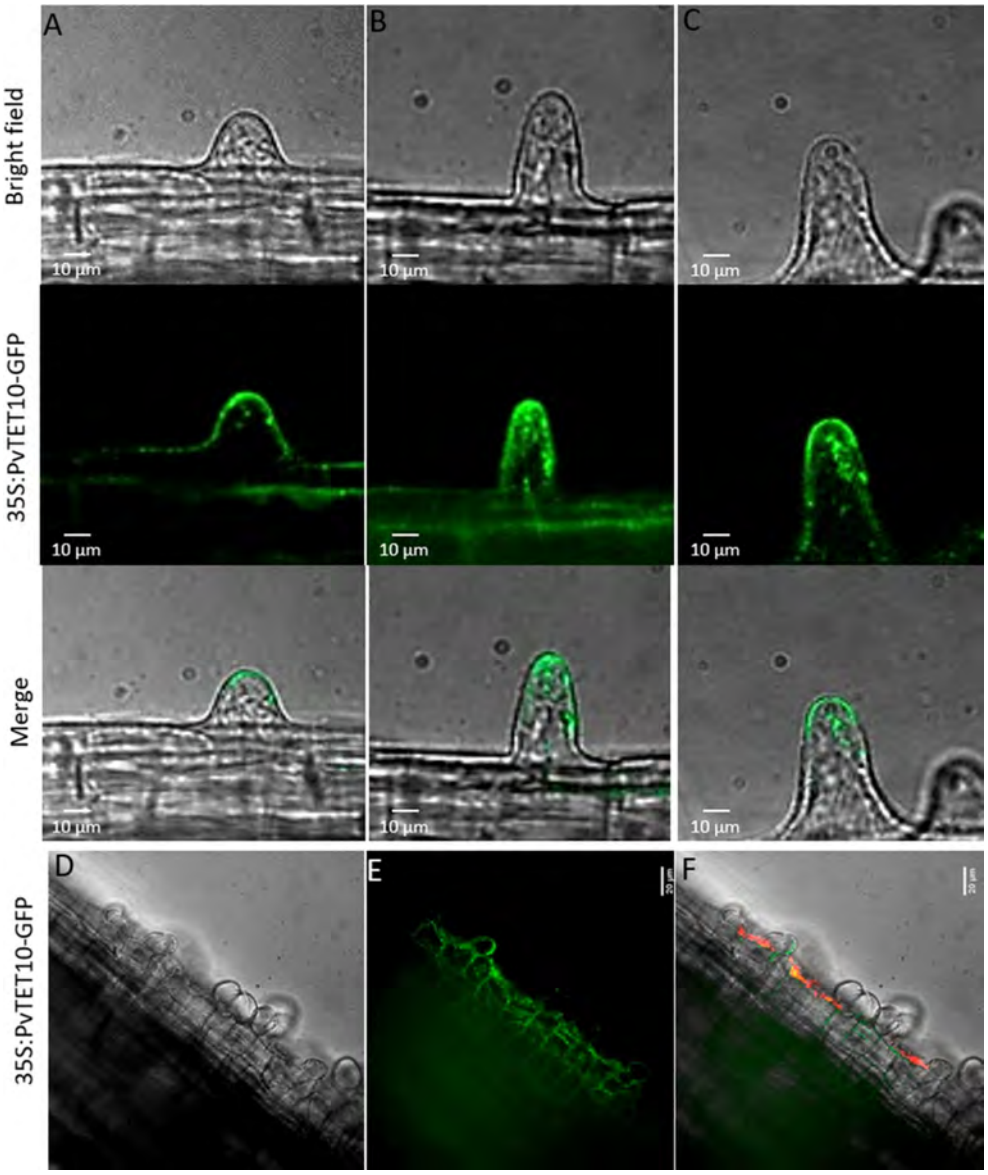

Fig 10. Subcellular localization of PVTET10 in growing root hairs from *P. vulgaris*. (A, B and C) Apical membrane localization of 35S:PvTET10-GFP at different developmental stages of the growing root hair. (D, E and F) Cytoplasmic vesicle localization for PvTET10, and its accumulation in the infection site where the infection thread and nodule primordia are induced. *P. vulgaris* plants were transformed by *A. rhizogenes* in order to generate the composite plants. Bacterial colonization is in red and the subcellular localization of PvTET10 is in green.

enriched in these cytoplasmic vesicles (Fig 10D–10F). Since TET3, TET6, and TET10 localized to moving vesicles, we further examined the dynamics and behavior of these vesicles.

We selected PvTET3, which we know localizes to vesicular structures in *N. benthamiana* (Fig 11A and 11B) and *P. vulgaris* composite plants (Fig 11C–11J), to determine the dynamics and shapes of these vesicles. In *P. vulgaris* epidermal cells, these vesicles were tracked in a time lapse of 1.6 seconds for 3 min in transgenic roots overexpressing 35S:PvTET3-GFP. We observed fusion events that resulted in larger vesicles, with amorphous shapes that resemble protrusions (Fig 11C–11J).

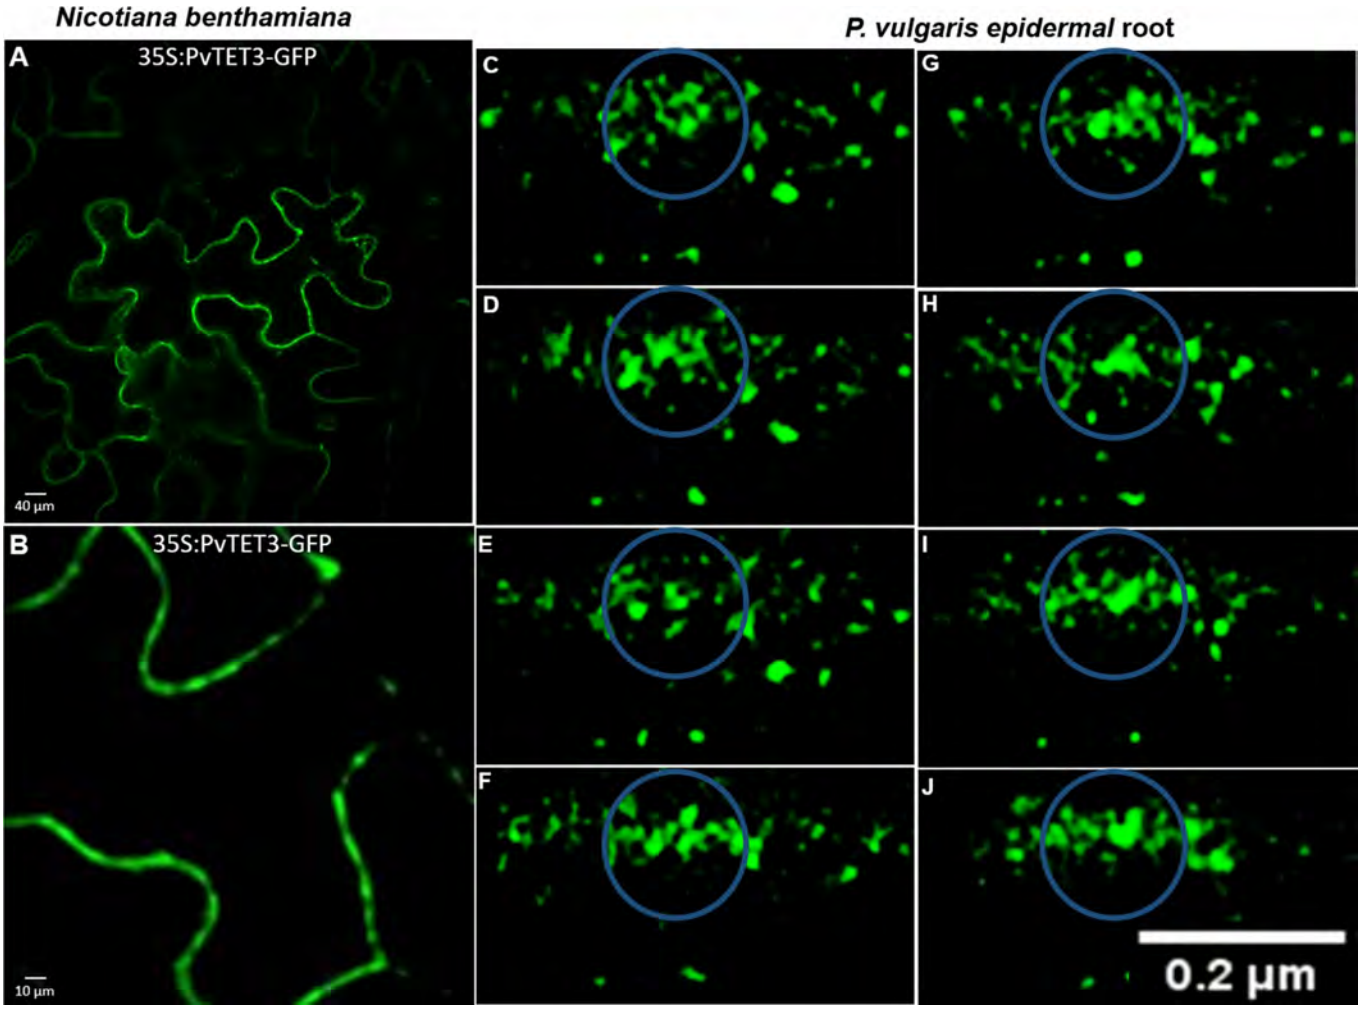

Fig 11. Subcellular localization of PvTET3 in *N. benthamiana* leaves and *P. vulgaris* roots. (A and B) 35S:PvTET3-GFP localization in cytoplasmic vesicles in agroinfiltrated *N. benthamiana* leaves. (C-J) Subcellular localization of 35S:PvTET3:GFP in *P. vulgaris* composite epidermal root cells. Cytoplasmic vesicles were tracked over time in order to show the fusion and morphological changes resembling protrusions during the cytoplasmic streaming. Vesicles were tracked in a time lapse of 1.6 seconds for 3 min in transgenic roots expressing 35S:PvTET3-GFP.

https://doi.org/10.1371/journal.pone.0219765.g011

Discussion

We found that *PvTET1A*, *PvTET3*, *PvTET4* and *PvTET8* are induced and differentially expressed during early nodule development, as depicted by transcript accumulation and promoter activity and in the fully grown and mature nodule, but with different timing and strength. Furthermore, these expression patterns resemble those found in primordia during lateral root formation which also requires a new program that involves cell division and ROS production. The finding that some tetraspanin presents a clear membrane localization at the tip of the root hairs and some others in what appears to be associated with plasmodesmata (PD), and cytoplasmic vesicles, suggest a role in symplastic communication trough regulation of PD or in cell trafficking as described in animal cells [18].

We identified the tetraspanin family in *P. vulgaris* and found *PvTET10* to be a conserved tetraspanin with at least one representative in each legume species examined, except for soybean, which contained more members due to a genome duplication event [61]. *PvTET10* clusters with *AtTET10* and *OsTET14*, which contain similar structural features of introns/exons,

INFORME DE LABORES 2019

suggesting that *PvTET10* is the ancestral tetraspanin gene, as is AtTET10 in the Brassicaceae and *OsTET14* in *O. sativa* [35, 50]. These structural intron/exon patterns indicate a similar origin as suggested for deuterostomes, in which tetraspanins are the product of a divergent evolutionary process and originated from at least one common ancestor [51, 62]. In our unrooted phylogenetic tree, *PvTET1A* and *PvTET1B* grouped with *AtTET1* (*TORNADO*) and *AtTET2*, while *PvTET8*, *OsTET7-9*, and *AtTET8-9* clustered together (S2 Fig and S3 Fig).

We found that *PvTET3* and *PvTET1A* transcripts are more abundant and ubiquitously expressed during root and root hair development (Fig 2A and 2B). In angiosperms plants such as *Arabidopsis* and *P. vulgaris*, primary root formation takes place during embryogenesis, whereas lateral roots form post-embryonically from pericycle founder cells, and both of these processes are mediated by changes in hormone levels [63, 64]. *PvTET1A* is expressed post-embryonically, between 2 and 4 dpg, in the seedling when root growth begins and before lateral roots emerge [38]. According with our phylogenetic data, *PvTET1A* is the homolog of *TORNADO* in *Arabidopsis* (*AtTET1* or *AtTRN1*), which regulates cell specification in the root epidermis during radial pattern formation and thus in agreement with our transcriptional profile for *PvTET1A* with a high expression in root [65]. However, our transcriptional profile does not correspond with the reported higher *TRN1* promoter activity in the meristematic zone in the root tip. This discrepancy with higher expression in root zone II and III and lower in zone I that correspond to the meristematic region could be due to the fact that the promoter region of *PvTET1A* does not contain a putative cis-regulatory element, GCCACT, that exists in *Arabidopsis TRN1*, and associated with meristematic expression and auxin dependency [65, 66]. Therefore, *PvTET1A* could have a different regulation, or its expression pattern could differ from that reported in *Arabidopsis*.

The finding that *PvTET3* transcript accumulation was downregulated under nodulation and mycorrhizal conditions in *P. vulgaris* roots and that the encoded protein localizes to the PM and PD, suggests that PD could be a regulated structure during the mutualistic interactions. We also found that *PvTET6* is specifically targeted to the PM and PD, in agreement with the subcellular localization of some homologous tetraspanins identified in *Arabidopsis*, such as *AtTET3* and *AtTET5* [35, 67–71]. PD are connections between cells that mediate symplastic communication from single cells to tissue domains, these structures have essential roles in cell-to-cell communication [72]. Both the density and aperture size of PD are developmentally regulated through the deposition or solubilization of callose by callose synthases or glucanases, allowing the formation of spatial symplastic domains that establish tissue-specific developmental programs [73]. Numerous non-cell-autonomous proteins (NCAPs) and small RNAs travel through the PD and play crucial roles in cell fate determination and organ patterning during plant development. In vascular plants, it has been suggested that PD networks are associated with shoot apical meristem (SAM) organization in *Arabidopsis* and maize (*Zea mays*) [74–76]. Typical PD proteins, such as AtPDLP1, have a specific signal peptide, LVL, located in a transmembrane domain [67], which was also found in PvTET6 and PvTET3. Transmembrane domains in tetraspanin have turned to play important roles. For instance, a single point mutation, L31S substitution in the third amino acid of TM1 has been associated with field-evolved resistance of cotton bollworm to transgenic Bt cotton [77].

In rice, blast disease caused by the hemibiotrophic fungus *Magnaporthe oryzae* grow from one cell to the next through PD. This response is coordinated by chitin perception that requires a receptor kinase (CERK1) and a chitin elicitor binding protein (CEBiP), which sense the chitin and induce a reduction in the cell-to-cell connectivity via PD [80, 81]. During the nodulation process it has been recently described that PD connection between the phloem-early primordium-epidermal cell forming the infection thread is a key step for the infection process [82, 83]. Again, it seems that PD are key components of the photogenic and

mutualistic response and PD localized tetraspanins could be important modulators of the intercellular flux regulating the symplastic continuity and molecular flux between cells. It could involve ROS to regulate PD permeability by facilitating the cross-linking process of callose [84]. Therefore, the observed downregulation or upregulation of *PvTET3* could affect PD composition by modulating the capability of tetraspanin to recruit some additional molecular components required to modify the callose composition in PD during mycorrhizal or rhizobia association. This may also facilitate the hypha or infection thread to move cell-to-cell through the PD connections or facilitate the diffusion of some proteins, such as transcription factors or metabolites, required to fine-tune the regulation of cortical and cortex responses.

Nodulation involves substantial crosstalk between NFs and auxin signaling in *Medicago truncatula*, with a high accumulation of auxin at the site of nodule meristem formation [85]. Indeed, there is a large overlap between genes induced in response to NFs and auxin, including two tetraspanin genes with homology to *PvTET3* (Medtr4g061010) and *PvTET1A* (Medtr8g101600) [85]. In addition, a previous report showed that *PIN1* expression was reduced in the *Arabidopsis trn2-1* mutant, which has compromised auxin transport activity during the transition from floral meristem termination to gynoecium development, which suggests a link between tetraspanin and auxin homeostasis [86]. Therefore, in addition to altering auxin transport, Nod factors could modulate the expression of specific tetraspanins that influence hormone levels, which could regulate cell division, a well-described process during nodulation [87]. If *PvTET1A* and *PvTET3* are downregulated during the interaction with NFs, this response could be associated with the disruption of auxin transport or the stimulation of auxin biosynthesis [88]. We suggest that NFs signaling has a profound impact on *PvTET1A* and *PvTET3* expression by affecting auxin levels and thereby coordinates nodule primordium development. Indeed, it is well known that NFs interfere with auxin transport, biosynthesis, and homeostasis [87, 89].

The finding that *PvTET4* and *PvTET8* are induced during early nodule development with different timing and localization, as depicted by transcript accumulation and promoter activity and in the fully grown and mature nodule. Our results indicate that *PvTET8* could be involved at different developmental stages of nodule primordia formation and in the infected thread region, and *PvTET3* although we did not find a high transcript accumulation, the promotor activity indicates that is expressed in root and mature nodule, suggesting a role in the mature nodule or later on during senescence. Furthermore, these expression patterns resemble those found during lateral root formation. Both lateral root primordium and nodule primordium formation require differentiated cells to become dedifferentiated and then to enter a new program that involves cell division. Therefore, this tetraspanin could be involved in the molecular mechanism that maintains meristem activity.

Furthermore, the roles of tetraspanin have been expanded beyond intercellular boundaries. It has been reported recently that *Arabidopsis* cells secrete exosome-like extracellular vesicles that are derived from the multivesicular bodies (MVBs), which contain cytoplasmic material, such as proteins, miRNA, and lipids [23, 90]. Under certain circumstances, these MVBs fuse to the plasma membrane and release the internal vesicles into the extracellular space. It has been demonstrated recently that tetraspanins are key components and specific markers for animal (CD63) and plant exosomes (*AtTET8* and *AtTET9*) [23]. In *Arabidopsis*, exosomes transport key miRNAs that induce silencing of fungal genes critical for pathogenicity in *Botrytis cinerea*, defining a role for tetraspanin and exosome biogenesis in intercellular and inter-kingdom communication [23]. This could explain why *AtTET8* expression is upregulated upon treatment with pathogen elicitors [38] and why, during our experimental conditions, *PvTET8* is induced when plants are infected with rhizobia. It is possible that exosomes could play an important role during the mutualistic interaction. Furthermore, tetraspanin genes are among

the induced genes in the reported legume transcriptome of wild peanut (*Arachis spp*) roots infected with nematodes, suggesting that the pathogenic response in legumes also involves tetraspanins [91].

The upregulation of *PvTET8* during the defense response also can be explained by the enrichment of defense response cis-regulatory elements in its promoter region. Indeed, it has been widely suggested that the molecular mechanism underlying mutualism was derived from that underlying pathogenic interactions, but suppression of the immune response allows the symbiont to colonize the plant host [92]. It will be interesting to determine the specific role of *PvTET8* during nodulation and mycorrhization and explore the role that vesicles and exosomes could play in recruiting proteins or membrane-associated proteins that are required in the plasma membrane during mutualistic interactions.

Our data showing that *PvTET12* is upregulated under phosphate scarcity, but not under mycorrhizal association, suggest that *PvTET12* expression is highly dependent on environmental nutrition conditions. In *Arabidopsis*, *AtTET12* has been identified in root hairs and in the pollen tube [57]. Furthermore, the microarray data of *Glycine max* reported on the Soybean Efb Browser website shows a differential expression of *GmTET12* in roots and root hairs at 24 h after inoculation with bacteria [35, 57, 93]. These data suggest a role for *PvTET12* in the massive proliferation of root hairs as a response to phosphate acquisition [94–96].

In animal cells, tetraspanins have multiple antagonistic effects. For example, the tetraspanin CD82 is downregulated during metastases, while the tetraspanin CD151 and tetraspanin 8 are induced and able to support tumor progression [21, 22]. It has been reported that the CD63 tetraspanin in animal cells recruits a H^+-ATPase beta-subunit in parietal cells that affects its trafficking. Also, saline stress has been used to induce changes in the H^+-ATPase localization mediated by tetraspanin [97, 98]. Here, we also found that NaCl could upregulate *PvTET12*. Furthermore, in *Arabidopsis*, a mutant of one isoform of PM H^+-ATPase, *AHA7*, exhibited reduced root hair density and lower H^+ density efflux in the root hair zone, while the transcript was upregulated under low-phosphate conditions [99]. Since phosphate scarcity affects *PvTET12* expression, it could affect the recruitment of protein related to the change in H^+ efflux, and it is tempting to think that tetraspanins are somehow related to the regulation or trafficking of H^+-ATPase. Furthermore, a PT4/PT11 H^+-ATPase has been found to be important for arbuscule maintenance and AM-mediated phosphate uptake [100, 101]. Plants have developed several strategies to increase phosphate acquisition, including changes to root architecture and the formation of root hairs [95, 102]. However, the finding that other TETs, such as tetraspanin-1, are also related to changes in root hair regulation suggests the existence of a more complex regulation [65].

There is an emerging association between tetraspanins and the mechanisms of ROS generation [24]. In the nematode *C. elegans*, the exoskeleton, the cuticle composed of collagen, is tyrosine cross-linked in a ROS-dependent manner, in a process assisted by BLI-3, a DUOX NADPH oxidase [29]. This process also requires the participation of tetraspanin TSP-15, which allows recruitment of the NADPH oxidase [24, 25, 30]. Inactivation of this tetraspanin or BLI-3 produces similar phenotypes. Furthermore, during plant infection with the pathogenic fungus *M. grisea* or *B. cinerea*, the tetraspanin PLS1 is required for infection site formation. Therefore, the tetraspanin and ROS generated by a NADPH oxidase is needed to coordinate ROS production at the infection site. In pathogenic *C. lindemuthianum*, a tetraspanin is also required to reestablish appressorium polarity [24, 25, 31–33]. Furthermore, in *Claviceps purpurea*, Nox2 and Pls1 are important for a balanced host–pathogen interaction, while in HeLa cells, the cotransfection of tetraspanin CD82 and GTPase Cdc42 induces apoptosis by generating ROS [103, 104]. These data add weight to the strong connection between tetraspanins and the ROS-generating machinery, both in animal and plant cells, to coordinate localized ROS production [24, 25, 30, 105].

During the mycorrhizal association of *P. vulgaris* with *R. irregularis*, only *PvTET3* was downregulated. This response coincides with previous reports in which a decrease in ROS production induced by RNAi of *PvRbOHB* enhanced colonization by *R. irregularis* [56]. Thus, a coordinated decrease in ROS production and *PvTET3* expression could be required for mycorrhizal colonization, as previously suggested [56, 78, 79].

This spatial ROS requirement is also observed during the Casparian strip lignification that occurs in plants, where CASP, a protein recruiting the NADPH oxidase, plays a role similar to tetraspanin, bringing together NADPH oxidase and peroxidase and ensuring localized activation of the oxidase [106]. Tetraspanins have also been localized to the tip of growing pollen tubes and root hairs (this work), and it is well known that the tip regions require NADPH oxidase activity for the generation of ROS, key players in the regulation of polar growth [12, 13]. The subcellular localization of some tetraspanins at the apical plasma membrane suggests that tetraspanins may play a key role during polar growth. Furthermore, the particular expression of *PvTET8* in root hairs in which an infection thread forms during early cell division in cortical cells could be related to the NADPH-oxidase-mediated ROS generation that is required for meristematic activity. Therefore, it is tempting to speculate that tetraspanins also play a role in recruiting the ROS-generating machinery to a specific cellular location. Moreover, tetraspanin also accumulates at the site of female gametophyte differentiation, a well-described ROS-dependent process [35].

Finally, the site-specific localization of *PvTET8* in root and nodule meristematic regions points to a role in meristem maintenance. The well-described role of $O_2^{\cdot-}$ accumulation in the root apical meristem (RAM) and shoot apical meristem (SAM) in inhibiting the transition from proliferation to differentiation suggests a key role for tetraspanins in undifferentiated cells to inhibit differentiation in plant. Indeed, the balance of $O_2^{\cdot-}/H_2O_2$ levels in undifferentiated and differentiated cells is crucial for WUSCHEL (WUS) activation to promote stem cell differentiation. For instance, ROS can activate *WUS* and thereby repress expression of the TF YABBY, which regulates the tetraspanin *TORNADO* at the transcriptional level. Therefore, the tetraspanin *TORNADO* could be involved in processes that regulate ROS production, both at the temporal and spatial level. It is interesting that the WUS-RELATED HOMEOBOX (*WOX*) family transcription factor *WOX5* like *PvTET8*, *PvTET3* (this work), are also highly expressed during nodule organogenesis, suggesting that *WOX* genes are common regulators of cell proliferation in different systems, such as the SAM, RAM, and nodule primordium, including in megasporogenesis [36, 40, 86, 107].

Calcium and ROS are important cellular messengers and key players during mutualistic interactions [9, 108]. ROS, and therefore the enzymes that generate ROS (e.g., NADPH oxidases), play a key role in root hair tip growth, both in the presence and absence of pathogenic or mutualistic interactions, and in the growth of other tip-growing cells such as pollen tubes [12]. The observation that FNs from rhizobia have a different effect on ROS accumulation than do pathogenic signals, such as elicitors, suggests that plant cells differentiate symbiotic from pathogenic signals [6, 14, 109]. We previously reported that *P. vulgaris* produces 9 NADPH oxidases (Rboh), some of which are mainly expressed in roots, root hairs, or nodules [43]. The overexpression of one, *RbohB*, results in increased nodulation, but with a reduced mycorrhizal association [56], suggesting that ROS are important players in mutualistic interactions [42, 43, 56]. We suggest that the co-occurrence of tetraspanin and NADPH oxidase in the apical root hair cells or the early infection thread, and nodule primordia, could be related to the ROS-generating machinery. The role of tetraspanins in regulating the plasma membrane by recruiting the required proteins to specific membrane microdomains enriched in tetraspanins (tetraspanin web) or by affecting its vesicular trafficking have been well described. It is important to bear in mind that the release of the rhizobia from the infection thread or the

INFORME DE LABORES 2019

arbuscule formation requires a complete coordination with the secretory system from the host plant cells for symbiont accommodation. This involves a high rate of exocytosis of specific components required for cell wall remodeling, including the extra membrane required to form the peribacteroideal membrane. In this scenery, tetraspanins could also play a central role organizing those membrane domains, but also facilitating the required vesicular trafficking to specific places as those reported for photogenic interactions that involves the specific exosomes secretion.

S8 Fig. Subcellular localization of 35S:PvTET3-GFP, 35S:PvTET6-GFP after plasmolysis. Agroinfiltrated cells from *N. benthamiana* leaves under plasmolysis induced by NaCl. **A**, **B** and **C**, 35S:GFP, 35S:PvTET3-GFP, 35S:PvTET6-GFP respectively, showing the regular cytoplasmic protein localization under control condition (left panel) and under plasmolysis (right small panels). Arrows in **B** and **C** indicates the 35S:PvTET3-GFP and 35S:PvTET6-GFP fluorescence associated with the retracted plasma membrane, while the 35S:GFP remains in the cytoplasm in **A**.
(TIF)

S1 Movie. Composite plants from *P. vulgaris* expressing the fusion protein 35S: PvTET6-GFP. Images were acquired with a spinning disk confocal system (Intelligent Imaging Innovations /3i, USA) consisting of a CSU-W1 confocal head (Yokogawa, Japan) and a modular solid-state laser stack; Slidebook software was used to control the system and capture images (Intelligent Imaging Innovations /3i, USA). Movie represent 40 images taken 15 seconds apart. Note the apical membrane localization and the cytoplasmic localization in vesicular structures that follows the cytoplasmic streaming.
(WMV)

S2 Movie. Composite plants from *P. vulgaris* expressing the fusion protein 35S: PvTET6-GFP in epidermal cells. Images were acquired with a spinning disk confocal system (Intelligent Imaging Innovations /3i, USA) consisting of a CSU-W1 confocal head (Yokogawa, Japan) and a modular solid-state laser stack; Slidebook software was used to control the system and capture images (Intelligent Imaging Innovations /3i, USA). Movie represent 40 images taken 15 seconds apart. Note the apical membrane localization and the cytoplasmic localization in vesicular structures that follows the cytoplasmic streaming.

The crystal structure of the chitinase ChiA74 of *Bacillus thuringiensis* has a multidomain assembly

Received: 20 June 2018
Accepted: 24 January 2019
Published online: 22 February 2019

Estefania O. Juárez-Hernández[1], Luz E. Casados-Vázquez[1,2], Luis G. Brieba[3], Alfredo Torres-Larios[4], Pedro Jimenez-Sandoval[3] & José E. Barboza-Corona[1,2]

There is no structural information about any chitinase synthesized by *Bacillus thuringiensis*, the most successful microbial insect larvicide used worldwide. In this study, we solved the 3D structure of the chitinase ChiA74 at 2.26 Å. The crystal structure shows that ChiA74 is composed of a modular arrangement formed by (i) a catalytic region (CD), (ii) a chitinase insertion domain (CID), (iii) a fibronectin type III domain (FnIII), and (iv) a chitin binding domain (CBD). The location of the CBD with respect to the CD has no structural similarity to other chitinases with known structures. The activity of a ChiA74 lacking its secretion signal peptide (ChiA74ΔSp) and a truncated version lacking its CBD/FnIII domains (ChiA74ΔSp-50) did not have statistical differences in activity against colloidal chitin. However, ChiA74ΔSp exhibits 4.5 and 2.0 higher activity than versions lacking the CBD (ChiA74ΔSp-60) and CBD/FnIII domains (ChiA74ΔSp-50), respectively, when crystalline chitin was used as substrate. Our data suggest that the CBD might plays a significant role in crystalline chitin hydrolysis. We also demonstrated the importance of the catalytic E211 in the CD, as mutants ChiA74ΔSp$_{E211N}$ and ChiA74ΔSp$_{D207N, E211N}$ were inactive against colloidal and crystalline chitins, chitosan and 4-MU-GlcNAc$_3$. ChiA74 has a processive activity producing oligosaccharides with degree of polymerization (DP) of 1 (GlcNAc) and 2 (GlcNAc$_2$).

Chitinases are secreted by many prokaryotes and eukaryotes and are utilized for hydrolysis of chitin (a homopolymer of N-acetyl-D-glucosamine, GlcNAc), a rich ubiquitous nutrient resource[1]. According with the CAZy database (http://www.cazy.org/Glycoside-Hydrolases.html), chitinolytic enzymes are classified as chitinases (EC 3.2.1.14) and β-*N*-acetylhexosaminidases (EC 3.2.1.52), formerly called endochitinases and exochitinases, respectively. The first type of enzyme cleaves the chitin chain at internal sites randomly, whereas the second one hydrolyzes chitin from the nonreducing end of chitin by removing GlcNAc residues. Chitinases and β-*N*-acetylhexosaminidases are classified into four (18, 19, 23 and 48) and six (3, 5, 18, 20, 84, 116) glycoside hydrolases (GH) families, respectively, based on their amino acid sequence similarities[2]. Most bacterial chitinases belong to the GH 18 family (GH-18), and share a TIM-barrel fold in their catalytic subunit, have a conserved DxDxE motif, and employ a substrate-assisted catalytic mechanism[3]. Structural studies of different chitinases show that subsites +1 and +2 of the enzyme interacts with the reducing end of the chitin, and the hydrolysis occurs in the binding cleft between subsites −1 and +1[4]. Family 18 chitinases are classified into three subfamilies (A, B, C), based on the amino acid sequence similarity. Chitinases from subfamily A have a modular structure composed of the catalytic domain (CD), a fibronectin type III domain (FnIII), and a chitin binding domain

(CBD). One of the main structural differences between the three subfamilies is that subfamily A has a small $\alpha+\beta$ domain (chitinase insertion domain, CID) inserted into the TIM barrel catalytic domain, which is absent in the subfamily B. Also, the substrate-binding cleft of chitinases from subfamily A is deeper than that observed in subfamilies B and C[5–10]. Although the definitive role of the CID has not been completely understood, it seems that its insertion into the TIM domain facilitate the orientation and strong association of the enzyme to the substrates[10]. CIDs have been reported in chitinases from *Vibrio harveyi*, the human cartilage glycoprotein-39, *Bacillus thuringiensis* and *Serratia marcescens*[7,11–13]. When the CID of *S. marcescens chiA* was deleted, the truncated enzyme showed a shallower tunnel in the catalytic domain than that of the intact enzyme, and also had reduction in thermal stability, specific activity and the substrate/product specificities[13]. A multiple sequence and structural alignment of twenty-seven CIDs shows the conservation of two motifs, YxR and [E/D]xx[V/I]. These conserved amino acids are predicted to be important for the interaction with the substrate through salt bridge and hydrogen bonds. Also five residues were identified into the CID that might be implicated in the formation of the hydrophobic core, as well as the stabilization of the domain[10].

B. thuringiensis is the most successful microbial insect larvicide used worldwide. Its toxic effect is primarily due to Cry (crystal) and Cyt (cytotoxic) proteins that aggregate into stable crystalline inclusions during sporulation[14,15]. Although *B. thuringiensis* is most known for the plethora of Cry and Cyt proteins it produces, strains of this microbe produces other proteins that have applied biotechnological value, including chitinases, vegetative insecticidal proteins (Vip) and enhancing-like proteins, antimicrobial peptides and parasporins which can be used to synergize the activity of Cry proteins, to control lepidopteran and coleopteran pests, to inhibit food-borne pathogenic bacteria and to kill human cancer cells of various origins, respectively[1,14,16]. In particular, ChiA74, a chitinase synthesized by a Mexican strain of *B. thuringiensis* subsp. *kenyae*, has been shown to synergize the insecticidal activity of Cry proteins, and to generate chitin-oligosaccharides with antimicrobial activity[17–19]. This chitinase has a molecular mass of ~74 kDa, and its bioinformatic analysis predicts that it is composed of four domains: TIM-barrel, chitinase insertion (CID), fibronectin type III (FnIII) and chitin binding domains (CBD)[12]. The presence of a putative CID in a chitinase of *B. thuringiensis* was first reported by Juárez-Hernández *et al.*[12,20,21]. It has been shown that when ChiA74 is secreted, a protein of ~70 kDa and two truncated versions of ~60 and 50 kDa, which are processed from the C-terminal end are generated by an unknown mechanism[12,22]. Biochemical data demonstrated that the 50 kDa containing the $(\alpha/\beta)_8$-TIM-barrel plus the CID is the minimum version of the enzyme that possesses similar activity and catalytic efficiencies (kcat/Km) that ChiA74 lacking its secretion signal peptide (i.e. ChiA74Δsp) when colloidal chitin is used as substrate[12].

To date, the three-dimensional (3D) structures for several proteins of biotechnological interest synthesized by *B. thuringiensis* have been elucidated[15,23–27]. However, there is no report about the tertiary structure of a chitinase synthesized by this bacterium. In this study, we solved the 3D structure of chitinase ChiA74 and demonstrated the importance of the conserved motif in the catalytic domain by site-directed mutagenesis. Our data demonstrate that this enzyme has a modular arrangement formed by four domains: (i) the catalytic region with an $(\alpha/\beta)_8$-TIM-barrel as a core structure, (ii) the chitinase insertion domain as a barrel insertion, (iii) the fibronectin type III and (iv) a chitin binding domain.

Results

Overall structure of ChiA74. Recombinant ChiA74 contains 676 amino acids including a N-terminal His-tag. ChiA74 crystallized in space group P 1 21 1 (Table 1). The cell content analysis in CCP4 suggest two copies of the molecule in the asymmetric unit. A molecular replacement solution was found with Phaser-MR using an alanine truncated model of the chitinase A1 from *B. circulans* (PDB ID 1ITX) as the search model. Side chains were completed from the initial MR solution in Coot as supported by electron density. The rest of the model was built manually in Coot (including the FnIII and the CBD) and several cycles of refinement in REFMAC5 were performed. The structure was refined to 2.26 Å resolution with a final R_{work} and R_{free} of 23.9% and 25.3%, respectively (Table 1). No electron density was observed for the N-terminal His-tag, residues 572 to 581 and residues 675 to 676, and were not included in the final model. Residues from the CBD showed poor electron density that may indicate its high flexibility. However, most of the CBD was modeled as alanines due to the poor electron density maps.

The crystal structure of the ChiA74 consists of an $(\alpha/\beta)_8$-TIM-barrel, a CID, a FnIII and a C-terminal CBD (Fig. 1). Chitinases from family 18 share a common active site shape, which is often called "tunnel shaped"[28]. The catalytic region is composed of 442 residues and forms a substrate binding cleft and a semi-closed tunnel-shaped active site, with both the $(\alpha/\beta)_8$-TIM-barrel and the CID, similar to other chitinases with CID, the substrate binding groove is partially closed[29]. Three disulfide bonds between residues C78-C100, C140-C146, and C453-C461 are located in the TIM-barrel, with an additional one formed between residues C348-C359 in the CID domain. Structural comparison of the catalityc region of ChiA74 with other chitinases shows structural differences (Fig. S1) Although the catalytic region of chitinase A1 of *B. circulans* WL-12 shows high similarity with ChiA74 (~60% of identity), ChiA74 differs mainly in a loop (residues 454 to 465) that is close to the CID (Fig. S1, loop in magenta) and in two segments of the CID-loop 1 defined as l′ and l″ (Fig. S1, regions of the CID-loop 1 are indicated in yellow and red, and corresponds to residue range 361 to 366 and 375 to 380, respectively). The two regions of the CID-loop 1 (l′ and l″), the loops of the TIM-barrel harboring the CID (Fig. S1, loops showed in magenta and orange), and the TIM-barrel loop 2 (Fig. S1, showed in green) are the main structural differences of ChiA74 with chitinase A from *S. marcescens*, chitinase A from *V. harveyi* and ChiW from *Paenibacillus sp.* str. FPU-7 (Fig. S2, PDB code 1FFR, 3B9A and 5GZT, respectively). ChiW from *Paenibacillus sp.* str. FPU-7 differs even more on its TIM-barrel loop 2, which is considerable smaller to the rest of the chitinases showed in Fig. S1.

In our structure, the FnIII-like domain is linked to the TIM-barrel through residues 476 to 484 at the opposite site of the catalytic region, defined as FnIII linker loop. A calcium ion is highly coordinated by residues D483 and E485 (witin the FnIII linker loop), residues D512 and N513 (within the FnIII loop 2 which harbors residues 508

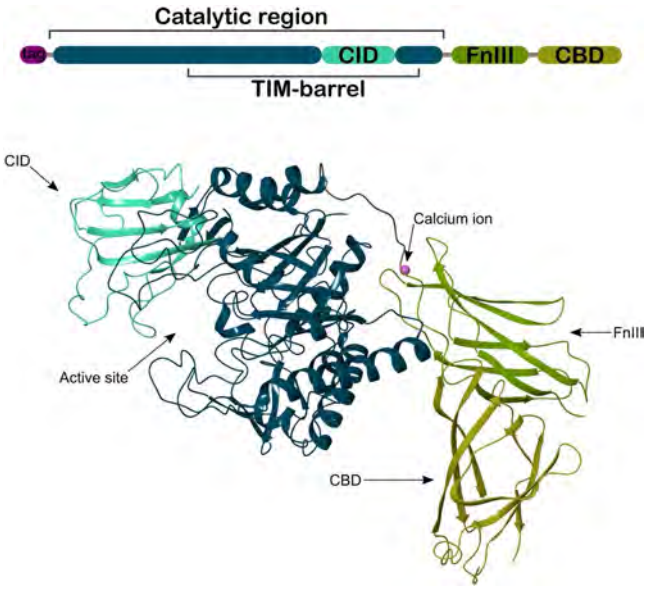

Figure 1. Overall structure of ChiA74. The scheme of the multidomain enzyme is shown at the top of the image. The catalytic region is composed of the characteristic $(\alpha/\beta)_8$-TIM-barrel and the chitinase insertion domain (CID), in dark blue and cyan, respectively. The fibronectin type III (FnIII) and the chitin binding domain (CBD), in green and lemon colors, respectively, are located at the C-terminal region. The rest of the image shows the active site into the cavity formed between the CID and the $(\alpha/\beta)_8$-TIM-barrel, indicated with an arrow. Two loops of the FnIII domain (green) and the linker loop to the $(\alpha/\beta)_8$-TIM-barrel keeps a highly coordinated calcium ion. The CBD at the C-terminal is shows in lemon color. The image only shows one molecule, for clarity, of two contained in the asymmetric unit.

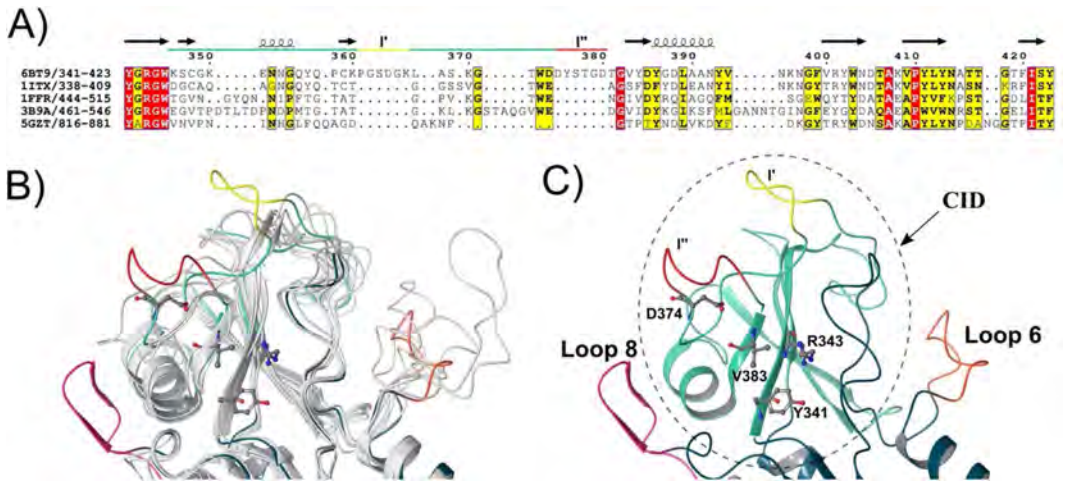

Figure 2. Structure-based sequence alignment of ChiA74 with other chitinases. The image shows the structure-based sequence alignment of the catalytic cleft of ChiA74 and others CID containing chitinases. Similar and conserved residues are indicated in yellow and red, respectively, according with ENDScript server[35]. UCSF Chimera[34] for structures superimposing. (**A**) Structure-based sequence alignment, only the region of the CID is shown. Main difference with other CIDs is the CID-loop 1 long. Regions l′ and 1″ are indicated in yellow and red, respectively. The PDB ID are the following: 6BT9 (chitinase ChiA74 from *B. thuringiensis*); 1ITX (catalytic domain of chitinase A1 from *B. circulans* WL-12); 1FFR (chitinase of mutant Y390F complexed with hexa-N-acetylchitohexaose from *S. marcescens*); 3B9A (*V. harveyi* chitinase A complexed with hexasaccharide) and 5GZT (chitinase ChiW from *Paenibacillus* sp. str. FPU-7). (**B**) Structural superimposition of ChiA74 with other chitinases where the differences between structures are shown with color. PDB codes of the superimposed structures are the same used in A. (**C**) CID in ChiA74 (dashed line) protrudes from Loops 6 and 8 of the TIM-barrel. Residues that would be interacting with substrate are indicated. Region 1′ of the CID-loop1 closes the substrate binding groove ″ of the active cleft (yellow).

to 516) and D554 (within the FnIII loop 6, residues 554 to 562); these loops are the linkers between β strands of the domain, i. e. loop 2 links β strand 2 to 3, and loop 6 links β strand 6 to 7. Other contacts of the N-terminal region of the FnIII occur with residues E248 to K251 of the TIM-barrel. FnIII does not form an extended substrate binding surface with the catalytic cleft as has been observed in other chitinases, for instance, chitinase ChiA of *Serratia marcescens*, and ChiA of *V. harveyi*, where this domain has multiple sites for substrate binding along the surface towards the active site, and which functions in enhancing binding and hydrolyzing activities against natural chitin[30,31]. The crystal structure of ChiA74 and the catalytic parameters of the truncated FnIII version of the enzyme[12], shows that FnIII (i) lacks exposed aromatic residues, and (ii) acts as a stable linker between the catalytic region and the CBD. A similar role of a FnIII domain has been suggested in chitinase ChiW from *Paenibacillus* sp. str. FPU-7[32], and other multimodular carbohydrate-interacting proteins containing FnIII domains[33]. Additionally, CBD shares interfaces between both FnIII and the $(\alpha/\beta)_8$-TIM-barrel. Briefly, N664 to E667 form hydrophobic and electrostatic interactions with the β-sheet 7of the FnIII (residues 563 to 568), and its loop 1 interacts with the α -helix 4 of the TIM-barrel (Figs 1 and S2).

Structure of the CID of ChiA74. The CID is located between the seventh alpha-helix and the seventh beta-strand of the $(\alpha/\beta)_8$-TIM-barrel. Residues in this loop assemble the "half active site wall" of the entire catalytic region. The CID consists of 82 residues, constrained between residues 341 and 423. In ChiA74 this domain is composed by five antiparallel beta-strands, one α -helix and one loop of 38 residues long between its first and the second β-strand of the CID, defined as CID-loop 1. A structure-based sequence alignment and a structural comparison with other chitinases (Fig. 2) carried out by the structure comparison tool MatchMaker of the UCSF Chimera program[34] showed that the CID-loop 1 is longer in ChiA74, with two segments that extend and closes the catalytic cleft, named as l′ and l″. CID-loop 1 is the less conserved region compared with similar chitinases of known structure. PDB codes indicated in Fig. 2A, and similar, conserved residues are indicated in yellow and red, respectively, according with ENDScript[35]. Those segments are considerably long when compared with other structures (Fig. 2B). PDB codes of the superimposed structures are the same that are indicated in Fig. 2A, ribbon representation images were rendered in Maestro program[36]. The CID-loop 1 together with the TIM-barrel loop 2 (residues 74 to 147) (Fig. S1) assemble into a structure that partially closes the substrate binding groove. This assembling is characteristic of exo-acting processive enzymes during the degradation of non-soluble polysaccharides[37], since processive chitinases possess partially closed tunnels at the active site and conserved aromatic residues that bind the substrate and allows substrate translocation and processivity[38], and is also an important structural element for endo-acting chitinases on soluble substrates[28,32]. Additionally, four residues in the CID are suggested to interact with the substrate at the catalytic cleft[10]; in ChiA74 these residues are Y341, R343, V383 and D374 (Fig. 2C).

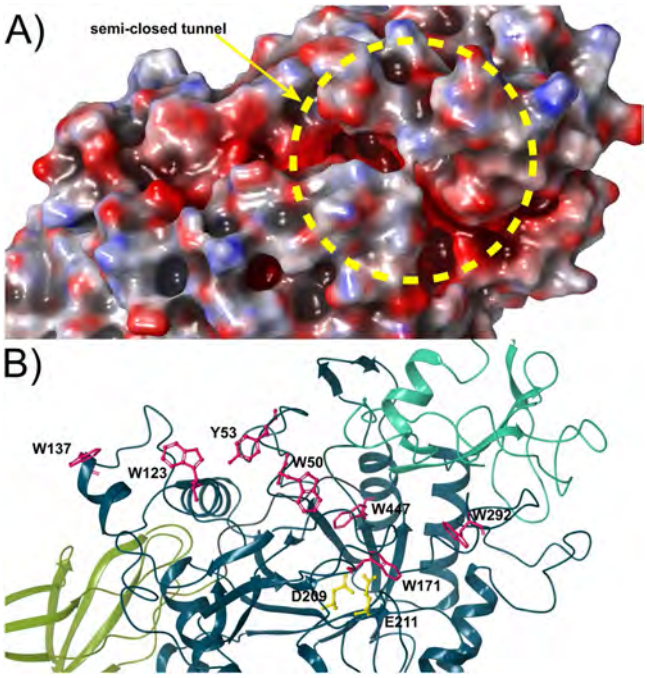

Figure 3. Structural details of the catalytic cleft in ChiA74. (**A**) Electrostatic surface potential of the semiclosed tunnel active site of ChiA74. Red and blue color indicate negative and positive charges, respectively, generated using Poisson-Boltzmann (APBS) method for the solvated molecule. The binding and catalytic area displays an extended negatively charged surface. The discontinued circle in yellow is indicating the semi-closed tunel. (**B**) A series of aromatic residues for substrate stabilization and binding are shown in magenta. Residues W137, W123, Y53, W50 and W447 form an extended surface towards the catalytic site (only D209 and E211 are shown, in yellow). Images are superimposables.

Structural details of the catalytic cleft of ChiA74. The catalytic semi-closed tunnel of ChiA74 formed by the TIM-barrel and CID displays a negatively charged surface (Fig. 3A). The $(\alpha/\beta)_8$-TIM-barrel harbors a series of aromatic residues through its molecular surface, that control substrate binding near the active site, subsites −5 to +2. The subsites −1 and +1 are between the cut-off site of the enzyme, the positive subsites (e.g.+2) toward the reducing end, and the negative subsites (−2, −3, −4, −5…) in the direction to the non-reducing end (Figs S3, S4B). Several studies in model enzymes from subfamily A of the family 18 chitinases[30,39] indicate that conserved exposed aromatic residues at the entrance of the catalytic cleft play a key role in hydrolyzing the chitin chain, when using crystalline chitin as a substrate, by guiding the entrance of the substrate into the active site. In ChiA74, the aromatic residues at the entrance of the catalytic cleft correspond to W123 and W137 which are similarly located as in chitinase from *B. circulans, S. marcescens* and *V. harveyi*, and may play the same role as substrate guiding residues (Figs 3B, S3). Residues Y53 and W50 are also conserved and they may be involved in extending from −5 to −3. These amino acids are structurally superimposable to Y56 and W53 of ChiA1 from *B. circulans*, and appear to be essential for crystalline chitin hydrolysis[30,40]. Due to their structural resemblance, residues Y53 and W50 may have the same function in hydrolyzing crystalline chitin. Residues W137, W123, Y53, and W50 are located on the extended surface at the entrance to the catalytic cleft in ChiA74, suggesting that this chitinase works as processive chitinases towards the non-reducing end of chitin[41] predominantly releasing disaccharides and also monosaccharides at +1 and +2 subsites, as it was recently observed with purified ChiA74[22]. For ChiA74, residues stacking in subsites +1 and +2 are W171 and W292, respectively (Fig. S3).

The catalytic domain harbors the motif (DxDxE) which is conserved in most family 18 chitinases, and whose role in the catalytic process has been demonstrated in other bacterial chitinases[21,34–43]. In the current accepted model, the second Asp within the DxDxE motif turns towards the Glu after substrate binding, enabling hydrogen bond interactions with the substrate and Glu, then the glycosidic oxygen acts as a nucleophile and the second Asp deprotonates the N-acetamido nitrogen during oxazolinium ion formation. Finally the Glu protonates the glycosidic oxygen and deprotonates the nucleophilic water, giving the hydrolysis of the oxazolinium ion[44]. In ChiA74 this motif harbors the following amino acids: D207, D209, and the catalytic E211[21] (Figs 3B, S3).

Chitinase activity of truncated versions and catalytic motif mutants against different substrates. ChiA74Δsp and its versions lacking the chitin binding domain (ChiA74Δsp-60) and chitin binding-fibronectin type III domains (ChiA74Δsp-50) were assayed against three natural substrates (crystalline chitin, colloidal chitin, chitosan) and one synthetic compound, i.e. 4-MU-$(GlcNAc)_3$ (Table 2). Also, mutants of ChiA74Δsp with one (ChiA74Δsp_{E211N}) and two (ChiA74$\Delta sp_{mD207N, E211N}$) amino acid replacements in the catalytic motif were generated, substituting D207 and the catalytic E211 (negative amino acids) with asparagines (N, uncharged amino acid). The importance of those amino acids in catalysis has been demonstrated in chitinase A1 of *B.*

Enzymes	crystalline-chitin*	Colloidal chitin*	Chitosan*	4-MU-GlcNAc$_3$**
ChiA74Δsp	$97.46 \pm 6^{a***}$	187.15 ± 13^{a}	48.73 ± 23^{a}	13093.16 ± 635^{a}
ChiA74Δsp-60	21.54 ± 1^{b}	60.53 ± 4^{b}	28.52 ± 14^{a}	10313.68 ± 500^{b}
ChiA74Δsp-50	47.76 ± 3^{c}	170.44 ± 12^{a}	51.28 ± 25^{a}	8846.54 ± 429^{c}
ChiA74Δsp$_{E211N}$	0.71 ± 0.0^{c}	0.71 ± 0.05^{c}	1.41 ± 0.7^{b}	64.97 ± 3^{d}

Table 2. Chitinase activity (U/μmol) of different versions of ChiA74 against several substrates. *One Unit of chitinase activity was defined as the amount of enzyme required to release 1 μmol of NAG in 1 h. **One Unit of chitinase activity was defined as the amount of enzyme required to release 1 μmol of MU in 1 h. ***Different letter in the same column (a, b, c) indicate significant difference at $P < 0.05$ determined by the Tukey multiple range test.

circulans and *S. marcescens*, primarily the glutamic acid which is directly involved in the hydrolysis of the oxazolinium ion intermediate[42,44]. In general, the highest activity with natural substrates was observed with colloidal chitin rather than crystalline chitin and chitosan in a time reaction of 12 h at 37 °C. As was previously reported[12], we confirmed that ChiA74Δsp and ChiA74Δsp-50 show the highest activity with colloidal chitin, without statistical difference. With crystalline chitin, ChiA74Δsp showed 4.5 and 2.0 higher activity than ChiA74Δsp-60 and ChiA74Δsp-50, respectively, but with chitosan the highest activity was detected with ChiA74Δsp-50. Using 4-MU-(GlcNAc)$_3$, truncated versions showed differences in the activity against this substrate. When mutants (ChiA74Δsp$_{E211N}$) and ChiA74Δsp$_{D207N, E211N}$ were assayed with crystalline chitin, colloidal chitin, chitosan and 4-MU-(GlcNAc)$_3$, no enzymatic activity was observed, demonstrating the importance of the catalytic E211 in the chitinase activity[42,44] of ChiA74Δsp.

On the other hand, TLC (Fig. S4) was carried out with colloidal chitin and crystalline chitin, the natural substrates that were most susceptible to the hydrolytic activity of purified ChiA74Δsp and ChiA74Δsp-50. Chitin-oligosaccharide derivatives with degree of polymerization of 1 and 2 were detected, as previously reported[22], which suggest a processive activity in substrate degradation. Similar results were reported with BthChi74, a chitinase that shares 98% identity with ChiA74[45].

Discussion

The crystal structure of ChiA74 shows that this enzyme has a modular structure formed by four domains: (i) the catalytic region with an (α/β)8-TIM-barrel as a core structure, (ii) the chitinase insertion domain as a barrel insertion, (iii) the fibronectin type III and (iv) a chitin binding domain, as previously hypothesized by Juárez-Hernández *et al.*[12].

The modular organization of ChiA74 has similarities, but it is not identical to the structure reported for other bacterial chitinases (e.g. ChiA1 from *B. circulans*, ChiA from *S. marcescens*, ChiA from *V. harveyi*, ChiW from *Paenibacillus* sp. str. FPU-7[30-32,40]. Some chitinases have immunoglobulin-like fold domains (FnIII, CBD or both), but ChiA74 differ from those enzymes mainly at the structural arrangement level, because of the very closed substrate binding groove of the catalytic cleft and in the multimodular assembly (Figs 1, 2). The TIM-barrel/CID catalytic domain of ChiA74 harbors the conserved motif in most family 18 chitinase involved in chitin hydrolysis (i.e. DxDxE), where E211 plays an important role as the catalytic amino acid initiator of the oxazolinium ion intermediate hydrolysis[42,44]. We demonstrated the importance of residues present in the conserved motif of the catalytic domain by site-directed mutagenesis, in particular, the significance of the catalytic E211 in ChiA74, as mutants ChiA74Δsp$_{E211N}$, ChiA74Δsp$_{D207N, E211N}$ were inactive against two natural polysaccharides (i.e. chitin, chitosan) and one short synthetic substrate (4-MU-GlcNAc$_3$) (Table 2), similar as reported for other chitinases[42]. The catalytic domain of ChiA74 from *B. thuringiensis* shows high identity with ChiA of *S. marcescens*, suggesting that ChiA74 might has similar catalytic mechanism. In the proposed mechanism for ChiA74, D209 interacts with D207, after binding of substrate D209 flips to its alternative position where it interacts with E211 forcing the substrate acetamido group of −1 sugar to rotate around the C2-N2 bond (Fig. S5)[29].

As ChiA74 contains a CID inserted into the TIM barrel catalytic domain, this enzyme can be classified in the subfamily A of the family 18 chitinases[10]. The location of the FnIII and CBD in ChiA74 is different with respect to other chitinases of the family 18, in which the FnIII domain is often located along the catalytic region and functions as a chitin binding module[29,46]. In ChiA74, the FnIII might act as a stable linker between the catalytic regions and the CBD in a similar way as has been proposed in ChiAW fom *Paenibacillus* sp. str. FPU-7 and *Microbacterium aurum* B8[32,33]. The modular arrangement of ChiA74 represents the first report of a full version chitinase structure with a CBD located slightly distal from the catalytic region linked by a FnIII domain, and suggests a different role (substrate binding and guiding to the active site) for the CBD. The location of the CBD with respect to the catalytic region has no structural similarity with other chitinases of known structure, and to date, represents the first report of this particular multimodular assembly. The structural arrangement of this domain remains unclear, but our data indicates that this domain could be important for crystalline chitin hydrolysis. For example, the activity of the truncated version against crystalline chitin is lower (from 0.22 X to 0.49X) than ChiA74Δsp, suggesting that CBD is necessary for crystalline chitin hydrolysis. We do not have experimental evidence, but as crystalline chitin has a fibrillar structure with high degree of crystallinity and polymorphism, and the chitin binding domain surface might facilitate the movement of the chitin chain toward the catalytic region, as suggested previously[7] or prevent dissociation from the crystalline substrate. In general, we observed a higher chitinase activity when using colloidal chitin as a substrate than using chitin in its crystalline form. It is likely

that colloidal chitin might interact more easily with the enzyme because the crystalline structure maintained by hydrogen bonds is disrupted due to the acid treatment, thus facilitating the interaction of the sugar chains of the colloidal chitin with ChiA74. Similar results have been observed with a chitinase from *V. harveyi*[7]. Our data confirmed that ChiA74Δsp and the truncated version ChiA74Δsp-50 (i.e., the enzyme version with the CD and CID) have the same activity against colloidal chitin, indicating the CBD and FnIII are not necessary for the chitinase activity against this substrate[12]. When crystalline and colloidal chitin were treated with ChiA74Δsp and analyzed by TLC, oligosaccharides of DP of 1 (GlcNAc) and DP of two ($GlcNAc_2$) were obtained, indicating that ChiA74Δsp has an exo-acting processive activity which is congruent with the presence of a partially closed substrate binding groove formed by the CID-loop 1 and the TIM-barrel loop 2, characteristics of enzymes with this activity[37]. Similar results were obtained previously in our laboratory using purified ChiA74Δsp and colloidal chitin[22]. The crystal structure and TLC data suggest that ChiA74 probably hydrolyses chitin chains from reducing toward non-reducing end, similar to ChiA by *S. marcescens*[47]. We previously reported that ChiA74 has an endo-chitinase activity which was determined using crude extracts and synthetic fluorescent substrates[21]. However, the putative endochitinase activity reported in that work might be erroneous considering the fact that ChiA74 was mixed with other proteins in the crude extract and the substrate was not a chitin polymer. In this regard, in future studies it is very important to confirm or discard, experimentally, whether ChiA74 cleaves the chitin chain at internal sites or hydrolyzes chitin from the end in a processive mode, or both, using more sensitive techniques than TLC (e.g. HPLC)[44,47].

Finally, we report for the first time the three-dimensional structure of a chitinase synthesized by *B. thuringiensis*, the most important microbial insecticide worldwide. The elucidation of the crystal structure of ChiA74 is an important advancement in the study of metabolites of *B. thuringiensis* and provides a foundation for future studies of chitinases synthesized by this bacterium, including protein engineering or directed evolution to enhance the applied versatility of these enzymes.

Materials and Methods

Bacterial strains and culture conditions. The recombinant plasmid, *pColdI-chiA74Δsp*, harbors *chiA74* lacking sequences coding for the secretion signal peptide, and its N-terminal end is fused to a heterologous sequence of 28 amino acids that includes the 6x-histidine tag and Factor Xa cleavage sites[12,22]. *Escherichia coli* TOP10 (Invitrogen, Carlsbad CA, EE.UU.) and *E. coli* BL21 Rosetta 2 (Merck Millipore, MA) were used as host cells for propagation or protein production, respectively. All bacteria were cultured at 37 °C in Luria-Bertani (LB) liquid medium (Invitrogen, Carlsbad CA, USA), supplemented with ampicillin (100 mg/ml) or chloramphenicol (34 mg/ml).

Expression and purification of ChiA74Δsp. *E. coli* BL21 Rosetta 2/*pColdI-chiA74Δsp* was grown overnight in 10 ml of LB broth supplemented with ampicillin and chloramphenicol, and then transferred to 1000 ml fresh medium supplemented with the same antibiotics. Culture was grown at 37 °C/200 rpm to reach an OD_{600} of 0.5, and then incubated at 4 °C for 15 min. Bacterial culture was incubated with agitation at 15 °C for 30 min, and IPTG was added to a final concentration of 0.5 mM. The culture was incubated for 24 h at 16 °C, 200 rpm, and then centrifuged, the supernatant was discarded, and the pellet was resuspended and incubated on ice for 30 min in 25 ml of buffer A (100 mM Tris-HCl, pH 7; 500 mM NaCl, 10 mM imidazole) supplemented with lysozyme (1 mg/ml). Samples were sonicated 10x, 30 s each, at an amplitude of 30 Hz using a 20 kHz ultrasonic processor (Sonic and Materials, Inc., New-town, CT 06470-1614 USA). The extract was centrifuged 30 min at 13,000 *g* and the supernatant was passed through a HisTrap HP column (GE Healthcare Bio-Sciences AB, Upsala Sweden) pre-equilibrated with buffer A. Unbound protein was removed with 15 ml of buffer A, 15 ml of buffer A-20 mM imidazole, 15 ml of buffer A-40 mM imidazole, and finally samples were eluted with 3 ml of buffer A-500 mM imidazole. Eluted samples were dialyzed at 4 °C in buffer E (100 mM Tris-HCl, pH 7; 150 mM NaCl) without imidazole. Collected fractions were analyzed by 10% SDS–polyacrylamide gel (SDS–PAGE) and zymogram. Samples, purified with the HisTrap HP column were loaded onto a Superdex 200 10/300 GL (GE Healthcare life science) column previously equilibrated with buffer A (100 mM Tris–HCl pH 7.0, 25 mM NaCl) and ChiA74Δsp was separated by fast protein liquid chromatography (FPLC) (Biologic Duo-Flow Pathfinder 20 System BioRad, Hercules CA, USA). Fractions of 1 ml were collected at a rate of 0.5 ml/min using buffer A and monitored at 280 nm. Fractions in the peak were collected and analyzed by 10% SDS–PAGE and zymograms. Protein concentration was determined at 595 nm using the Quick Start Bradford 1 x Dye reagent (BioRad, HerculesCA, USA) in a Synergy HTX Biotek (Winooski, VT).

SDS-PAGE and zymograms. Fractions containing ChiA74Δsp were monitored by SDS-PAGE and zymogram to corroborate the presence and activity of the purified recombinant protein. Portions of each fraction were treated with Laemmli's disruption buffer supplemented with β-mercaptoethanol. Identical samples were fractionated by electrophoresis in a 10% SDS–PAGE. One gel was stained with coomassie blue and the second was washed with casein-EDTA buffer [1% (w/v) casein, 2 mM EDTA, 40 mM Tris–HCl, pH 9], and activity detected with 25 μM of the fluorogenic substrate 4-MU-$(GlcNAc)_3$ (Sigma, St. Louis, MO), as previously described[21].

Protein crystallization and data collection. Initial crystallization tests were performed by using a Crystal Gryphon robot (Art Robbins Instruments, Sunnyvale CA, USA) using MRC 3 well crystallization plates (Jena Bioscience, Jena, Germany). Approximately 300 conditions were tested for crystallization at 292 K and crystals were formed in 30 conditions after two weeks using protein at 15 mg/ml, whereby a selection of the most appropriate crystals was made to improve their size. New drops were set in VDX plates (Hampton Research, Aliso Viejo CA, USA) using hanging-drop vapor diffusion technique by mixing equal volumes of the pure protein with selected precipitants from a sparse matrix screen. All the crystals were grown as a sheet clusters; no individual

crystals were obtained even after crystal seeding. Crystals were selected for diffraction from a condition containing 25% (w/v) PEG 6000, 100 mM HEPES/NaOH pH 7.0 and 200 mM NaCl. A single sheet crystal was obtained by breakage and cryoprotected in a similar solution containing 20% (w/v) of glycerol prior to flash cooling in liquid nitrogen. Two crystals were used to collect diffraction data at 100 K using a MarMosaic 225 CCD detector at APS beam line LS-CAT 21-ID-F with 1° rotation per image.

Structure determination and refinement. Diffraction intensities were integrated and scaled as monoclinic P 1 21 1 lattice symmetry with DIALS using xia2[48] and AIMLESS[49] from the CCP4 software suite, respectively. The program MATTHEWS_COEF[50], through the cell content analysis task in CCP4 suggests two copies of ChiA74 in the asymmetric unit. A molecular replacement solution was found with Phaser-MR[51], using a poly alanine model of the chitinase A1 structure from *B. circulans* (PDB ID 1ITX) as the search template. Residues of the catalytic region were modeled in Coot according with sequence as they were supported by electron density. Crystallographic refinement was performed with REFMAC5[52]. A total of 3145 reflections (5.0%) were used as the test set. Simulated annealing, individual atomic coordinate and individual atom isotropic displacement parameter refinement strategies were performed with non-crystallographic symmetry (NCS) restraints. The model was adjusted to improve the fit to likelihood weighted electron density maps using Coot[53], and the rest of the model corresponding to the fibronectin type III and carbohydrate binding domains were constructed manually in agreement with electron density maps, in Coot. Some solvent molecules were added where they were supported by both chemistry and geometry. The quality and stereochemistry of the model were evaluated using Coot validation tools, Molprobity and the wwPDB Validation Server[54].

Construction of ChiA74 mutant. Mutations in the catalytic domain were carried out by site-directed mutagenesis using pCold-*chiA74*Δsp as template[22]. This recombinant plasmid was amplified with the Phusion high-fidelity DNA polymerase (Thermo Scientific, MA, USA) using 5′ phosphorylated oligonucleotides allowing the plasmid's re-ligation. Two *chiA74*Δsp mutants, encoding proteins with one (E211N) or two (D207N, E211N) amino acids changes in the catalytic motif were obtained. The following primers were used, respectively: Fw E211N: 5′-CGTAGATTTAGACTGGAACTATCCGGGCGTTGAAA-3′, Rv E211N: 5′-TTTCAACGCCCGGATAGTTCCAGTCTAAATCTACG-3′, and Fw D207N,E211N: 5′-GATGGCGTAAACTTAGACTGGAACTATCCGGGCGTT-3′, Rv D207N,E211N: 5′-AACGCCCGGATAGTTCCAGTCTAAGTTTACGCCATC-3′. Amplicons were treated with DpnI to eliminate DNA templates and then visualized in 0.8% agarose. Samples were purified with the agarose gel extraction kit (Jena Biosciences, Jena, Germany) and dialyzed. *E. coli* Top10 was transformed with the purified amplicons by electroporation at 2.5 kV and transformants were selected on LB agar with ampicillin at 37 °C. The presence of point mutations was corroborated by sequencing and analyzed with the program LALING (https://embnet.vital-it.ch/software/LALIGN_form.html).

Enzymatic activity. Chitinase activity was determined in triplicate assays at 37 °C in 20 mM phosphate buffer, pH 7, using the substrate 4-methylumbelliferyl β-D-N,N′,N″-triacetylchitotrioside (4-MU-GlcNAc$_3$) (Sigma, St. Louis, MO) and purified recombinant enzymes at final concentrations of 100 µg/ml. The amount of 4-MU released from the substrate was calculated spectrofluorometrically (excitation at 360 nm and emission at 455 nm) with a Synergy HTX Biotek (Winooski, VT) instrument using a 4-MU standard curve. One unit (U) of chitinolytic activity was defined as the amount of enzyme required to release 1 µmol of 4-methylumbelliferone in 1 h. To determine chitinase activity with crystalline chitin (Sigma-Aldrich, St. Louis MO, USA), colloidal chitin (Sigma-Aldrich, St. Louis MO, USA) and chitosan, a suspension containing 0.5% of these substrates was mixed with 0.036 mg/ml of purified enzyme to reach a final volume of 0.5 ml using 20 mM phosphate buffer, pH 7, and then incubated at 37 °C with gentle agitation. Aliquots of 40 µL were taken after 12 h of incubation and mixed with 40 µL of 3,5-dinitrosalicylic acid. The samples were boiled for 5 min, allowed to cool and water was added to a final volume of 200 µl, then the absorbance was measured at 540 nm to determine the concentration of reducing sugars[19,21].

Analysis of chitin hydrolysis with ChiA74Δsp using thin layer chromatography. Mixtures containing 0.036 mg/ml of ChiA74Δsp, 0.5% (w/v) colloidal chitin, and 20 mM phosphate buffer (pH 7.0) were incubated at 37 °C, 200 rpm for 12 h to generate chitin-derived oligosaccharides (OGS). Reaction was terminated by heating at 100 °C for 5 min. Samples were centrifuged, supernatants were collected and concentrated in a DNA120 SpeedVac (ThermoSavant), then pellets were resuspended in 10 µl of double distilled water and 10 µl of methanol. OGS were analyzed by silica gel (Merk) thin layer chromatography (TLC) using 5:4:3 (v/v/v) n-butanol: methanol:16% aqueous ammonia as the mobile phase. Samples were visualized by staining with 20% (v/v) sulfuric acid in ethanol and incubated at 80 °C until chitin-derived oligosaccharides signals were developed. Molecular markers (Sigma, St. Louis, MO) *N*-acetyl-D-glucosamine (GlcNAc) and *N,N′*-diacetylchitobiose (GlcNAc$_2$) were used to determine the degree of polymerization (DP)[22].

Data Availability

All reagents and data described in this manuscript are available upon request. The coordinates and structure factors of ChiA74 have been deposited in the PDB under Accession code 6BT9.

In Brief

Kim et al. determine the structure of the betaglycan orphan domain (BG_O) and show that the edge β strand that endoglin uses to bind its cognate growth factor is blocked by an insertion. Binding studies and SAXS show that BG_O binds its cognate growth factor differently compared with endoglin.

Highlights

- Structure of the betaglycan orphan domain (BG_O) was determined by crystallography
- Structure reveals an insertion compared with the endoglin orphan domain (ENG_O)
- Insertion blocks the edge β strand used in the ENG_O to bind BMP-9 or BMP-10
- BG_O binds TGF-β in a different manner than ENG_O binds BMP-9 or BMP-10

SUMMARY

Betaglycan (BG) and endoglin (ENG), homologous co-receptors of the TGF-β family, potentiate the signaling activity of TGF-β2 and inhibin A, and BMP-9 and BMP-10, respectively. BG exists as monomer and forms 1:1 growth factor (GF) complexes, while ENG exists as a dimer and forms 2:1 GF complexes. Herein, the structure of the BG orphan domain (BG_O) reveals an insertion that blocks the region that the endoglin orphan domain (ENG_O) uses to bind BMP-9, preventing it from binding in the same manner. Using binding studies with domain-deleted forms of TGF-β and BG_O, as well as small-angle X-ray scattering data, BG_O is shown to bind its cognate GF in an entirely different manner compared with ENG_O. The alternative interfaces likely engender BG and ENG with the ability to selectively bind and target their cognate GFs in a unique temporal-spatial manner, without interfering with one another or other TGF-β family GFs.

INTRODUCTION

Temporal and spatial control of cell signaling is critical for normal development of embryos and for tissue maintenance in adults. The signaling molecules that regulate temporal-spatial control include those of the Wnt and Notch families, but also those of the transforming growth factor β (TGF-β) family, which have essential roles in patterning (Bier and De Robertis, 2015; Zinski et al., 2018) organogenesis (Mullen and Wrana, 2017) in embryos, and maintenance of the heart (Goumans and Ten Dijke, 2018), vasculature (Goumans et al., 2018; Roman and Hinck, 2017), and musculoskeletal system (Walker et al., 2016) in adults. TGF-β family signaling proteins have greatly diversified, with more than 30 family members in humans. The proteins of the family can be classified as belonging either to the ancestral bone morphogenetic protein (BMP)/growth and differentiation factor (GDF) branch of the family, or the more recently evolved TGF-β/activin branch (Hinck et al., 2016). The proteins of both branches bind and bring together two type I and two type II receptors to initiate a transphosphorylation cascade and intracellular Smad signaling (Hata and Chen, 2016; Wrana et al., 1994). TGF-β family signaling proteins are well-suited to enable temporal-spatial control because multiple mechanisms exist for targeting them with high spatial and temporal resolution. These range from cell- and tissue-specific expression of receptors, co-receptors, or soluble antagonists specific for a subset of TGF-β family growth factors (GFs), to proteolytic release of the mature signaling GF dimers from their inhibitory pro-domains (Brazil et al., 2015; Hinck et al., 2016; Nolan and Thompson, 2014; Robertson and Rifkin, 2013).

The membrane-anchored co-receptors of the TGF-β family, betaglycan (BG) and endoglin (ENG), do not directly participate in the transphosphorylation cascade that leads intracellular Smad signaling, but have essential roles in promoting receptor binding and signaling by select family members (Brown et al., 2005; Lewis et al., 2000; Lopez-Casillas et al., 1993; Nickel et al., 2018; Scharpfenecker et al., 2007). The co-receptor BG has been shown to promote binding of low-affinity TGF-β2 to the TGF-β type II receptor, TβRII ($K_D \sim 20$ μM for binding to the monomeric TβRII ectodomain [Baardsnes et al., 2009]), and to restore cellular sensitivity to concentrations comparable with that of high-affinity TGF-β1 and TGF-β3 ($K_D \sim$ 50–150 nM for binding to the monomeric TβRII ectodomain [Cheifetz et al., 1990; Lopez-Casillas et al., 1993; Radaev et al., 2010]). TGF-β2 is essential for transformation of endothelial progenitor cells required for normal development and maintenance of the heart and liver, and knockout of either TGF-β2 or BG in mice leads to similar defects in heart and liver development (Sanford et al.,

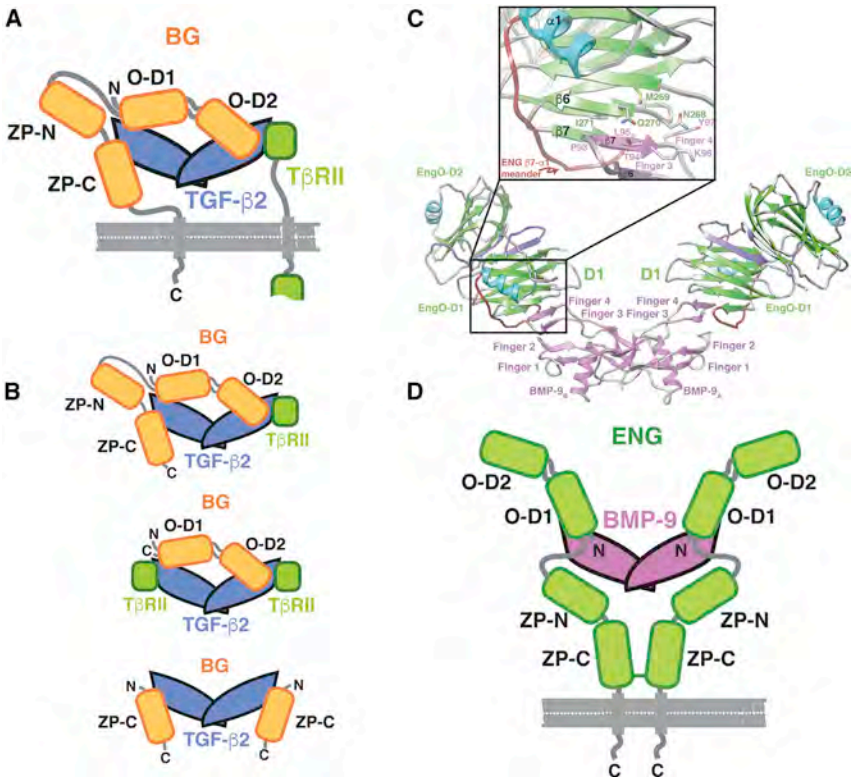

Figure 1. Schematic of BG and ENG Binding to their Cognate GFs

(A) Proposed model for BG binding of TGF-β2 homodimer with 1:1 stoichiometry (Villarreal et al., 2016). The orphan domain binds around the center of the dimer without interfering with either TβRII site, while the ZP-C domain binds in one of the TβRII sites, leaving one TβRII site accessible for binding.

(B) Complexes and subcomplexes shown by SEC, SEC-MALS, and SPR that led to the model shown in (A).

(C) Structure of the 2:1 $hENG_O$:BMP-9 complex determined by crystallography (Saito et al., 2017). The super β sheet formed by finger 4 of BMP-9 and β6 of O-D1 of $hENG_O$ is shown in the inset.

(D) Schematic of the 2:1 ENG:BMP-9 complex, in which the orphan domain binds symmetrically, and only through orphan domain (O-D1), to finger 4 of the growth factor (GF). The ZP domain, which is covalently dimerized by formation of a disulfide bond in its ZP-C domain, does not directly contact the GF and is connected to the orphan domain by a flexible linker.

1997; Stenvers et al., 2003). TGF-β2 and BG therefore function together to enable signaling essential for the proper development and maintenance of these organs. BG is also expressed by gonadotropic cells in the anterior pituitary and binds the TGF-β family heterodimer inhibin A (inhA) to promote activin type II/IIB receptor (ActRII or ActRIIB) binding, which is essential for inhibiting activin-stimulated follicle-stimulating hormone β secretion by gonadotropic cells in the anterior pituitary (Lewis et al., 2000; Li et al., 2018; Wiater et al., 2006). The co-receptor ENG is expressed on the surface of vascular endothelial cells and selectively binds BMP-9 and BMP-10 to promote binding of the type I receptor, activin-like kinase 1 (Alk1), and signaling (Alt et al., 2012; Castonguay et al., 2011; Scharpfenecker et al., 2007). This signaling stimulates migration of the endothelial cells and is essential for normal development and maintenance of the vasculature, as shown by vascular abnormalities known as arteriovenous malformations, which are the result of germline mutations in either Alk1 or ENG (Goumans et al., 2018; Roman and Hinck, 2017).

The extracellular domains of BG and ENG are comprised of two subdomains, the N-terminal membrane-distal orphan domain and the membrane-proximal zona pellucida (ZP) domain (Figures 1A and 1D) (Alt et al., 2012; Esparza-Lopez et al., 2001; Mendoza et al., 2009). The structure of the BG orphan domain, BG_O, is not known, but is likely a tandem β sandwich, designated orphan domain 1 (O-D1) and O-D2, similar to the ENG orphan domain (ENG_O), whose structure was recently reported (Saito et al., 2017). The BG ZP (BG_{ZP}) domain is likely comprised of tandem immunoglobulin-like domains, designated $BG_{ZP\text{-}N}$ and $BG_{ZP\text{-}C}$, based on available structures of $BG_{ZP\text{-}C}$ from rat (Lin et al., 2011) and mouse (Diestel et al., 2013) and homology to the ENG ZP (ENG_{ZP}) domain, whose structure was also recently reported (Saito et al., 2017). Through biochemical studies, rat BG, which has 5 cysteines within its orphan domain and 10 in its ZP domain, is found on cells as a monomer (Lopez-Casillas et al., 1993) and binds TGF-β homodimers asymmetrically with an overall 1:1 stoichiometry (Villarreal et al., 2016) using both its orphan domain and the C-terminal portion of its ZP domain, $BG_{ZP\text{-}C}$ (Henen et al., 2019; Mendoza et al., 2009; Villarreal et al., 2016) (Figure 1A). Human ENG (hENG), on the other hand, which has 5 cysteines in its orphan domain and 11 in its ZP domain, is found on cells as a disulfide-linked dimer and binds BMP-9 and BMP-10 using only its orphan domain (Alt et al., 2012). Recent structural studies revealed that ENG_O binds BMP-9 homodimers with 2:1 stoichiometry by forming a super β sheet with finger 4 of the GF through an exposed β strand, β6, in domain 1 (O-D1) (Figure 1C) (Saito et al., 2017). ENG's ZP domain is known to form a disulfide-linked dimer (Alt et al., 2012) and thus ENG binds BMP-9/-10 dimers in an antibody-like manner, in which the disulfide-linked ZP domain forms the F_c domain and the orphan domain the "antigen-binding" F_{ab} domain (Saito et al., 2017) (Figure 1D).

The objective of this study was to identify the structural basis for the different modes of GF binding by BG and ENG. Toward this end, the high-resolution structure of zebrafish BG_O ($zfBG_O$) was determined. This showed that BG_O has the same two-domain architecture as ENG_O, but differs in that the loop connecting β strand 7 to α helix 1 in O-D1 includes an additional α helix and β strand. The additional strand, β8, pairs with putative O-D1 GF-interacting β6, sequestering β6 and likely preventing it from pairing with finger 4 of the GF, as does ENG_O. To investigate if this modification engendered BG_O with an alternative manner of binding, binding studies were carried out with BG_O

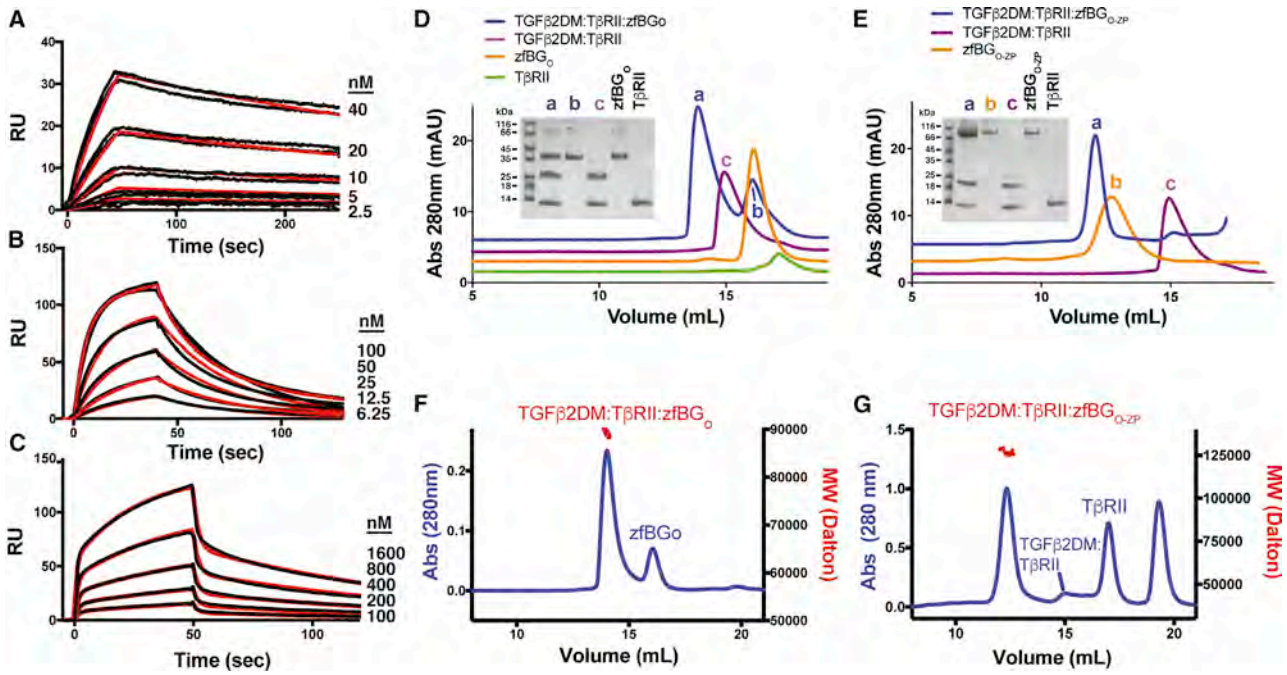

Figure 2. Characterization of zfBG Binding

(A–C) SPR sensorgrams of zfBG$_{O-ZP}$ (A), zfBG$_O$ (B), and zfBG$_{ZP-C}$ (C) binding to immobilized TGF-β2. Kinetic fits are shown in red over duplicate experimental curves in black.

(D and E) Complexes formed between zfBG$_O$ (D) and zfBG$_{O-ZP}$ (E) with TGF-β2DM and TβRII in solution as assessed using SEC. Shown in the insets are non-reducing SDS-PAGE gels of the major peaks that eluted.

(F and G) SEC-MALS analysis of the TGF-β2DM:TβRII:zfBG$_O$ (F) and TGF-β2DM:TβRII:zfBG$_{O-ZP}$ (G) complexes, with the blue trace corresponding to the UV absorbance and the red data points the molecular mass. Observed/anticipated masses for the TGF-β2DM:TβRII:zfBG$_O$ and TGF-β2DM:TβRII:zfBG$_{O-ZP}$ complexes are 89.6 ± 1.8/88.2 and 127 ± 1/121 kDa, respectively.

See also Figure S2.

O-D1 and O-D2 and an engineered TGF-β monomer. These studies, together with accompanying small-angle X-ray scattering (SAXS) measurements, supported an alternative 1:1 manner of binding in which BG$_O$ recognizes more than just the finger region and does so by utilizing both O-D1 and O-D2 to bind the GF. The alternative interfaces between BG and TGF-β and ENG and BMP-9 likely engender these otherwise structurally similar co-receptors with the ability to selectively bind their cognate GFs, enabling them to selectively target the heart, liver, and anterior pituitary and vasculature, respectively, without interference from one another or TGF-β family GFs.

RESULTS

Zebrafish and Rat BG Bind Human TGF-β2 in the Same Overall Manner

Previous surface plasmon resonance (SPR), size-exclusion chromatography (SEC), and isothermal titration calorimetry (ITC) binding studies showed that the full-length rat BG (rBG) ectodomain (rBG$_{O-ZP}$) bound TGF-β2 dimers with 1:1 stoichiometry, with the orphan and ZP-C domain (rBG$_O$ and rBG$_{ZP-C}$, respectively), both directly binding the GF (Mendoza et al., 2009; Villarreal et al., 2016) (Figure 1A). SPR, ITC, and SEC showed that this asymmetric manner of binding, which blocked one of the TβRII binding sites, but left the other accessible, was driven by the orphan domain, which alone bound TGF-β dimers with 1:1 stoichiometry and did not interfere with TβRII binding (Villarreal et al., 2016) (Figure 1B). SPR, SEC, and structural studies, showed in contrast, that the hENG ectodomain (hENG$_{O-ZP}$) bound BMP-9 dimers symmetrically with 2:1 stoichiometry, with only the orphan domain (hENG$_O$) bound to the GF (Alt et al., 2012; Saito et al., 2017) (Figures 1C and 1D). To decipher the origins of these disparate modes of binding, crystallization of rBG$_O$ was pursued. Although unsuccessful, parallel efforts with the zfBG orphan domain (zfBG$_O$), which has 54% identity with rBG$_O$ (Figure S1A), succeeded.

Previously, zfBG had been shown to bind TGF-β, but, when knocked down in zebrafish embryos, it had effects on blood vessel development (Kamaid et al., 2015), a phenotype not seen in BG null mice (Stenvers et al., 2003), raising questions as to whether zfBG was a true ortholog of mammalian BG. SPR experiments with the full-length zfBG ectodomain (zfBG$_{O-ZP}$) and its component domains, zfBG$_O$ and zfBG$_{ZP-C}$, and immobilized human TGF-β2 (hTGF-β2), were therefore performed to determine whether zfBG possessed the same binding properties as rBG (Figures 2A–2C). Similar experiments with rBG$_{O-ZP}$, rBG$_O$, and rBG$_{ZP-C}$ were also performed to enable a direct comparison (Figures S2A–S2C). In accord with previous results (Kamaid et al., 2015; Mendoza et al., 2009; Villarreal et al., 2016), the rat and zebrafish full-length BG ectodomain bound hTGF-β2, but in contrast to either the

[a]k_m, mass transfer rate constant.
[b]ND, not determined.

orphan or ZP-C domain alone, both of which also bound hTGF-β2, the full-length ectodomains dissociated more slowly, presumably due to bivalent binding. Kinetic analysis of the sensorgrams showed that the K_D values were 5 nM for $zfBG_{O\text{-}ZP}$, 27 nM for $zfBG_O$, and 480–1,100 nM for $zfBG_{ZP\text{-}C}$, 3- to 10-fold weaker compared with $rBG_{O\text{-}ZP}$, rBG_O, and $rBG_{ZP\text{-}C}$, which bound with K_D values of 0.5, 10, and 90–610 nM (Table 1). Human and rat TGF-β2 differ at three positions, while human and zebrafish TGF-β2 differ at ten positions (Figure S1B), which may account for the lower affinities of the zfBG constructs compared with rat.

Binding stoichiometry and effects on TβRII binding were assessed by combining $zfBG_{O\text{-}ZP}$ or $zfBG_O$ with the TGF-β:TβRII binary complex and analyzing the complexes that formed by SEC and SEC-multiangle light scattering (SEC-MALS). To enable a direct comparison, the same experiments were also performed with $rBG_{O\text{-}ZP}$ and rBG_O; to minimize disassociation of TβRII, TGF-β2 K25R K94R or TGF-β2DM was used, which binds TβRII with high affinity (Baardsnes et al., 2009; De Crescenzo et al., 2006). In accord with previous findings with rBG (Villarreal et al., 2016), the orphan and full-length ectodomains of both zebrafish and rat BG formed ternary complexes, as shown by a peak in the SEC profiles (labeled a) that eluted earlier than either the corresponding BG domain (labeled b) or the TGF-β2DM:TβRII binary complex (labeled c) (Figures 2D, 2E, S2D, and S2E). In accord with previous findings with rBG (Villarreal et al., 2016), the apparent molecular weights of ternary complexes were consistent with the 1:1:1 TGF-β2DM:TβRII:$BG_{O\text{-}ZP}$ complex anticipated for the full-length ectodomain (127 ± 1 and 129 ± 2 kDa observed, versus 121 and 123 kDa anticipated, for zfBG and rBG, respectively) and the 1:2:1 TGF-β2DM:TβRII:BG_O complex anticipated for the orphan domain (89.6 ± 1.8 and 94.9 ± 2.0 kDa observed, versus 88.2 and 91.1 kDa anticipated, for zfBG and rBG, respectively) (Figures 2F, 2G, S2F, and S2G). In summary, the binding data show that zfBG binds TGF-β2 in the same overall manner as rBG (Villarreal et al., 2016), indicating that it is a true ortholog of mammalian BG and justifying it as a model system for deciphering the function of mammalian BG.

Structure of $zfBG_O$

The crystal structure of $zfBG_O$ was determined to 2.10 and 2.38 Å from orthorhombic ($P2_12_12_1$) and tetragonal ($P4_1$) crystal forms, respectively (Table 2). The initial efforts to determine the structure focused on the tetragonal form, but these were unfruitful as molecular replacement with $hENG_O$, which has 20% sequence identity with $zfBG_O$ (Figure S3A), proved unsuccessful, as did phasing with heavy atoms, primarily due to difficulty reproducing the crystals. To overcome these obstacles, we reasoned that $zfBG_O$, which has six cysteines in its orphan domain (Figure S1A), has two free cysteines, which might be forming disulfide-linked aggregates. This hypothesis is based on the observation that four of the six cysteines of $zfBG_O$ are conserved with the four cysteines in $hENG_O$, which form two disulfide bonds, while the other two cysteines are at positions expected to be far apart in the three-dimensional structure (Figure S3A). Therefore, $zfBG_O$ was pre-treated with iodoacetamide before SEC and final purification. This led to more consistent crystal formation, in an orthorhombic space group, and enabled

preparation of two derivatives, one platinum and one iodide. Using multiple isomorphous replacement with anomalous scattering phasing (Table 2), this led to an interpretable map, a portion of which is shown in Figure S4. This map enabled building of a nearly complete model, which in turn enabled solution of the tetragonal form by molecular replacement. The asymmetric unit of the tetragonal and orthorhombic forms contained one and two molecules, respectively. The tetragonal form and one of the chains in the orthorhombic form, chain A, were well ordered, with weak electron density in only a few loop regions (Table S3). The other chain in the orthorhombic form, chain B, had overall weaker density and higher B factors (Table 2), especially in domain 2 and was difficult to model, with additional regions of weak density compared with chain A (Table S3). The weak density in this region appears to be because the nature of the lattice packing, which, as shown in Figure S5, places domain 2 of chain B in a solvent void without lattice contacts to either domain of either chain (Figure S5).

The structure of $zfBG_O$ is comprised of two β sandwich domains arranged in an arch-like manner (Figure 3A). The two β sandwich domains are each comprised of 10 β strands and share the same fold (Figures 3B, 3D, and 3E). They are decorated with two α helices, one in the loop following β7 (α1), and the other packed against the convex surface of the arch-like structure formed by the two β sandwiches (α2) (Figures 3A, 3D, and 3E). One of the unusual features is that the N terminus of the protein is comprised of two extended segments, each approximately 10 amino acids in length, connected by a bend: the N-terminal half is tethered to the N-terminal β strand (β1) of O-D1 by a disulfide bond (C31-C225), while the C-terminal half is paired with the C-terminal β strand of O-D1 (β10) and extends into O-D2 (Figures 3A, 3C, and 3D). A similarly structured extended "exit" segment is present in O-D2, where, after exiting the C-terminal β strand of O-D2 (β10), it is tethered to the N-terminal β strand (β1) by a disulfide bond (C55-C201), paired with the C-terminal β strand (β10), and extends into O-D1 (Figures 3A, 3C, and 3E). One further point is that a sequence alignment of the repeating element present in $zfBG_O$, that is the O-D1 exit sequence followed by the O-D2 β sandwich and the O-D2 exit sequence followed by the O-D1 β sandwich, shows that these share significant (20%) sequence identity (Figure S1C), and thus are likely the result of gene duplication. One important consequence is that, similar to $hENG_O$ (Saito et al., 2017), $zfBG_O$ is pseudosymmetric, not only in terms of its architecture, but also its sequence.

The paired antiparallel β strands that connect O-D1 and O-D2, seen previously in $hENG_O$ (Saito et al., 2017), represent another unique structural feature and might be important in restricting the orientation of O-D1 and O-D2. To gauge the extent of this restriction, the two $zfBG_O$ orthorhombic structures and one $zfBG_O$ tetragonal structure were aligned by minimizing coordinate differences for one domain, but not the other. This showed that the structures of individual domains were, on the one hand, very consistently determined, with root-mean-square deviation (RMSD) well under 1.0 Å for both O-D1 and O-D2 when all three structures were compared (Figure S6A). The relative domain orientations in the three structures, on the other hand, were more variable, with displacements ranging from 1.3 Å at the centroid of unaligned domain when the orthorhombic chain A and tetragonal structures were compared, to 3.7 Å, when orthorhombic chain A and chain B were compared (Figures S6B and S6D). This suggests some degree of hinge bending, although evidently this must be limited, as solution-based SAXS measurements with $zfBG_O$ showed that the experimental scattering curves, as well as P(r) function and calculated electron density, correlated well with the three $zfBG_O$ structures or parameters calculated from them (Figures S7A–S7C, S7G, and S7H). The rat BG orphan domain also appeared to have an overall structure similar to the zebrafish orphan domain because the experimental SAXS data for rBG_O also correlated very well with the three $zfBG_O$ structures or parameters calculated from them (Figures S7D–S7F, S7I, and S7J).

Structural Comparison of $zfBG_O$ and $hEng_O$

The overall architecture and domain structures of $zfBG_O$ and $hENG_O$ are similar (Figures 4A–4C), despite only 20% sequence identity (Figure S3A). There are nonetheless differences, the most prominent of which is a shift of O-D2 downward and toward the concave surface of O-D1 in $zfBG_O$ (Figure 4A). This shift, which corresponds to a 17.6-Å displacement in the centroid of the zfBG O-D2 relative to hENG O-D2 when the residues of O-D1 are aligned, results in an arch-like structure in $zfBG_O$, but not in $hENG_O$ (Figure 4A). The primary reason for the more arch-like structure in $zfBG_O$ compared with $hENG_O$ is the O-D1 exit sequence. In zfBG O-D1, after exiting the domain, the β strand of the exit sequence bends upward before extending into the N-terminal β strand of O-D2 (Figure S8). In contrast, in hENG O-D1, the exit sequence is shorter and has a sharp bend downward before it leads into the N-terminal β strand of O-D2 (Figure S8). Importantly the lengthening of the exit sequence and opposite direction of the bend as it exits the domain leads to very different positioning of the N-terminal β strand of O-D2 in $hENG_O$ and $zfBG_O$, and thus relative positioning of O-D1 and O-D2 (Figure S8). To accommodate the difference in domain orientation, the β strand of the O-D2 exit sequence of $zfBG_O$ pairs mostly with the O-D1 exit sequence, while that of $hENG_O$ pairs with the C-terminal β strand of O-D2 and the O-D1 exit sequence (Figure S8).

Although more subtle, another difference pertains to the loop region following OD-1 β7. In hENG O-D1, immediately after β7 there is a sharp bend followed by an extended meander that leads into the three-turn α helix (α1) packed against the convex surface of the sandwich (Figure 4B). In zfBG O-D1, after β7 there is an insertion of a one-turn helix (α1) that traverses the gap between the concave and convex surfaces of the sandwich (Figure 4B). Immediately following α1, there is an insertion of a β strand (β8), which pairs with β6 on the convex surface, followed by an extended meander that connects into three-turn α2 packed against the convex surface (Figure 4B). Importantly, in $hENG_O$, the absence of β8 and altered positioning of the meander leaves O-D1 edge β strand 6 accessible on the convex surface, while, in $zfBG_O$, the O-D1 α1-β8 insertion sequesters β6, making it inaccessible.

The structure of the 2:1 $hENG_O$:BMP-9 complex shows that BMP-9 and $hENG_O$ bind through a super β sheet formed between the exposed finger region of BMP-9, specifically finger 4 β7 and the exposed edge β strand, β6, of hENG O-D1 (Figures 1C and 4D). Through positioning of the $zfBG_O$

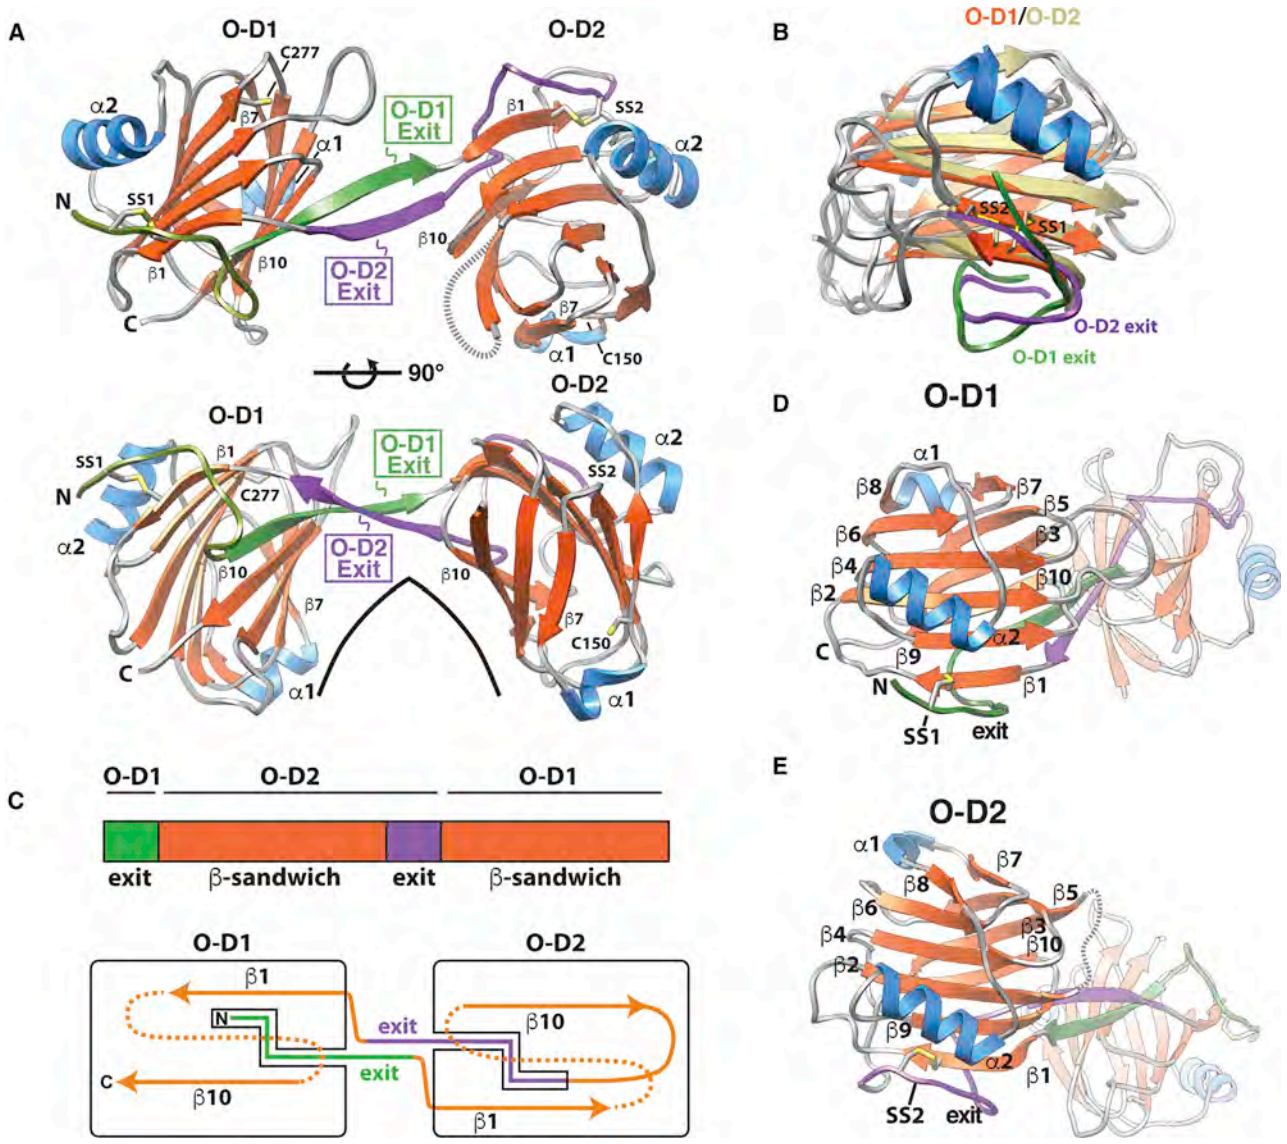

Figure 3. Structure of zfBG$_O$

(A) Structure of zfBG$_O$ with "exit" sequences for O-D1 and O-D2 in green and lavender, respectively. Positionally conserved disulfide in the O-D1 and O-D2 subdomains, C31-C225 and C55-C201, are labeled SS1 and SS2, respectively. Single free cysteines in O-D1 and O-D2, C277 and C150, respectively, are also shown. Residue numbering can be deduced by reference to the secondary structure/residue numbering shown for zfBG$_O$ in Figure S3.

(B) Overlay of zfBG$_O$ O-D1 and O-D2 with the β strands of O-D1 depicted in orange, the β strands of O-D2 depicted in tan, the α helices of O-D1 and O-D2 in blue, and the exit sequences of O-D1 and O-D2 in green and lavender, respectively.

(C) Schematic showing the overall architecture of zfBG$_O$.

(D and E) Similar orientations of the zfBG$_O$ O-D1 (D) and O-D2 (E) subdomains, illustrating the conservation of their folds and secondary structure.

See also Figures S1 and S4–S7, and Table S3.

structure onto the hENG$_O$ structure at the hENG$_O$:BMP-9 interface, zfBG$_O$ O- D1 β8 is shown to sterically clash with BMP-9 finger 4 β7 (Figure 4E). The region corresponding to β6-β7-α1-β8 in zfBG O-D1 is consistently determined by the three zfBG$_O$ structures (Figure 4F) and is well-defined by the electron density in zfBG$_O$ (Figure 4G); it is, therefore, unlikely that β8 would be displaced by GF binding. Thus, zfBG$_O$ is unlikely to use β6 to bind its cognate GF, TGF-β2, in an hENG$_O$-like manner.

Binding of zfBG$_O$ to the TGF-β Mini Monomer

Using previous functional and structural studies, mmTGF-β2-7M, an engineered form of TGF-β that includes the finger region and cystine knot, but not the heel helix, was shown to maintain the same high affinity for TβRII as TGF-β1 and TGF-β3, and to have a structure, both alone and as bound to TβRII, essentially indistinguishable from that of TGF-β1 and TGF-β3 (Figure S9A) (Kim et al., 2017). The intact finger region in mmTGF-β2-7M can therefore be used to determine

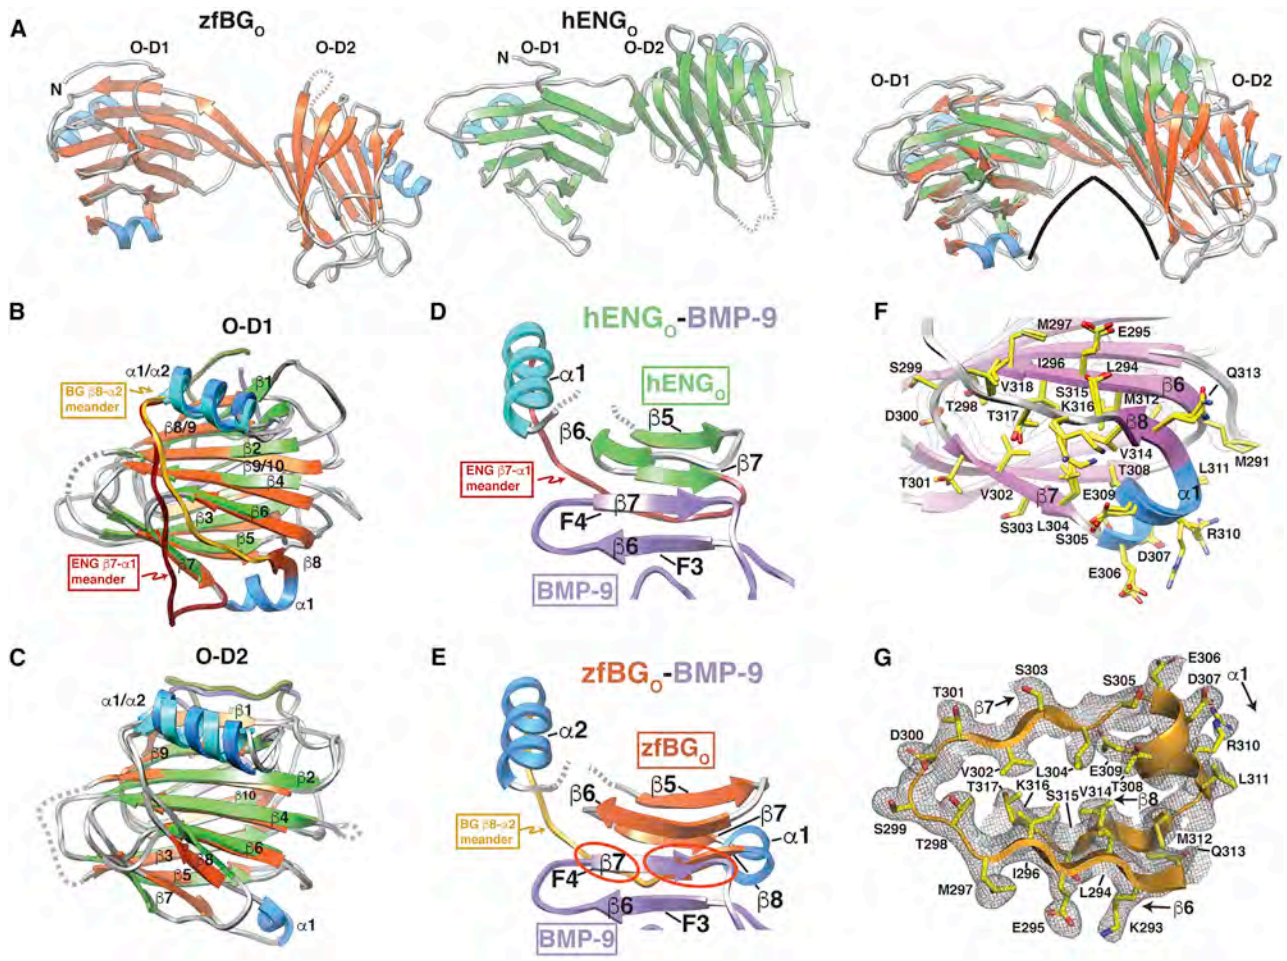

Figure 4. Structural Comparison of zfBG$_O$ and hENG$_O$

(A) Comparison of the overall structures of zfBG$_O$ and hENG$_O$, whose strands and helices are shaded orange and blue and green and blue, respectively. Changes in the relative domain orientation of zfBG$_O$ and human ENG$_O$ (green, β strands; cyan, helices) is shown in the right-most subpanel in which only the backbone atoms of O-D1 have been superposed.

(B and C) Superposition of zfBG$_O$ and hENG$_O$ O-D1 (B) or O-D2 (C). Distinct orientation of the O-D1 "meander" loop connecting β8-α2 in zfBG$_O$ and β7-α1 in hEng$_O$ is highlighted. Structures are shaded as in (A), with additional shading of the β8-α2 meander in zfBG$_{O\text{-}D1}$ and β7-α1 meander in hENG$_{O\text{-}D1}$ in gold and dark red, respectively.

(D) Region of super β sheet formation in the hENG$_O$:BMP-9 complex, but only with the β strands corresponding to fingers 3 and 4 (F3 and F4) of BMP-9 shown, and the segment of hENG$_O$ extending from β5 to α1 shown.

(E) The same as that shown in (D), but with zfBG$_O$ in place of hENG$_O$; the structure shown was generated by superimposing zfBG$_O$ onto hENG$_O$ in the structure of the hENG$_O$:BMP-9 complex and then by undisplaying hENG$_O$. The superposition highlights clashes (red ovals) between zfBG$_O$ β8 and finger 4 of BMP-9 for this mode of binding.

(F) Overlay of the two $P2_12_12_1$ zfBG$_O$ models and one $P4_1$ zfBG$_O$ model in the region including an additional α helix (α1) and β strand (β8) compared with hENG$_O$.

(G) $2mF_o - DF_c$ electron density for $P2_12_12_1$ zfBG$_O$ (chain A) extending from β6 to α2; the map shown was calculated with phenix.maps with a bulk solvent correction and anisotropic scaling and was contoured at 1σ.

See also Figures S1, S3, and S8.

if zfBG$_O$ recognizes and binds the finger region of TGF-β2, similar to hENG$_O$, or whether it recognizes and binds features beyond those in mmTGF-β2-7M. To test this, zfBG$_O$ was combined with equimolar amounts of the mmTGF-β2-7M:TβRII binary complex and analyzed by SEC. The mmTGF-β2-7M:TβRII binary complex was used for these experiments, rather than mmTGF-β2-7M alone, because it has improved solubility compared with mmTGF-β2-7M alone and because models showed that TβRII should not interfere with binding of zfBG$_O$ to mmTGF-β2-7M (Figure S9B). The SEC chromatogram of the ternary mixture corresponded to that of zfBG$_O$ alone, and the mmTGF-β2-7M:TβRII binary complex alone (Figure 5A), which indicated that zfBG$_O$ binds mmTGF-β2-7M:TβRII weakly. To further assess binding, the SPR response was measured as increasing concentrations of zfBG$_O$ were injected over immobilized mmTGF-β2-7M (Figure 5B). This led to a barely detectable response, consistent with the weak binding detected by SEC. There were, however, robust responses in control experiments in which TβRII was injected over mmTGF-β2-7M (Figure 5E) or zfBG$_O$ was injected over

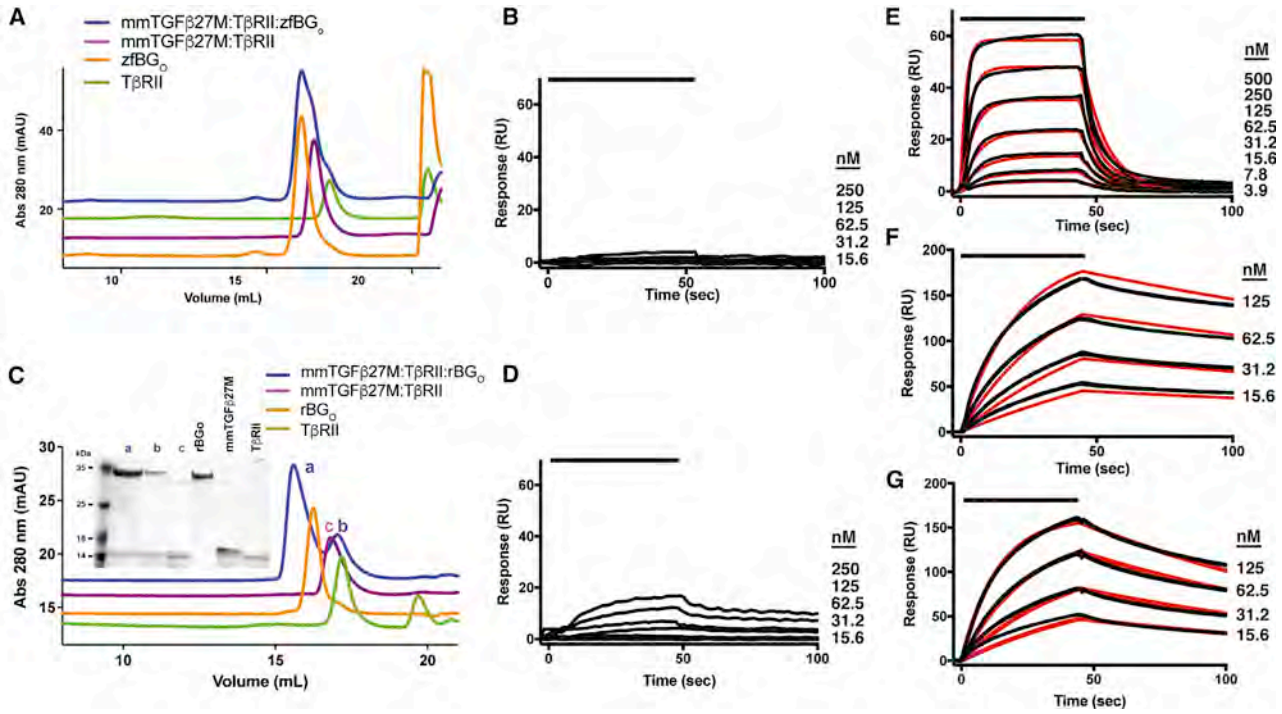

Figure 5. Binding of Monomeric TGF-β by BG$_O$

(A and C) SEC chromatograms to assess binding of zfBG$_O$ (A) or rBG$_O$ (C) to the mmTGF-β2-7M:TβRII binary complex. Chromatograms of the mmTGF-β2-7M:TβRII:BG$_O$ ternary complex, the mmTGF-β2-7M:TβRII binary complex, TβRII, and BG$_O$ are shown in blue, magenta, green, and orange, respectively. Shown in the inset in (C) is a non-reducing SDS-PAGE gel of the major peaks that eluted.

(B and D) SPR sensorgrams for binding of zfBG$_O$ (B) or rBG$_O$ (D) to immobilized mmTGF-β2-7M.

(E) SPR sensorgrams for binding of TβRII to mmTGF-β2-7M. Kinetic fit is shown in red over the experimental data shown in black.

(F and G) SPR sensorgrams for binding of zfBG$_O$ (F) or rBG$_O$ (G) to immobilized TGF-β2. Kinetic fit is shown in red over the experimental data shown in black. SPR experiments shown in (B, D, and E) were performed using the same neutravidin-coupled CM5 sensor chip with captured biotinylated avi-mmTGF-β2-7M.

See also Figure S9.

immobilized TGF-β2 (Figure 5F). The fitted disassociation constants for TβRII:mmTGF-β2-7M and zfBG$_O$:TGF-β2 interactions were 63 and 15 nM, respectively (Table 3), comparable with the previously reported values (Table 1) (Kim et al., 2017). These results show that zfBG$_O$ binds mmTGF-β2-7M weakly and must therefore attain its high affinity for TGF-β2 by recognizing more than just finger 4 of the GF.

To determine if this property was also shared with rBG$_O$, the same experiments were performed, but using rBG$_O$ rather than zfBG$_O$. The SEC experiments showed that, unlike zfBG$_O$, rBG$_O$ was able to form a detectable ternary complex with mmTGF-β2-7M and TβRII because these three proteins were each present in a peak (labeled a) that eluted before either rBG$_O$ or the mmTGFβ2-7M:TβRII binary complex alone (Figure 5C). The formation of this complex is, however, evidently a result of weak binding, because SPR experiments showed that, when rBG$_O$ was injected over immobilized mmTGFβ2-7M, only a very weak response was obtained relative to that of TβRII, which itself is only one-third of the mass of rBG$_O$ (Figures 5D and 5E). The weak response when rBG$_O$ was injected over immobilized mmTGFβ2-7M, which could not be fitted to derive a reliable binding constant, stood in contrast the robust response when rBG$_O$ was injected over TGF-β2 (Figure 5G), which could be readily fitted to derive a binding constant (Table 3). The fact that rBG$_O$ did form a detectable complex with mmTGF-β2-7M and TβRII by SEC, while zfBG$_O$ did not, may be because of the higher overall affinity of rBG$_O$ for TGF-β2 relative to zfBG$_O$ (Figures 2 and S2; Table 1).

Binding of zfBG$_{O\text{-}D1}$ and zfBG$_{O\text{-}D2}$ to TGF-β2

The structural differences relative to hENG$_O$ revealed by the zfBG$_O$ crystal structure, together with impaired binding of zfBG$_O$ to the TGF-β mini monomer, suggest that zfBG$_O$ binds TGF-β2 in a manner different to that by which hENG$_O$ binds BMP-9. To determine whether zfBG$_O$ uses both of its subdomains to contact TGF-β2, SEC and SPR binding experiments were performed using the zfBG$_{O\text{-}D1}$ and zfBG$_{O\text{-}D2}$ subdomains. zfBG$_{O\text{-}D2}$ was made as a secreted protein in HEK-293 cells, similar to the full-length zfBG$_O$, by expressing a construct that began a few residues before it entered O-D2 and ended a few residues after it exited (Table S2). zfBG$_{O\text{-}D1}$ was made similarly by expressing a construct that included most of the N-terminal exit sequence, an artificial two-residue Thr-Asp dipeptide, the C-terminal part of the O-D2 exit sequence, and the O-D1 β sandwich fused C-terminally to human serum albumin and an engineered thrombin cleavage site (Table S2). Before the final purification step for zfBG$_{O\text{-}D1}$, the fusion protein

was treated with thrombin, which enabled separation of $zfBG_{O\text{-}D1}$ from albumin.

To assess binding, TGF-β2DM:TβRII binary complex was combined with $zfBG_O$, $zfBG_{O\text{-}D1}$, or $zfBG_{O\text{-}D2}$ and analyzed by SEC. The results showed that, in contrast to full-length $zfBG_O$, $zfBG_{O\text{-}D1}$ and $zfBG_{O\text{-}D2}$ both failed to form a peak that eluted earlier than the TGF-β2DM:TβRII binary complex or $zfBG_{O\text{-}D1}$/$zfBG_{O\text{-}D2}$ alone (Figures 6A and 6B). To further investigate, SPR experiments were performed in which $zfBG_{O\text{-}D1}$ and $zfBG_{O\text{-}D2}$ were injected over the same immobilized TGF-β2 used for the experiments shown in Figures 2 and S2. Although the concentrations of $zfBG_{O\text{-}D1}$ and $zfBG_{O\text{-}D2}$ injected were the same as those used for $zfBG_O$, the maximal responses obtained were nonetheless only 10%–20% of that compared with $zfBG_O$ (Figures 6C, 6D, and 2B). Using kinetic analysis, the data for O-D1 could be fitted to a 1:1 model, with a K_D of 12 μM, while the data for O-D2 could only be fit to a heterogeneous ligand 1:1 model, with K_D values of 0.008 and 1.2 μM (Figures 6C and 6D; Table 3). The K_D of 0.008 μM for $zfBG_{O\text{-}D2}$ is not likely meaningful, as the response attained upon injection of $zfBG_{O\text{-}D2}$ over TGF-β2 (Figure 6D) was significantly lower compared with that of $zfBG_O$ when injected at the same concentrations over the same TGF-β2 surface (Figure 2B). Thus, both $zfBG_O$ subdomains bind TGF-β2 weakly, suggesting that both simultaneously engage TGF-β2 to enable high-affinity binding (K_D = 27 nM) of TGF-β2 by full-length $zfBG_O$ (Figure 2B; Table 1). To rule out the possibility that the weak binding of TGF-β2 by $zfBG_{O\text{-}D1}$ or $zfBG_{O\text{-}D2}$ was due to misfolding of the domains, NMR natural abundance ^1H-^{13}C shift correlation spectra of the methyl resonances were recorded. These spectra both revealed a well-dispersed pattern of peaks, with several resonances upfield of 0.0 ppm ^1H (Figures 6E and 6F), indicating that both were natively folded.

Structural Modeling of the Complex of BG_O with TGF-β2 and TβRII

The finding that BG_O bound TGF-β dimers with 1:1 stoichiometry, together with the results above that BG_O binds more than just the finger region and does so by contacting the GF with both O-D1 and O-D2, suggests an entirely different manner of GF binding compared with ENG_O. To determine, at low resolution, how BG_O might bind TGF-β, 1:2:1 TGF-β2TM:TβRII:BG_O complexes formed with both $zfBG_O$ and rBG_O were isolated by SEC and analyzed by SAXS over a range of concentrations (1, 2, and 4 mg mL^{-1} and 2 and 4 mg mL^{-1}, respectively) (Figures 7A and 7B). The overall shape of the scattering curves of the two complexes were similar, consistent with the SEC and SEC-MALS results (Figures 2D–2G and S2D–S2G), which showed that $zfBG_O$ and rBG_O form similar complexes in solution. There was, however, a concentration-dependent increase in scattering in the low-q region for the zebrafish complex, which indicates aggregation (Figure 7A). Thus, all subsequent modeling was performed with the scattering data for the rat protein, which was almost perfectly behaved (Figure 7B).

To determine whether an alternative manner of binding was required, a model was constructed with rBG_O placed onto the 1:2 TGF-β3:TβRII complex (Hart et al., 2002) in the same 2:1 manner that $hENG_O$ binds BMP-9 (the structure of rBG_O was obtained by building a $zfBG_O$-based homology model) (Figure 7D).

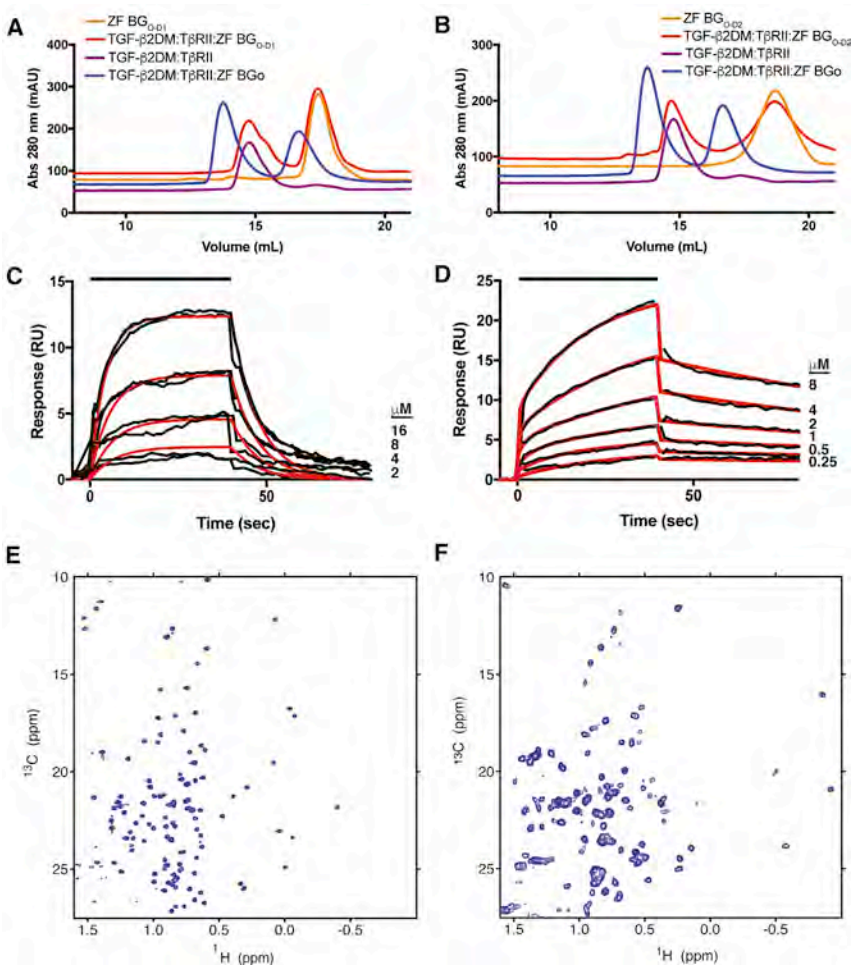

Figure 6. Binding of zfBG$_{O-D1}$ and zfBG$_{O-D2}$ to TGF-β2

(A and B) SEC chromatograms of complexes between zfBG$_O$ and zfBG$_{O-D1}$ (A) and zfBG$_O$ and zfBG$_{O-D2}$ (B) with TGF-β2DM and TβRII are depicted in blue and red, respectively. Chromatograms of the TGF-β2DM:TβRII binary complex and zfBG$_{O-D1}$/zfBG$_{O-D2}$ alone are shown in purple and orange curves, respectively.

(C and D) SPR sensorgrams for binding of zfBG$_{O-D1}$ (C) and zfBG$_{O-D2}$ (D) to immobilized TGF-β2. Kinetic fit is shown in red over the experimental data shown in black. The SPR sensor chip with immobilized TGF-β2 is the same as that used for the experiments shown in Figures 2 and S2.

(E and F) Methyl region of natural abundance ^{1}H-^{13}C HSQC spectra of BG$_{O-D1}$ (E) and BG$_{O-D2}$ (F).

The scattering curve was then calculated from this model and compared with the experimentally measured scattering curve for the rat complex. This revealed large systematic deviations over the entire scattering curve and a very high χ^2 value (65.2) (Figure 7C), indicating that this model poorly describes the structure of the TGF-β:TβRII:rBG$_O$ ternary complex in solution. This model was also poorly described by the electron density calculated from the experimental scattering data, with a significant portion of both molecules of rBG$_O$ protruding from the density (Figure 7E).

To determine whether models with an altered stoichiometry (1:1 BG$_O$:TGF-β) and manner of binding (direct binding by O-D1 and O-D2 at sites beyond the fingertip region) might be more consistent with the experimental data, the program pyDockSAXS (Jimenez-Garcia et al., 2015) was used to construct 1:2:1 TGF-β2:TβRII:rBG$_O$ models that optimized favorable van der Waals, H-bonding, and electrostatic contacts at the interface, and consistency with the experimental SAXS data. The complex that best met these criteria, shown in Figures 7G and 7H, had the orphan domain straddling the TGF-β dimer, with O-D1 and O-D2 in contact with residues protruding from the C-terminal end of the TGF-β N-terminal helix, α1, and the heel helix, α3, within each monomer. This manner of binding, which had the pseudosymmetry axis of rBG$_O$ near, but not coincident with the symmetry axis of TGF-β2, agreed well with the experimental scattering data (χ^2 = 1.38) and resulted in no significant protrusions of the structure from the calculated electron density (Figures 7F and 7I). The manner of binding described above was well-represented within the ensemble of the ten best scoring structures, with the first six best scoring structures having an overall RMSD within 1.0 Å of that shown in Figures 7G and 7H. The next two best scoring structures had a similar staggered positioning of the orphan domain, but were rotated by approximately 100° around an axis connecting the centroid of O-D1 and O-D2. The next two structures within the ensemble were bound closer to the fingertips in a manner that would enable two molecules of the orphan domain to bind, which based on the SEC-MALS data shown in Figures 2F and S2F, is not feasible. The experimental SAXS data are therefore sufficient to rule out a 2:1 ENG$_O$-like manner of binding, and while it suggests and is consistent with a pseudo-symmetric 1:1 manner of binding, it is not sufficient to unambiguously determine the structure of such a complex.

DISCUSSION

The TGF-β pathway has expanded and diversified as organisms have diversified, with 3 family members in nematodes, 7 in flies, and more than 30 in vertebrates (Hinck, 2012). Although the type I and type II receptors have also similarly expanded, there are consistently fewer signaling receptors than GFs—flies, for example, have three type I and two type II receptors for 7 family GFs (Upadhyay et al., 2017), while humans have seven type I and five type II receptors for 33 family GFs (Hinck, 2012). The type I receptors of the family also couple to and activate just two classes of R-Smads: the GFs of the TGF-β/activin branch of the pathway bind type I receptors that activate R-Smads 2 and 3, while those of the BMP/GDF branch bind type I receptors that activate R-Smads 1, 5, and 8 (Chen et al., 1998; Hinck, 2012). The functional diversity that can be attained through intrinsic

Calculated electron density map for the 1:2:1 TGF-β3:TβRII:rBG_O complex contoured at 1.5 σ with the hENG_O-like 1:2:2 TGF-β3:TβRII:rBG_O model fitted into the density.

(F–I) Comparison of the experimental SAXS data for the 1:2:1 TGF-β3:TβRII:rBG_O complex (red) with the calculated scattering curve (blue) (F) from the best scoring 1:2:1 TGF-β3:TβRII:rBG_O model derived from positioning rBG_O onto the 1:2 TGF-β3:TβRII binary complex using pyDockSAXS (G and H). Calculated electron density map for the 1:2:1 TGF-β3:TβRII:rBG_O complex contoured at 1.5 σ with the pyDockSAXS 1:2:1 TGF-β3:TβRII:rBG_O model fitted into the density (I). Estimated resolution of the electron density map shown in (E and I) from Fourier shell correlation analysis is 30.9 Å.

See also Figure S10.

differences in signaling is therefore limited and cannot account for the functional diversity of the 33 TGF-β family GFs in humans.

The membrane-anchored co-receptors of the TGF-β family, BG and ENG, have essential roles potentiating the signaling activity of TGF-β2 and inhA and BMP-9 and BMP-10, respectively (Lewis et al., 2000; Lopez-Casillas et al., 1993; Nickel et al., 2018; Scharpfenecker et al., 2007). The selectivity with which BG and ENG recognize these GFs (Castonguay et al., 2011; Henen et al., 2019), together with the restricted pattern of their expression, is vital in enabling unique temporal-spatial patterns of signaling that underlie the unique functions of these GFs *in vivo*—for TGF-β2, morphogenetic transformation of endothelial progenitors in the developing heart and liver (Brown et al., 1999; Stenvers et al., 2003), for inhA antagonism of activin A and B in the anterior pituitary (Bernard et al., 2002; Lewis et al., 2000), and for endoglin activation of BMP-9 and BMP-10 signaling on endothelial cells required for normal development and maintenance of the vasculature (Roman and Hinck, 2017).

The previous studies aimed at uncovering how BG and ENG recognize their cognate GFs, and potentiate assembly of their signaling complexes showed that they differ in terms of the overall manner with which they engage their respective GFs: ENG exists as a covalent dimer and uses only its orphan domain to engage the GF dimer with 2:1 stoichiometry (Alt et al., 2012; Castonguay et al., 2011), while BG, which exists as a monomer, uses both its orphan and ZP-C domains to engage the GF dimer with 1:1 stoichiometry (Esparza-Lopez et al., 2001; Mendoza et al., 2009; Villarreal et al., 2016). The two co-receptors also have different effects on the binding of the signaling receptors, with ENG_O competing against type II receptors that BMP-9 and BMP-10 bind, such as ActRII and ActRIIB, but not the type I receptor Alk1 (Alt et al., 2012; Castonguay et al., 2011), while BG_O

potentiates the binding of the TGF-β type II receptor, TβRII, but competes against the TGF-β type I receptor, TβRI (Villarreal et al., 2016).

The recent structural studies of the human ENG ZP domain alone, and human ENG_O, both alone and bound to its cognate GF BMP-9, showed that ENG binds the GF dimer with 2:1 stoichiometry in an antibody-like manner, with the covalently dimerized ZP domain homologous to the F_c region, and the orphan domain, bound to the GF by formation of a super β sheet with the extended finger region, homologous to the F_{ab} region (Figures 1C and 4D) (Saito et al., 2017). If BG_O were to bind TGF-β2 in the same manner as the ENG_O, it would on the one hand be consistent with the observed effects of ENG and BG on type II receptor binding, because structural studies show that ActRII/ActRIIB and TβRII bind their cognate GFs differently: ActRII/ActRIIB bind the knuckle in a way that would directly overlap with the co-receptor (Greenwald et al., 2003; Thompson et al., 2003; Townson et al., 2012), while TβRII binds the fingertips in a way that would not directly overlap with the co-receptor (Figure S9B) (Groppe et al., 2008; Hart et al., 2002; Radaev et al., 2010). On the other hand, this manner of binding, in addition to being inconsistent with the observed 1:1 binding of BG_O to TGF-β dimers (Villarreal et al., 2016), would also be inconsistent with effects on type I receptor binding, because previous structural studies showed that Alk1 and TβRI both bind in a similar, although not identical, manner, on the underside of the fingers of one monomer and the heel helix of the other monomer in a way that would not directly overlap with that of the co-receptor (Groppe et al., 2008; Radaev et al., 2010; Townson et al., 2012).

The structure of $zfBG_O$ shows that, while it shares the same tandem β sandwich architecture as $hENG_O$, it nonetheless differs in that there is an additional helix (α1) and β strand (β8) following β7 within subdomain 1 (O-D1). The additional β strand, β8, is shown to pair with β6. This would block BG O-D1 from pairing and forming a super β sheet with finger 4 of TGF-β, as does β6 of ENG O-D1. Three observations consistent with the α1-β8 insertion fulfilling this "blocking" role are as follows: (1) the electron density for BG_O α1 and β8, as well as most of the meandering loop that follows, is well-defined (Figure 4G). (2) The backbone conformation, and even the conformation of many of the side chains in the region spanning from β6 to α2, are consistently determined in the orthorhombic and tetragonal $zfBG_O$ structures, indicating that this region is relatively rigid and would not likely be displaced by binding of the GF (Figure 4F). (3) Residues involved in the formation of the additional α helix (α1) and β strand (β8) in BG O-D1 are either conserved or invariant in species ranging from fish to mammals (Figure S3B), consistent with these fulfilling the same role in blocking β6 as they do in $zfBG_O$.

The structural modification above, together with the absence of any additional edge β strands that could possibly form a super β sheet with the GF, suggest that BG_O engages TGF-β2 in an entirely different manner than ENG_O engages BMP-9. To test this, binding studies were performed with full-length $zfBG_O$ and rBG_O and an engineered TGF-β monomer that had the finger region and base of the fingers with the cystine knot intact, but lacked the heel helix as well as all of the second monomer. To further test this, binding studies were also performed with $zfBG_O$ constructs that included only subdomain 1, O-D1, or subdomain 2 O-D2, and intact TGF-β2 dimers. The results demonstrated weak binding, both for intact $zfBG_O$ and rBG_O to the engineered TGF-β monomer, and both of the orphan subdomains to intact TGF-β2. This suggested that the orphan domain recognizes and binds to features beyond those present in the engineered monomer and that the BG orphan domain gains its high affinity by utilizing both of its subdomains to contact TGF-β2 dimers. This sets BG_O apart from ENG_O as the latter recognizes only the finger region of the GF and does so by utilizing only subdomain 1, O-D1. The alternative explanation, that weak binding is a consequence of an altered conformation or misfolding of the domain-deleted constructs, is unlikely because the engineered monomer was shown to bind TβRII through the fingertips with the same affinities as native TGF-β dimers, and NMR spectra clearly showed that both zfBG O-D1 and O-D2 were natively folded. Thus, binding studies with domain-deleted constructs are consistent with the structure-based hypothesis that BG_O will be unable to bind to TGF-β by formation of a super β sheet as does ENG_O, and, as a consequence, must bind in an alternative manner.

The observations above, together with the previous observations that the orphan domain binds TGF-β dimers with 1:1 stoichiometry and in a manner that partially blocks binding of TβRI, but not TβRII, suggested that the orphan domain binds across the TGF-β dimer interface with at least one of its subdomains protruding into the TβRI site, but neither subdomain protruding into the TβRII site. This is supported by the SAXS data for the 1:2:1 TGF-β2DM:TβRII:rBG_O complex, which was most consistent with models of the complex in which the orphan domain straddled the dimer interface and subdomains 1 and 2 both contacted the N-terminal and heel helices (α1 and α3, respectively). This manner of binding, in addition to accounting for the lack of competition against TβRII binding and competition against TβRI binding, had the pseudosymmetry axis of the orphan domain near the symmetry axis of TGF-β, but not exactly coincident. This accounts for the 1:1 stoichiometry with which BG_O binds TGF-β dimers, because positioning of a second symmetry-related molecule is impossible due to steric overlap. There were notably alternative models that were nearly as consistent with the SAXS data, but were rotated around an axis passing through the centroid of orphan subdomains 1 and 2. To determine if the predicted modes of binding might involve regions of BG_O with a high density of conserved surface-exposed residues, the product of an amino acid conservation index and the solvent accessible surface (SAS) area was calculated and smoothed over a 10-residue window (Figure S10). This highlighted three regions with a high conservation/SAS index, residues 199–211, 249–255, and 308–322, the first and second of which had close contact with TGF-β in the first and second class of models. This provides further, albeit indirect, support for the SAX-derived models; however, even with this additional information, there is insufficient information to uniquely determine the positioning of the orphan domain on TGF-β2. There is, however, ample evidence to rule out 2:1 models with an ENG_O-like manner of binding, because these are inconsistent with the SEC and SEC-MALS data, the analysis of the domain-deleted forms of TGF-β and BG_O, and the experimental SAXS data. Thus, it is concluded that BG_O binds its cognate GF, TGF-β2, in a

completely different manner compared with ENG_O, and that the general features of the complex are likely similar to those shown in Figures 7G and 7H. However, because the docking algorithm used does not allow for flexibility of the backbone and because no effort was made to validate the interfaces, the actual structure, which must await the direct determination of the TGF-β:BG_O complex using crystallography, could certainly differ from that presented in Figures 7G and 7H.

The alternative manner by which evolutionary latecomers to the family, such as the TGF-β family, bind their type II receptor, TβRII, compared with other more ancestral GFs of the family, such as BMPs, GDFs, and activins (Allendorph et al., 2006; Greenwald et al., 2003; Groppe et al., 2008; Hart et al., 2002; Hinck, 2012; Kirsch et al., 2000; Radaev et al., 2010; Weber et al., 2007), has already shown how structurally homologous proteins of the TGF-β family can diverge from one another in terms of the interfaces they use to assemble into functional complexes. The alternative interfaces expand the range of receptor binding specificity and provide an effective means of segregating the binding, and thus function, of different subclasses of TGF-β family GFs from one another. The different modes of GF binding for BG and ENG are therefore not unprecedented. The different modes likely engender BG and ENG with the ability to selectively bind their cognate GFs, imparting them with the ability to selectively target the heart, liver, and anterior pituitary and vasculature, respectively, without interfering with one another or TGF-β family GFs.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCES TABLE
- LEAD CONTACT AND MATERIALS AVAILABILITY
- EXPERIMENTAL MODEL AND SUBJECT DETAILS
- METHOD DETAILS
  - Protein Preparation
  - SPR Measurements
  - SEC and SEC-MALS
  - Crystallization, Structure Determination, and Refinement
  - NMR Spectroscopy
  - Small Angle X-Ray Scattering
- QUANTIFICATION AND STATISTICAL ANALYSIS
- DATA AND CODE AVAILABILITY

SUPPLEMENTAL INFORMATION

LEAD CONTACT AND MATERIALS AVAILABILITY

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Andrew P. Hinck (ahinck@pitt.edu).

EXPERIMENTAL MODEL AND SUBJECT DETAILS

The BL21(DE3) strain of *E. coli* was purchased from EMD-Millipore (Cat# 69450-3) and plasmids of interest used for protein expression that encode β-lactamase for antibiotic resistance were directly transformed into the competent cells provided and plated onto LB plates with 50 μg/mL carbenicillin. The resistant cells were cultured at 37°C, both before and after the induction of protein expression, on liquid medium containing 50 μg/mL carbenicillin with shaking at 250 rpm in baffled 2.8 L Fernbach flasks.

The expi293 strain of HEK-293F (female) cells (Cat# A14527) and the corresponding expi293 growth medium (Cat# A14351-01) were purchased from Invitrogen. Cells were grown in baffled flasks with shaking (125 rpm) at 37°C with 8% CO_2. Cells are passaged every 3-4 days when the cells reach 5 x 10^6 cells/mL by diluting the cells in fresh media to 5 x 10^5 cells mL^{-1}. Low passage stocks of 1 x 10^7 cells mL^{-1} were frozen back with 10% DMSO. For protein expression, the day before transfection cells were diluted to 2.5 x 10^6 cells mL^{-1} and allowed to continue growing for 20 – 24 h. The transfection solution was prepared in 1/10th the volume of the total desired expression growth. For the transfection solution, CsCl purified DNA (1.5 μg per mL total culture volume) was diluted with media to 1/20th the culture volume. Linear polyethylenimine MW 2500 (Polysciences Cat# 23966-1) (4.5 ug per mL total volume) was diluted with media to 1/20th the culture volume. These two components were then combined and gently agitated. The transfection solution was allowed to incubate at room temperature for 30 min before being added to enough of the overnight cell culture to make 2.5 x 10^6 cells mL^{-1} of the desired volume. Medium was then added to adjust the volume to the desired amount. Cells were grown in the presence of the transfection solution for 14-16 hrs before protein production was stimulated by the addition of 2.2 mM valproic acid (Alfa Aesar Cat# A12962-18). Cells were allowed to continue to grow for 4 days and the conditioned media containing the desired protein was harvested.

METHOD DETAILS

Protein Preparation

Recombinant human TβRII extracellular domain and TGF-βs, including TGF-β2, TGF-β2DM, TGF-β2TM, mmTGF-β2-7M, avi-mmTGF-β2-7M, and TGF-β3, were expressed in *E. coli* at 37°C in the form of insoluble inclusion bodies, refolded, and purified as described (Hinck et al., 2000; Huang and Hinck, 2016; Kim et al., 2017). Zebrafish and rat betaglycan constructs were expressed in transiently transfected suspension cultured human embryonic kidney (HEK) 293 expi cells (Invitrogen, Carlsbad, CA) and purified

by metal affinity chromatography (NiNTA) and size exclusion chromatography (SEC) as described (Qin et al., 2016). Iodoacetamide treated $zfBG_O$ for crystallization was prepared by dialyzing NiNTA-purified protein into 25 mM sodium carbonate, 50 mM NaCl, pH 8.0, followed by the addition of freshly prepared iodoacetamide to a concentration of 20 mM. Following a 1 hr incubation at 25°C, the reaction was quenched with ethanolamine and the protein was purified by SEC. Sequences, along with database references and short descriptions, are provided in Supplemental Information (Tables S1 and S2).

SPR Measurements

Minimally biotinylated TGF-β2 for SPR was prepared by reaction of 5 nmol TGF-β2 in 40% DMSO with 60 nmol ethyl-3-[3- dimethylaminopropyl]carbodiimide hydrochloride (EDC, Pierce, Rockford, IL), 120 nmol sulfo-N-hydroxysulfosuccinimide (Sulfo-NHS, Pierce, Rockford, IL), and 480 nmol (+)- biotinyl-3,6,9,- trioxaundecanediamine (EZ-Link Amine-PEG3-Biotin, Pierce, Rockford, IL) for 1 h at 25°C at pH 6.0. Electrospray ionization time of flight mass spectrometry showed that roughly 10% of the growth factor was singly modified, while the remaining 90% was unmodified. Biotinylated avi-tagged mmTGF-β2-7m for SPR was prepared by enzymatic biotinylation with BirA biotin ligase as previously described (Kim et al., 2017).

SPR binding studies were performed with a BIAcore X100 instrument (GE Lifesciences, Piscataway, NJ) with biotinylated GFs captured onto neutravidin-coated CM-5 sensor chips (GE Lifesciences, Piscataway, NJ) at a density of 50 – 150 RU. Kinetic binding assays were performed by duplicate injections of the analytes in 20 mM HEPES, pH 7.0, 150 mM NaCl, 0.05% surfactant P20 (Pierce, Rockford, IL) at 100 uL min^{-1}. Regeneration of the surface was achieved by a 30 sec injection of 4 M guanidine hydrochloride. Baseline correction was performed by subtracting the response both from the reference surface with no immobilized ligand and 5 – 10 blank buffer injections. Kinetic analyses were performed by fitting the results to either a simple 1:1 model with a single set of kinetic constants (k_a, k_d) using the program Scrubber (BioLogic Software, Canberra, Australia) or a 1:1 model with high and low affinity classes of immobilized ligands and two sets of kinetic constants (k_{a1}, k_{d1} for binding to one class of immobilized ligand and k_{a2}, k_{d2} for binding to the other class of immobilized ligand) using the program BIAevaluation (GE Lifesciences, Piscataway, NJ). Importantly the latter model was used only if the data could not be satisfactorily fit to the simpler model and was needed only in three instances, binding of $zfBG_{ZP\text{-}C}$, $rBG_{ZP\text{-}C}$, or $zfBG_{O\text{-}D2}$ to TGF-β2.

SEC and SEC-MALS

Protein complexes were prepared by combining 1:2.5 TGF-β2DM:TβRII binary complex with a concentrated stock of full-length betaglycan or its component subdomain at the desired ratio. Samples for SEC and SEC-MALS were prepared in 25 mM HEPES, 150 mM arginine, pH 7.4, concentrated to 100 μL, and loaded onto a Superdex 200 Increase 10/300 GL column (GE Lifesciences, Piscataway, NJ) equilibrated in the same buffer. SEC measurements were made using an Akta FPLC (GE Lifesciences, Piscataway, NJ), while SEC-MALS measurements were made using a Waters high-performance liquid chromatography system (Waters, Milford, MA) and a Wyatt DAWN HELEOS-II multiangle light scattering detector and Optilab T-rEX refractive index detector (Wyatt, Santa Barbara, CA). SEC-MALS instrument control and data analyses were performed with the ASTRA software package (Wyatt, Santa Barbara, CA).

Crystallization, Structure Determination, and Refinement

Native orthorhombic crystals were grown using hanging-drop vapor diffusion at 25°C with drops consisting of 2.0 μL 9.2% v/v PEG 5K mono methyl ether, 4.6% w/v PEG 20K, 0.1M MES pH 6.2, 1.6 μL 20 mg mL^{-1} iodoacetamide-treated $zfBG_O$ in 10 mM MES pH 6.0, and 0.4 μL crushed $zfBG_O$ crystals (formed from non-iodoacetamide treated protein) as micro-seeds. For data collection, harvested crystals were mounted in nylon loops, cryo-protected in well solution containing 10% ethylene glycol, and flash-cooled in liquid nitrogen. Data were acquired at the Advanced Photon Source (APS) SER-CAT 22-ID and integrated and scaled using XDS (Kabsch, 2010). For phasing, platinum and iodide derivatized crystals were prepared by soaking the native crystals in crystallization well buffer with 5 mM K_2PtCl_4 or 4% saturated KI for 20 min and 20 s, respectively. For the platinum-derivatized crystals, data were collected at the APS SER-CAT 22-ID with the X-ray wavelength optimized for platinum anomalous scattering. Iodide-derivatized crystal data were collected at the Cu K-α wavelength with a Rigaku FR-E generator and RAXIS HTC image plate detector at the University of Pittsburgh Department of Structural Biology X-ray facility. Data reduction and processing of the derivative data sets were performed using iMOSFLM (Battye et al., 2011) and Pointless, Aimless, and Ctruncate (Collaborative Computational Project; Number 4, 1994; Winn et al., 2011). MIRAS phasing to 2.80 Å in autoSHARP (Bricogne et al., 2003) yielded an overall figure of merit of 0.52 for acentric reflections and 0.49 for centric reflections. Solvent flattening yielded interpretable electron density, which after autobuilding with phenix.autobuild (Adams et al., 2010) and manual adjustment with COOT (Emsley et al., 2010), could be traced to build nearly the complete model for Chain A except for four loop regions with weak density (Table S3). Chain B had weaker density and additional breaks, especially in domain 2 (Table S3).

Native tetragonal crystals were grown using hanging-drop vapor diffusion at 25°C with drops consisting of 2 μL 8% v/v PEG 5K mono methyl ether, 4% w/v PEG 20K, 0.1M MES pH 6.5, 1.6 μL 20 mg mL^{-1} non-iodoacetamide treated protein, and 0.4 μL micro-seeds (formed from non-iodoacetamide treated protein). For data collection, harvested crystals were mounted in nylon loops, cryo-protected in well solution containing 10% ethylene glycol, and flash-cooled in liquid nitrogen. Data were acquired at the Advanced Photon Source (APS) SER-CAT 22-ID and integrated and scaled using XDS (Kabsch, 2010). For phasing, structure model A from the asymmetric unit of the orthorhombic crystal form was used as a search model for molecular replacement in Molrep (Vagin and Teplyakov, 2010).

Coordinates were refined using Buster (Bricogne G. and Roversi P, 2018) with TLS (Schomaker and Trueblood, 1968), alternated with manual rebuilding in COOT (Emsley et al., 2010). TLS groups were identified with the TLSMD server (Painter and Merritt, 2006) and corresponded to most of domain 1 (residues 233-360), all of domain 2 (residues 58-215), and the extended segments that exit (residues 29-48) and re-enter domain 1 (residues 216-232) from domain 2. The refinement procedure was supported/accompanied by analysis of composite omit maps (Terwilliger et al., 2008). X-ray sources, data collection and refinement statistics are provided in Table 2. Figures were prepared using UCSF Chimera (Pettersen et al., 2004), except for Figures 4G and S4 which was prepared using PyMOL (DeLano, 2019).

NMR Spectroscopy

Natural abundance ^{1}H-^{13}C HSQC spectra of the methyl bearing residues of $BG_{O\text{-}D1}$ and $BG_{O\text{-}D2}$ were collected by preparing samples at 3 - 4 mg mL^{-1} in 25 mM sodium phosphate, 50 mM NaCl, pH 7.0 and by recording spectra at 30°C using a Bruker AVI 700 or AV-II 900 MHz spectrometer equipped with a 5 mm $^{1}H\{^{13}C,^{15}N\}$ TCI cryogenically cooled probe (Bruker Biospin, Billerica, MA).

Small Angle X-Ray Scattering

Experimental SAXS data of $zfBG_O$ and rBG_O, both alone and as SEC-purified complexes with either TβRII:TGF-β2TM or TβRII:TGF-β3, were collected at APS beamline 12-ID-B. Samples were prepared at 1.0, 2.0, and 4.0 mg mL^{-1} in 20 mM CHES, 100 mM NaCl, pH 9.5. Scattering data was recorded with sample oscillation as 30 2 sec exposures with a 1 sec delay between exposures. Raw scattering data were radially averaged, and after removing outliers, the data were averaged and subtracted from a buffer alone reference using the program PRIMUS (Konarev et al., 2003). Data corresponding to different concentrations were scaled, and if shown to not exhibit any systematic deviation over the $0 < q < 0.5$ range, were merged using PRIMUS (Konarev et al., 2003). Solution scattering curves were calculated from PDB coordinate files and fit to the concentration merged curves using the program CRYSOL (Svergun et al., 1995). Electron density envelopes were calculated from the merged scattering curves using the program DENSS (Grant, 2018). Models of $ratBG_O$ bound to the 1:2 TGF-β3:TβRII complex were generated using the program pyDockSAXS (Jimenez-Garcia et al., 2015), with the merged scattering curve for the 1:2:1 TGF-β3:TβRII:rBG_O complex, the structure of the 1:2 TGF-β3:TβRII complex (extracted from the structure of the TGF-β3:TβRII:TβRI complex, PDB 2PJY (Groppe et al., 2008)), and a homology model of rBG_O (built based on the $zfBG_O$ structure) as input.

QUANTIFICATION AND STATISTICAL ANALYSIS

The statistics of the X-ray crystallographic data processing, phasing, refinement, and structure validation are summarized in Table 2. The quality of the fit of the experimental SAXS data to that calculated from the corresponding structures was determined using the program CRYSOL, and the molecular weights and corresponding errors estimated from the SEC-MALS measurements were determined using the ASTRA software package (Wyatt, Santa Barbara, CA). The quality of the fit of the experimental SPR data to the kinetic constants and R_{max} was determined using either Scrubber (for data fit to a 1:1 binding model) or Biaeval (for data fit to a 1:1 heterogenous ligand model).

DATA AND CODE AVAILABILITY

The accession number for the structure factor and coordinate files of zfBGO reported in this paper are Protein Data Bank (PDB) 6MZP and 6MZN (orthorhombic and tetragonal forms, respectively).

Dopaminergic and serotonergic neurons modulate and control processes ranging from reward signaling to regulation of motor outputs. Further, dysfunction of these neurons is involved in both degenerative and psychiatric disorders. Elucidating the roles of these neurons has been greatly facilitated by bacterial artificial chromosome (BAC) transgenic mouse lines expressing channelrhodopsin to readily enable cell-type specific activation. However, corresponding lines to silence these monoaminergic neurons have been lacking. We have generated two BAC transgenic mouse lines expressing the outward proton pump, enhanced ArchT3.0 (eArchT3.0), and GFP under control of the regulatory elements of either the dopamine transporter (DAT; Jax# 031663) or the tryptophan hydroxylase 2 (TPH2; Jax# 031662) gene locus. We demonstrate highly faithful and specific expression of these lines in dopaminergic and serotonergic neurons respectively. Additionally we validate effective and sensitive eArchT3.0-mediated silencing of these neurons using slice electrophysiology as well as with a well-established behavioral assay. These new transgenic tools will help expedite the study of dopaminergic and serotonergic system function in normal behavior and disease.

INTRODUCTION

Neuroscience research has been revolutionized by cell-type specific access to neurons, by optical control of neuronal firing, and particularly by the intersection of the two. Since initial reports of optically gated ion channels and pumps, many new varieties and variants with increased sensitivity, kinetics, and various improved properties have been generated (Fenno et al., 2011; Mattis et al., 2011). Previously we generated a suite of cell type-specific bacterial artificial chromosome (BAC) transgenic lines to drive channelrhodopsin-2 (ChR2) expression in parvalbumin, serotonergic, cholinergic and GABAergic neurons (JAX# 012355, 014555, 014548, 014545, 014546; Zhao et al., 2011), which have been used widely in the field (Herde et al., 2013; Nelson et al., 2014; Van Dort et al., 2015; Li et al., 2016b; Latchoumane et al., 2017; Zhang et al., 2018).

However, a complementary suite of silencing lines has been lacking. Here, we present two mouse lines expressing enhanced ArchT3.0 (eArchT3.0) that allow efficient optogenetic silencing of dopaminergic and serotonergic cells. By brightly co-expressing GFP, these lines are also useful for visualization of these neurons. ArchT is an outward proton pump from *Halorubrum sodomense* strain TP009 (Han et al., 2011). In eArchT3.0, the addition of endoplasmic reticulum export and neurite trafficking sequences produces enhanced membrane localization with correspondingly reduced intracellular accumulation, leading to subsequently much larger photocurrents. eArchT3.0 has a two-fold increase in photocurrent compared to unoptimized ArchT or Arch, measured *in vitro*, and double the current of the enhanced halorhodopsin chloride pump (eNpH3.0; Mattis et al., 2011).

Dopaminergic and serotonergic neurons control many diverse processes in the brain. Classically the main dopaminergic centers in the midbrain, the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), are mostly associated with reward processing in varied contexts (Wise, 2004). In particular, these neurons fire for reward prediction error (Schultz et al., 1997; Bayer and Glimcher, 2005; Cohen et al., 2015). In the clinic, dysregulation of dopamine leads to both motivational changes, for instance with drug abuse (Everitt and Robbins, 2005), and to movement disorders, such as difficulties initiating movement seen in Parkinson's disease due to dopaminergic neuron degeneration in the sNC (Redgrave et al., 2010). The serotonergic system, in particular the raphe nuclei in the brainstem, the largest of which is the dorsal raphe nucleus (DRN), has also been associated with reward learning (Liu et al., 2014; Cohen et al., 2015). In the clinic, serotonin misregulation has been particularly implicated in depression, impulsivity, and anxiety in psychiatric disorders (Ansorge et al., 2004; Michelsen et al., 2007). Indeed, both dopaminergic and serotonergic signaling are key targets of some of the most widely used antipsychotic and antidepressant drugs (Li et al., 2016a; Yohn et al., 2017). However, our understanding of the functional roles of these circuits remains far from complete and a much more detailed and nuanced understanding is required to design better medications. The complexity and wide-ranging roles of these systems is beginning to be revealed using tools such as optogenetics which allow cell-type specific manipulations and fine temporal control. For example, the use of optogenetics has identified causal roles of VTA dopaminergic neurons in mediating depression symptoms from chronic stress (Tye et al., 2013), chronic defeat (Chaudhury et al., 2013), social interaction reward (Gunaydin et al., 2014) and dissected the dynamics of prediction error learning (Steinberg et al., 2013). For the serotonergic system, optogenetics has helped elaborate a complex role in reward-related behavior on multiple time scales (Liu et al., 2014; Miyazaki et al., 2014; Cohen et al., 2015) as well as diverse roles from signal processing in the olfactory system (Kapoor et al., 2016; Lottem et al., 2016) to regulating respiration and body temperature (Ray et al., 2011).

Here, we present two mouse lines with sensitive eArchT3.0-mediated silencing and high fidelity of expression in dopaminergic and serotonergic neurons. We characterize the specificity of the lines and their electrophysiology and validate the effectiveness of one of the lines in a well-established behavioral assay.

MATERIALS AND METHODS

Vector Construction

To construct the targeting vectors, a pBlueScript-derived vector iTV1-WPRE was used to generate BAC targeting vectors, as previously described (Ting and Feng, 2014). BAC specific homology arms [dopamine transporter (DAT) box A and B or tryptophan hydroxylase 2 (TPH2) box A and B] were PCR amplified from template BAC DNA and cloned into iTV1-WPRE. In a separate mammalian expression vector, eArchT3.0 [ArchT (Han et al., 2011) but with a trafficking sequence and ER export motif added to the C-terminus similar to Mattis et al. (2011)] and enhanced green fluorescent protein cDNAs were combined using the P2A linker. We selected P2A with a C-terminal GSG linker because this combination was shown to be the most efficiently processed of all viral 2A elements (Kim et al., 2011) and thus was the most likely to enable a complete physical uncoupling of the opsin and fluorophore with no significant unprocessed protein fraction. Verification of proper expression and functionality were performed by transient transfection of the eArchT3.0-P2A-EGFP plasmid DNA into HEK293 cells and primary rat hippocampal neurons, followed by epifluorescent imaging and patch clamp recording. The eArchT3.0-P2A-EGFP cassette was then sub-cloned into the multiple cloning site of iTV1-A/B-WPRE to complete the BAC targeting vectors. In this final cloning step great care was taken to ensure minimal disruptions to the junction between 5′ homology arm and the start of the eArchT3.0 sequence, except for addition of a Kozak consensus sequence. BAC recombineering steps, including trimming of the DAT BAC clone, have been described previously (Ting and Feng, 2014).

Animals

All experiments were done in accordance with NIH guidelines and approved by the MIT Institutional Animal Care and Use Committee. Mice were housed with a standard 12 h light/12 h-dark cycle (lights on at 07:00, lights off at 19:00) and given food and water *ad libitum*. eArchT3.0+ and eArchT3.0− mice of both genders from the same litters were used for experiments. Only heterozygous eArchT3.0+ mice were used for all experiments.

Surgery

Five- to six-month-old mice were anesthetized with isoflurane and placed in a small animal stereotax (David Kopf Instruments, St. Tujunga, CA, USA). They were implanted with a manually-constructed optic fiber [200 um core, NA = 0.22 (FG200UCC, Thorlabs, Newton, NJ, USA)] held in a ceramic ferrule (CF270-10, Thorlabs, Newton, NJ, USA). Measurements were made relative to Bregma, coordinates: −3.1, 0.35–0.37, −4.3. The fiber was held in place to the skull with adhesive cement (C&B Metabond; Parkell Inc., Brentwood, NY, USA). The incision was

closed with vetbond and mice were recovered on a heat pad in a clean cage. Mice were group housed pre and post surgery. Fiber placement was confirmed after behavior with serial coronal sections, anti-TH staining to identify the VTA and epifluorescent imaging (**Supplementary Figure S1**).

Conditioned and Real-Time Place Aversion

Behavioral testing was performed 3.5 weeks post-surgery, allowing time for recovery. Mice were tested between 7 am and 7 pm during their light cycle. Pre-testing, mice were habituated at least 1 h in the behavioral testing room. For testing, single mice were place in a clear plexiglass open top chamber with equally sized left and right chambers (22 × 22 cm) and a smaller central chamber (9 × 22 cm) separated by dividers leaving a gap (9 cm) between the center chamber and the side chambers. Each trial began with placement of the mouse in a corner of the central chamber. Between each trial, the chamber was cleaned with 70% ethanol. On the 1st day mice were allowed to freely explore the chamber for 15 min with the light turned off. On the 2nd and 3rd days mice were allowed to freely move between the compartments for 30 min. Entry into one of the side chambers was paired with photostimulation (532 nm light, GL532T3-100 mW Shanghai Laser and Optics Century Co.). Laser power was approximately 5 mW at tip of fiber, but substantial ramping up of the laser seen upon turn on could have led to approximately ±1 mW during stimulation. To avoid overheating, optical stimulation was paused for 30 s if the mouse stayed in the stimulated zone over 30 s. The stimulated side was counterbalanced between animals and genotypes but kept constant for each individual animal between days. On the 4th day mice were allowed, as on the 1st day, to explore freely for 15 min with the laser turned off. Mouse movement was tracked and paired with photostimulation control using a video camera and EthoVision software (EthoVision XT, Noldus, Wageningen, Netherlands) through a Master-9 Pulse Stimulator (A.M.P.I, Jerusalem, Israel). For analysis, tracks were edited for the correct start and end times blind to condition. Dwell time in each predefined area was calculated automatically using EthoVision software.

Immunohistochemistry and Image Quantification

Mice were deeply anesthetized with isoflurane, transcardially perfused with ice-cold PBS solution followed by fresh ice-cold 4% paraformaldehyde (PFA) in PBS. Brains were dissected out and postfixed overnight with 4% PFA at 4°C, and stored in PBS at 4°C. Sixty to hundred microgram sections were cut on a vibratome (Leica VT100S). Floating brain slices were permeabilized with 1.2% Triton X-100 in PBS for 15 min, washed 3 × 5 min in PBS and blocked 1 h in 5% normal goat serum, 2% BSA, 0.2% Triton X-100 in PBS (blocking buffer) for 1 h at room temperature. Sections were incubated with primary antibodies in blocking solution 1–3 overnights at 4°C. Slices were then washed three times with PBS for 20 min, incubated with secondary antibodies for 1–2 h at room temperature, washed 1× with DAPI (1:10,000) in PBS for 20 min then 2× with PBS for 20 min. Slice were mounted with 50% glycerol in Tris Buffer. Primary antibodies used were ms anti-TPH2 (1:500, Sigma, St. Louis, MO, USA to678), ms IgG1 anti-TH (1:1,000, immunostar 22941), rb anti p2A (1:1,000 Millipore, Burlington, MA, USA ABS31), and rat anti-DAT (1:1,000 Millipore, Burlington, MA, USA MAB369). Widefield epifluorescent images were capture using a 4× lens on a Olympus BX61 microscope with a PRIOR ProScan III motorized stage (Prior Scientific Instruments, UK) and CellSens Dimension 1.11 stitching software (Olympus). To quantify overlap, images were captured using Olympus Fluoview FV1000 confocal microscope, 20× lens. Three mice were imaged per condition, three sections per mouse. DAT sections, since they were coronal, were imaged bilaterally. Cells were counted manually using the ImageJ Cell Counter plugin (Schindelin et al., 2012). To quantify cell number and TPH2 and DAT expression levels in old animals over 1 year old, serial 60 um sagittal sections were collected from TPH2 and DAT-eArchT3.0 BAC transgenic animals and immunostained with TPH2, DAT or TH. Every third section from three animals was confocal imaged as described above; sections were matched referenced to the midline. Cells were counted automatically with CellProfiler (Lamprecht et al., 2007) using primary object detection and the Otsu global thresholding method. For the DAT-eArchT3.0 transgenic line, DAT immunostaining did not clearly distinguish individual dopaminergic cell bodies, so TH staining was used. To quantify DAT expression levels, DAT staining in the striatum was used to take advantage of relatively uniform coverage by dopaminergic terminals. To correct for absence of terminals around nuclei and fibers of passage, a mask was used to remove those areas from quantification. For the TPH2 transgenic line, TPH2 immunostaining was used both to quantify cell number and to assess expression levels. To correct for variable cell number between sections and animals, intensity levels were only measured from detected cells and normalized to total cell area per image.

Slice Preparation for Electrophysiological Recordings

Sagittal or coronal slices (250 μm) were obtained from DAT-eArchT3.0 or TPH2- eArchT3.0 expressing mice at 30–40 p.n. days. Mice were anesthetized *via* isoflurane inhalation and perfused transcardially using cold saline containing (in mM): 194 sucrose, 30 NaCl, 4.5 KCl, 1.2 NaH_2PO_4, 0.2 $CaCl_2$, 2 $MgCl_2$, 26 $NaHCO_3$, and 10 D-(+)-glucose saturated with 95% O_2 and 5% CO_2, pH = 7.4, 320–340 mOsm/L. Slices were cut using a slicer (VT1200 S, Leica Microsystems In., Grove, IL, USA) and then incubated for 10–15 min in a holding chamber (BSK4, Scientific System Design Inc., Little Ferry, NJ, USA) at 32°C with regular artificial cerebral spinal fluid containing the following in mM: 136 NaCl, 3.5 KCl, 1 $MgCl_2$, 2.5 $CaCl_2$, 26 $NaHCO_3$ and 11 glucose saturated with 95% O_2 and 5% CO_2, followed by at least 1 h recovery at room temperature (21–25°C) before recording.

Electrophysiological Recordings

We performed whole cell patch-clamp recordings with borosilicate glass pipettes (KG33, King Precision Glass) heat polished to obtain direct current resistances of ∼4–6 MΩ.

Pipettes were filled with an internal solution containing in mM: 120 K-Gluconate, 2 $MgCl_2$, 10 HEPES, 0.5 EGTA, 0.2 Na_2ATP, and 0.2 Na_3GTP. The recordings were made with a microelectrode amplifier with bridge and voltage clamp modes of operation (Multiclamp 700B, Molecular Devices, San Jose, CA, USA). Cell membrane potential was held at −60 mV, unless specified otherwise. Signals were low-pass filtered at 2 kHz and sampled at 10–20 kHz with a Digidata 1440A (Molecular Devices, San Jose, CA, USA), and data were stored on a computer for subsequent off-line analysis. Cells in which the series resistance (Rs, typically 8–12 MΩ) changed by >20% were excluded for data analysis. In addition, cells with Rs more than 20 MΩ at any time during the recordings were discarded. In some cases conventional characterization of neurons was made in voltage and current clamp configurations.

DAT+ or TPH+ neurons were identified for recordings on the basis of GFP expression visualized with a microscope equipped with a GFP filter (BX-51WI, Olympus). We also targeted GFP negative (−) neurons to confirm the specificity of eArchT3.0 effects in neurons. Photo stimulation parameters were 532 nm and 1–4 mW per mm^2 (GL532T3-100 mW Shanghai Laser and Optics Century Co.). Neurons were held at −70 mV during photocurrent measurements. To confirm the ability of photo stimulation to inhibit action potential firing, action potentials were induced by continuous positive current injection until tonic firing was reached.

Statistics

All data were transferred to GraphPad Prism for analysis and graphing. Electrophysiological data are presented as mean ± SEM, and with the values given for each experiment referring to the number of cells analyzed unless noted otherwise. All error bars indicate SEM. The significance level for all tests was $p < 0.05$. Group results were compared by using an unpaired Student's *t*-test. Quantification of cell immunohistochemistry results are presented as mean ± SD. Cell number quantification in old animals is presented as a scatter plot showing the number of cells across three sections per animal with mean ± SD overlaid. For immunofluorescent intensity the median intensity of each section from three animals is shown and for TPH2 staining the intensity is normalized to the cell area coverage in each section. Immunohistochemistry results were compared using an unpaired Student's *t*-test; the significance level for all tests was $p < 0.05$. Behavioral testing data is presented as a scatter plot with individual animal's performance with mean and SEM error bars overlaid. Results were compared using one-way analyses of variance (ANOVA) and adjusted *P* values were calculated using Sidak's multiple comparison.

RESULTS

Generation of eArchT3.0 BAC Transgenic Lines

Two eArchT3.0 lines were generated, the first to silence dopaminergic neurons and the second to silence serotonergic neurons using an optimized archeorhodopsin, eArchT3.0 (Han et al., 2011; Mattis et al., 2011). Both lines were generated using an improved BAC-transgenic approach that avoids overexpression of endogenous genes (Ting and Feng, 2014). In both cases, the eArchT3.0 cDNA was inserted into the BAC clone followed by the self-cleaving peptide p2A and GFP. This allows both bright visualization of expressing neurons, including in fresh tissue, through cytoplasmic GFP expression as well as localization of the Arch protein by immunochemical detection of the P2A fragment remaining at the eArchT3.0 C-terminus. To improve RNA stability, and hence protein expression levels, a woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) and a bovine growth hormone polyadenylation signal (BGHpA) were added. For dopaminergic expression, this engineered cDNA was placed after the translation initiation codon, ATG, of the DAT gene in a BAC clone. DAT is present in dopaminergic neurons to reuptake dopamine from the synaptic cleft to be repackaged into synaptic vesicles and is selective for dopaminergic neurons (Augood et al., 1993; Lammel et al., 2015). For serotonergic expression, a TPH2 BAC clone was used. TPH2 is an enzyme that catalyzes the first and rate limiting step in serotonin production and is specific for serotonergic neurons (Walther et al., 2003).

eArchT3.0 Expression in Dopaminergic Neurons of DAT-eArchT3.0 BAC Transgenic Mice

Accurate expression of GFP and eArchT3.0 protein in dopaminergic neurons was found in neurons of the VTA and SNc with excellent overlap between tyrosine hydroxylase (TH) staining, the rate-limiting enzyme for dopamine synthesis, and GFP expression (**Figure 1**). Quantification shows very high overlap between GFP and TH with both high specificity of GFP expression, most GFP positive cells were also TH positive (**Figure 1C**; 96 ± 2%, VTA, **Figure 1D**; 96 ± 3%, SNc) and high coverage of GFP expression, most TH positive cells were also GFP positive (**Figure 1C**; 95 ± 3% VTA, **Figure 1D**; 98 ± 2% SNc). These neurons were also DAT positive (**Supplementary Figure S2**). Although TH is specific for dopaminergic neurons of the midbrain, because TH catalyzes the first step in catecholamine biosynthesis, TH is also expressed in some neurons that are not dopaminergic or DAT positive, such as the catecholamine neurons of the locus coeruleus (Augood et al., 1993; Lorang et al., 1994). Highlighting the specificity of this line, the locus coeruleus (**Figure 1A″**) though labeled by TH is not correspondingly labeled by GFP (**Figure 1A′**). GFP expression was also present in dopaminergic neurons of the olfactory bulbs (Pignatelli and Belluzzi, 2017; **Supplementary Figure S2**) as well as small TH-positive interneurons in the striatum (Ibáñez-Sandoval et al., 2010; Xenias et al., 2015; **Supplementary Figure S3F**). Notably, the GFP signal was bright enough to be seen and quantified without enhancement. This indicated a high level of eArchT3.0 expression since production of the two was stoichiometric at the mRNA level and likely protein level. Bright GFP expression also makes these mice a useful tool for targeting dopaminergic neurons in slice recordings. To determine possible effects of long-term eArchT3.0 expression

or the transgenic approach on dopaminergic neuronal number or DAT gene expression levels, cell number in the midbrain (**Supplementary Figures S4A,D**) and DAT intensity levels in the striatum (**Supplementary Figures S4B,E**) in old animals over 1 year old were quantified. There was no difference in cell number (689 ± 201, 793 ± 189, n.s. unpaired *t*-test, $n = 3$ animals, **Supplementary Figure S4D**) or protein levels (0.014 ± 0.006, 0.015 ± 0.004, n.s. unpaired *t*-test, $n = 12$ sections, **Supplementary Figure S4E**) between the controls and DAT-eArchT3.0 animals.

We observed some off-target expression of eArchT3.0-GFP in subplate neurons and subiculum (**Supplementary Figure S3F**). A low level of expression was also seen sparsely in cells of the cortex (**Supplementary Figure S3E**). However, these neurons are spatially distinct from the VTA and SNc. Thus, separable control of these two populations should be easily achieved with optic fiber placement.

eArchT3.0 Expression in Serotonergic Neurons of TPH2-ArchT3.0 BAC Transgenic Mice

Serotonergic neurons in both the DRN and the ventral brainstem, which contains multiple more sparsely distributed serotonergic nuclei, all faithfully expressed eArchT3.0-GFP (**Figure 2**). Expression of GFP was as bright as in the DAT-eArchT3.0 line as was the excellent fidelity of expression. Quantification confirmed high overlap between GFP expression and TPH2; assessing specificity of GFP expression determined most GFP positive cells were also TPH2 positive (**Figure 2C**, 96 ± 1% in DRN, **Figure 2D**, 86 ± 8%, ventral brainstem) and assessing coverage of GFP expression determined most TPH2 positive cells were GFP positive (88 ± 4% in DRN, **Figure 2D**, 89 ± 4% ventral brainstem). TPH2 immunostaining was sometimes faint so overlap may be underestimated. Altogether this indicates faithful and robust expression of eArchT3.0 in serotonergic neurons in the brain. As for the DAT line, we determined possible long-term effects of the transgene in old animals over 1 year old by quantifying serotonergic neuronal number and TPH2 intensity levels in the DRN (**Supplementary Figures S4C,F,G**). There was no difference in cell number (1,032 ± 159, 728 ± 224, n.s. unpaired *t*-test, $n = 3$ animals, **Supplementary Figure S4F**) or protein levels (0.006 ± 0.005, 0.004 ± 0.004, n.s. unpaired *t*-test, $n = 9$ sections, **Supplementary Figure S4G**) between the controls and TPH2-eArchT3.0 animals.

Off-target expression of eArchT3.0-GFP at a lower level of expression was present in granule cells of the cerebellum (**Supplementary Figures S5A′,B′**), as well as sparse scattered cells in the cortex (**Supplementary Figures S5A‴,B‴**).

Electrophysiological Characterization of eArchT3.0-Expressing Dopaminergic Neurons

To analyze the ability of genetically encoded eArchT3.0 to enable reversible silencing of neuronal activity, we recorded from GFP-positive neurons in the VTA ($n = 10$, from five mice; **Figure 3A**). These neurons had characteristic properties of TH cells including: presence of a depolarized resting membrane potential (RMP; −52 ± 8 mV), wide action potentials (1.7 ± 0.16 ms half width) and Ih current (sag amplitude 34.9 ± 5.2 mV; **Figure 3B**; Chieng et al., 2011; Krashia et al., 2017). We demonstrated that GFP-positive neurons were sensitive to 532 nm light which led to eArchT3.0 mediated-hyperpolarization and evoked photocurrent with similar kinetics as reported previously (**Figures 3C–E**; Han et al., 2011; Mattis et al., 2011). A roughly linear relationship between photocurrent and light intensity was found as shown by the input-output curve (**Figure 3E**). At −45 ± 4.1 mV neurons had spontaneous tonic firing around 2.5 ± 0.9 Hz and application of 532 nm light (1–4 mW) for 10 s was highly effective at silencing firing precisely during light exposure (**Figure 3D**, paired *t*-test, $p = 0.01$). We repeated this manipulation 3–5 times on each neuron recorded and all cells showed inhibition. Lastly, to confirm the specificity of GFP-eArchT3.0 expression we also targeted GFP negative (−) cells in the VTA (**Supplementary Figures S6A–C**). We did not observe any evoked photocurrent in neurons recorded in VTA, or any significant changes in the RMP (light OFF −52.4 ± 2.2 mV and light ON −53.2 ± 2.1 mV, n.s. unpaired *t*-test, $n = 9$) or firing rate when there was spontaneous spiking (light OFF 5.9 ± 2 Hz and light ON 6.1 ± 2.2, n.s. unpaired *t*-test, $n = 5$; **Supplementary Figure S6C**). These results give us confidence that neurons that do not express GFP do not express eArchT3.0 and they are not affected by photo stimulation.

Electrophysiological Characterization of eArchT3.0-Expressing Serotonergic Neurons

The same characterization was carried out in DRN neurons. Recordings from GFP-positive cells ($n = 11$, from four mice) showed typical characteristics of serotonergic neurons (**Figure 4A**) with a RMP of −59 ± 2.5 mV and action potential threshold of −40.5 ± 0.9 mV (**Figure 4B**; Mlinar et al., 2016; Asaoka et al., 2017). As reported before for eArchT3.0 activation and found in the dopaminergic neurons, 532 nm light led to neuron hyperpolarization and sustained evoked photocurrent (**Figure 4C**; Han et al., 2011; Mattis et al., 2011). Similarly, a linear relationship between photocurrent and light intensity was found (**Figure 4E**). At −45 mV neurons had spontaneous tonic or irregular firing patterns at 0.96 ± 0.3 Hz and application of 532 nm light (1–4 mW) for 10 s was highly

effective at silencing neuronal activity (**Figure 4D**, paired *t*-test, $p = 0.014$). We repeated this manipulation 3–5 times on each neuron recorded and all cells showed inhibition. Again, to confirm the specificity of GFP-eArchT3.0 expression we also targeted GFP (−) cells in the DRN (**Supplementary Figures S6D–F**). We observed that GFP (−) neurons did not show any current when stimulated with light and only showed a slight change in the firing frequency (light OFF 0.85 ± 0.26 Hz and light ON 0.81 ± 0.35 Hz, n.s. unpaired *t*-test, $n = 8$) likely due to changes in the surrounding inhibited neurons (**Supplementary Figure S6F**). These results give us confidence that neurons that do not express GFP do not express eArchT3.0 and they are not affected by photo stimulation.

Optogenetic Activation of eArchT3.0 in VTA Is Sufficient to Drive Conditioned Place Aversion

Our slice experiments determined that eArchT3.0 expression was effective at silencing dopaminergic and serotonergic neurons. To determine whether eArchT3.0 was effective in a behavioral assay we used the dopaminergic eArchT3.0 line. Inhibition of dopaminergic neurons has been shown to be sufficient to mediate place aversion (Tan et al., 2012; Danjo et al., 2014). In place aversion, a location in an arena is paired with either an aversive condition, such as a foot shock, or a neuronal signal, such as inhibition of the VTA, over several conditioning days. In conditioned place aversion, aversive conditioning is delivered to an animal restrained to the location. In real-time place aversion, aversive conditioning is delivered to a freely exploring animal upon entry into the location. In both assays, animals avoid the aversive conditioned-location in a post-conditioning test day. In real-time place aversion, a decreased dwell time in the conditioned location can also be observed during conditioning days. Both conditioned place aversion and real-time place aversion have been reported previously upon inhibition of dopaminergic neurons *via* optogenetic activation of local inhibitory neurons in the VTA (Tan et al., 2012) or by direct optogenetic inactivation of the VTA with viral-driven expression of eNpH3.0 (Tan et al., 2012) or eArchT3.0 in a TH Cre mouse (Danjo et al., 2014).

To validate our DAT eArchT3.0 line in a similar assay, we used a three chamber arena with two equivalent larger chambers connected by a smaller third one (**Figure 5A"**), allowing mice to explore freely between the chambers, performing the assay over 4 days (**Figure 5A'**). On the first, pretest, day mice were allowed to explore with the laser turned off. On the next two, conditioning, days, the laser was triggered when mice entered the designated conditioning side, leading to unilateral eArchT3.0-mediated inhibition of the VTA. On the 4th day, mice were tested as on day one without light delivery. As expected, on the 1st day at pretest, mice showed no preference for one chamber vs. the other (**Figures 5B,D**). Following conditioning using eArchT3.0-mediated inhibition of DAT^{+} VTA neurons, aversion to the conditioned side was seen upon the fourth test day (**Figures 5B,D**). Mice spent significantly less time in the conditioned side (**Figure 5C**) both in the fraction of time spent (**Figure 5B**) and in net time (**Figure 5D**). Real-time place aversion during training was also observed with less time spent in the conditioned area each conditioning day (**Figure 5B**). These changes were not seen for the control, wildtype, littermate mice, which were implanted and stimulated the same way but did not express eArchT3.0. Overall this demonstrates that the DAT-eArchT3.0 line is a sensitive tool for effectively inducing inhibition of dopaminergic neurons *in vivo*.

DISCUSSION

We have generated and characterized two new lines of transgenic mice for optogenetically silencing dopaminergic or serotonergic neurons robustly and reproducibly. These two mouse lines will be shared with the community *via* Jackson Laboratory: DAT-eArchT3.0-GFP (Jax# 031663) and Tph2-eArchT3.0-GFP

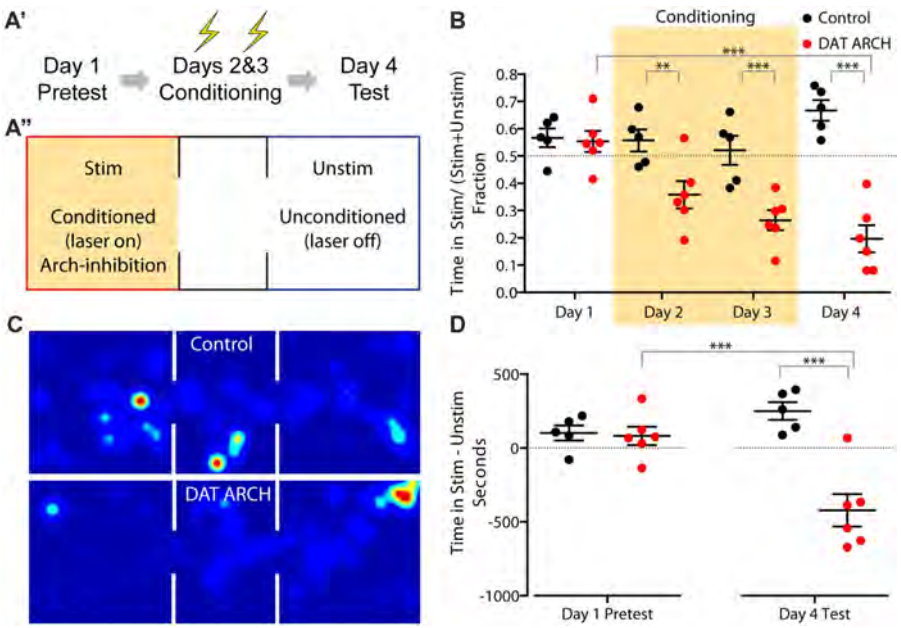

FIGURE 5 | Place aversion induced by DAT-eArchT3.0 mediated VTA inhibition. **(A)** Experimental timeline **(A')** and schematic of arena **(A")**. Mice were stimulated unilaterally when in the stimulated (stim) zone during conditioning days. **(B)** Fraction of time spent in the stimulated zone on each day. **(C)** Heatmap of time spent in each area (schematized above) on day 4 by example control or DAT-eArchT3.0 animal. **(D)** The difference in time spent in the stimulated zone vs. the unstimulated zone before and after conditioning. (Jax# 031662). Generating these lines using optimized trimmed BACs avoided unwanted overexpression of other genes in the BAC clones, a concern with previous lines such as Chat-ChR2 (Kolisnyk et al., 2013; Ting and Feng, 2014). Reassuringly quantification of cell number and DAT or TPH2 intensity levels in old animals showed little long-term effects in transgenic animals. Additionally, the characteristic electrophysiological properties of both dopaminergic and serotonergic neurons expressing eArchT3.0 were consistent with the published literature for non-eArchT3.0 expressing neurons. Both lines also showed good fidelity and coverage for dopaminergic and serotonergic neurons. The co-expressed GFP fluorescence is also clearly visible without immunostaining amplification and can be used both to target cells for *in vitro* recordings and for morphological studies, making these lines useful for a range of eArchT3.0-independent applications. Both lines show excellent and sensitive silencing *in vitro*, although it is worth noting that the same level of photostimulation may not completely bock firing *in vivo*, where neurons can display higher firing rates and have additional extrinsic drives. Nonetheless our robust behavioral results in the conditioned place aversion assay using the DAT line indicate a substantial reduction in neuronal activity.

Compared to the original ArchT pump (Han et al., 2011), eArchT3.0 has an added endoplasmic reticulum export sequence and neurite trafficking sequencing, enhancing localization of the pump at the membrane (Mattis et al., 2011). Further, in our lines, GFP is not fused to the pump and instead is produced ratiometrically through a P2A self-cleaving peptide. Compared to the other widely used pumps, eNpHR3.0 (Gradinaru et al., 2010), unmodified Arch (Chow et al., 2010) and unmodified ArchT (Han et al., 2011), eArchT3.0 has much greater photocurrent and this difference is greater with increased light power density (Mattis et al., 2011). Both enhanced Arch (eArch3.0) and enhanced ArchT (eArchT3.0) proteins pass significantly more current than the original variants and this difference increases as the light power density increases (Mattis et al., 2011). Of consideration for certain applications, the maximum wavelength sensitivity of eArchT3.0 is between 520–560 nm. This is green shifted compared to eNPHr3.0 which is 560–590 and Jaws, which is further red shifted, with more photocurrent at 632 nm compared to eNpHR3.0 (Gradinaru et al., 2010; Mattis et al., 2011; Chuong et al., 2014). With all of these pumps caution is warranted (Wiegert et al., 2017); all three for instance exhibit comparable post-illumination rebound spiking (Chuong et al., 2014; Mahn et al., 2016) which can be avoided using a gradual off-ramp of illumination (Chuong et al., 2014; Mahn et al., 2016). Additional challenges can arise from use of these inhibitors at axon terminals. In such small cellular compartments, ionic changes can be exacerbated. In particular, prolonged activation of terminals on the 2–5 minute timescale using eArchT3.0 can cause significant increase in spontaneous activity, due to alkalinization of the boutons and the subsequence pH-dependent increase in intracellular calcium (Mahn et al., 2016; Wiegert et al., 2017).

The use of transgenic lines for targeted opsin expression presents several advantages compared to expressing opsins virally in combination with a Cre-line. Unlike virally mediated opsin expression, these lines will have less variable levels of expression from mouse to mouse which can result from variable viral injection and neuronal uptake and will eliminate the need to wait for viral expression post surgery. The ability to drive earlier eArchT3.0 expression could also facilitate future studies of the developmental roles of serotonergic and dopaminergic signaling. Admittedly, the need to implant fibers to optically silence the neurons may still limit developmental questions to acute experiments, up to an age when mice are not rapidly growing and when they are not still dependent on maternal care. Additionally, by dissociating eArchT3.0 expression from Cre expression, crossed in Cre lines can be used to target additional tools or neuronal populations of interest, for instance either for gene knockout or other opsin expression. By expressing eArchT3.0 in one cell population and channelrhodopsin in another, either using Cre-mediated recombination or a different transgenic line, different populations of neurons could be stimulated and inhibited in the same animal. Such a combination of tools could prove particularly powerful when exploring the effects of neuromodulatory neurons on other circuits on both the short and long timescales at which they act. We hope that these two new DAT and TPH2-eArchT3.0 lines will help facilitate a refined understanding of the roles of dopaminergic and serotonergic systems.

AUTHOR CONTRIBUTIONS

AK, JT and GF conceived the study and oversaw the project. AK screened the founder mouse lines for successful transgenics, performed the staining, imaging and quantification to characterize transgene expression as well as surgeries and place aversion behavior. VL-H performed the electrophysiology and analysis. TC helped screen the founder lines, performed quantification and mapped fiber placement. KD provided the original eArchT3.0 construct. JT created and tested the BAC constructs and generated the mice. AK and GF wrote the manuscript with input from all authors.

FUNDING

Research related to this work in the laboratory of GF is supported by the Poitras Center for Affective Disorders Research at MIT, Stanley Center for Psychiatric Research at Broad Institute of MIT and Harvard, National Institute of Neurological Disorders and Stroke (R01NS098505, R21NS079992), Nancy Lurie Marks Family Foundation, Simons Foundation Autism Research Initiative (SFARI Grant No. 307913), and Simons Center for the Social Brain at MIT. AK is supported by a fellowship from the Simons Foundation to the Simons Center for the Social Brain at MIT. Recurrent moderate hypoglycemia exacerbates oxidative damage and neuronal death leading to cognitive dysfunction after the hypoglycemic coma

Gabriela Languren, Teresa Montiel, Leticia Ramírez-Lugo, Israela Balderas, Gustavo Sánchez-Chávez, Francisco Sotres-Bayón, Federico Bermúdez-Rattoni and Lourdes Massieu

Abstract

Moderate recurrent hypoglycemia (RH) is frequent in Type 1 diabetes mellitus (TIDM) patients who are under intensive insulin therapy increasing the risk for severe hypoglycemia (SH). The consequences of RH are not well understood and its repercussions on neuronal damage and cognitive function after a subsequent episode of SH have been poorly investigated. In the current study, we have addressed this question and observed that previous RH during seven consecutive days exacerbated oxidative damage and neuronal death induced by a subsequent episode of SH accompanied by a short period of coma, in the parietal cortex, the striatum and mainly in the hippocampus. These changes correlated with a severe decrease in reduced glutathione content (GSH), and a significant spatial and contextual memory deficit. Administration of the antioxidant, N-acetyl-L-cysteine, (NAC) reduced neuronal death and prevented cognitive impairment. These results demonstrate that previous RH enhances brain vulnerability to acute hypoglycemia and suggests that this effect is mediated by the decline in the antioxidant defense and oxidative damage. The present results highlight the importance of an adequate control of moderate hypoglycemic episodes in TIDM.

Keywords

Diabetes, antioxidants, cognitive impairment/decline, glucose, hippocampus, hypoglycemia, risk factors, selective neuronal death

Received 3 March 2017; Revised 17 August 2017; Accepted 1 September 2017

Introduction

Glucose is the major metabolic substrate in brain and its continuous supply from blood is mandatory for its correct functioning. Repeated episodes of moderate hypoglycemia are frequently observed in 70–80% of Type-1 (T1DM) and 40% of Type-2 (T2DM) diabetes mellitus patients due to insulin therapy.[1,2] Recurrent moderate hypoglycemia (RH; $<70->55$ mg/dl blood glucose) increases the risk for severe hypoglycemia (SH; <55 mg/dl), which has been reported in 36% and 7% of TIDM and T2DM patients, respectively, with an incidence of one episode per patient per year.[3–5] Hypoglycemia is alleviated by the hormonal autonomic counter-regulatory response, which stimulates glycogenolysis and glyconeogenesis.[6,7] This response is blunted in T1DM patients, who are unable to respond to the autonomic signs of hypoglycemia (hypoglycemia unawareness).[4,7,8] A single episode of hypoglycemia induces defective glucose counter-regulation, favoring recurrent hypoglycemia (RH) and increasing the patient's vulnerability to SH.[6,9] Conversely, patients

INFORME DE LABORES 2019

treated for SH are at risk for RH.[10] SH can progress to seizures and the hypoglycemic coma in approximately 25% of the episodes.[11] A prolonged period of hypoglycemic coma induces oxidative stress and neuronal death[12,13] and associates with cognitive dysfunction in rodents and humans.[10,14–16] However, the effect of previous episodes of RH on brain damage induced by SH, is poorly understood.

Moderate hypoglycemia is more common than SH in T1DM patients, particularly in children and adolescents. Although not an immediate threat, a repeated history of RH might cause cognitive dysfunction.[17,18] Studies show that RH in healthy animals induces synaptic alterations, oxidative stress and limited neuronal death in the cerebral cortex[13,19,20] and even improvement of spatial memory.[20–22] In diabetic animals, RH associates with increased cognitive deficit and oxidative damage, suggesting that diabetes exacerbates the damaging effects of hypoglycemia.[13,23–25] Conversely, diabetes is associated with oxidative stress[26,27] and cognitive decline, which might be enhanced by hypoglycemia.[28–31]

The repercussions of RH on brain function after a subsequent episode of SH are not well understood. In the present study, we have addressed this question in healthy animals, precluding the influence of diabetic pathology. Results indicate that animals exposed to RH do not show neuronal death, oxidative damage or cognitive decline despite a partial decrease in the content of reduced glutathione (GSH) and increased lipoperoxidation (LPO). However, RH notably augmented oxidative damage and the number of dead cells in the cortex, the striatum and mainly in the hippocampus of animals exposed to a subsequent short period of hypoglycemic coma. These animals showed a large decrease in GSH content and severe cognitive impairment. Treatment with the antioxidant, N-acetyl-L-cysteine (NAC), significantly reduced neuronal death and prevented cognitive decline. The present results demonstrate that in non-diabetic animals, previous RH can enhance brain vulnerability to SH and suggest that this effect is mediated by a decrease in the antioxidant defense and oxidative damage.

Material and methods

Three-month-old male Wistar rats (280–300 g) obtained from Instituto de Fisiología Celular (IFC), Universidad Nacional Autónoma de México were treated according to The National Institute of Health Guide for the care and use of laboratory animals (NIH publication No.80-23 revised 1996), and experimental protocols were approved by the Committee for the Care and Use of Laboratory Animals (CICUAL) of the IFC (LMT101-16). All efforts were made to minimize the number of animals used. Animals were housed in individual cages under standard dark/light cycle and temperature conditions with food and water at libitum. Experiments are reported in compliance with the ARRIVE guidelines (Animal Research: Reporting in Vivo Experiments). A sample size of six to seven animals per group was used to achieve reliable statistical power and minimize the number of animals used.

Induction of recurrent moderate hypoglycemia

RH was induced (in the home cage) in non-anesthetized non-fasted animals receiving a daily intraperitoneal (i.p.) injection of 6.5 insulin units (IU, Humulin 70/30, Eli Lilly, Indianapolis, USA) between 11 and 12:00 a.m. during seven consecutive days, while control animals were injected with vehicle solution (0.1% acetic acid) (Supplementary Figure 1(a)). Moderate hypoglycemia was defined as blood glucose between 40 and 55 mg/dl, without loss of consciousness or seizures. Blood glucose was measured from the tail vein using a One Touch Ultra meter, every 60 min after insulin injection, and was maintained at 2.2–3.0 mM (40–55 mg/dl) for 2.5–3 h (Supplementary Figure 1(a)). Rats spontaneously recovered euglycemia after food addition. Twenty-four hours after the last hypoglycemic episode, animals were euthanized under pentobarbital overdose anesthesia and brains were prepared for histology (see below). Independent groups were used for behavioral tests (see below).

Induction of hypoglycemic coma (SH)

One week before the induction of hypoglycemia, animals were implanted with epidural electrodes under 2.5–3.0% isofluorane anesthesia for two channel (right and left hemispheres) electroencephalographic recordings (EEG). Meloxicam (1 mg/kg i.p) was used as post-surgery anesthesia. Before SH induction, food was restricted to four pellets overnight. For EEG recording, animals were maintained in acrylic special cages. The experimental animals were randomly distributed among the different experimental groups as follows: (1) SH: animals received an i.p injection of 32 IU (Humulin 70/30, Eli Lilly, Indianapolis, USA) and after 2–3 h of SH (blood glucose levels <1.0 mM), they lost their righting reflex and hypoglycemia was left to progresses to EEG isoelectricity (coma) for 7–10 min. Animals were immediately rescued with an i.p. (300 µl) bolus of 25% glucose in Krebs-Henseleit Buffer followed by a continuous intravenous perfusion at a rate of 1.5 ml/h during 3 h through the tail vein using a perfusion pump (Harvard Apparatus 22, South Natik, MA, USA) (Supplementary Figure 1(b)). (2) RH/SH: animals were treated with moderate

INFORME DE LABORES 2019

RH during seven days and 24 h after the last episode SH was induced and left to progress to 7–10 min coma. Immediately afterwards, rats were rescued with glucose as described above (Supplementary Figure 1(c)). (3) NAC: animals were identically treated to those of the RH/SH group, except that they received one subcutaneous administrations of 100 mg/kg NAC in distilled water (Sigma–Aldrich St. Louis MO, USA) 1 h after glucose reperfusion and one daily injection during the following four days (five total administrations at 2:00 p.m.). Experimental protocols are described in Supplementary Figure 1. Twenty-four hours after all treatments, animals were anesthetized (pentobarbital overdose) and intracardially perfused with 0.9% saline solution followed by 4% paraformaldehyde in 0.1 mol/L phosphate buffer, pH 7.3; brains were extracted and fixed during 24 h in paraformaldehyde and transferred to a 20–30% sucrose gradient (24 and 72 h, respectively) and 25 µm coronal slides were obtained in a cryostat for histological analysis. Independent groups were treated and randomly distributed for behavioral tests; they were euthanized at the indicated times. Animals showing seizures (less than 10%) were discarded. One animal from the NAC group was discarded due to the lack of exploratory activity in the open field test.

Evaluation of neuronal death

Neuronal death ($n = 68$ total animals, distributed as follows: $n = 7$ per group evaluated at 24 h; $n = 6$ per group evaluated at 5 days and $n = 7$ per group evaluated at 16 days after the different treatments) was evaluated using Fluoro Jade B (FJB) for the identification of degenerating neurons, as described.[32] Sections were imaged under a fluorescence microscope (Leica DM1000) using a FITC filter (395–590 nm). The total number of FJB-positive cells in the parietal cortex and the striatum was quantified in 18 coronal sections of 25 µm (3.20 to −4.20 from bregma), while 4 sections were used for the hippocampus. In this case, cells were counted in an area of 200 μm^2 of the different hippocampal subregions (CA1, CA3, dentate gyrus (DG) and hilus) using the Image J program. Data are expressed as the total number of degenerating cells in these four sections. Cell damage was confirmed by Nissl staining at 24 h ($n = 7$ per group) and five days ($n = 4$ per group), and the number of condensed darkly stained cells or pyknotic nuclei were counted in consecutive brain sections to those labeled with FJB. In the case of the NAC experiment, FJB and Nissl-positive cells were counted in three areas of 200 μm^2 of the DG comprising the inferior and superior blades and the crest of the DG. To monitor DNA fragmentation, the TUNEL Roche In Situ Cell Death Detection Kit was used following the manufacturer instructions (Roche Applied Science, USA). Briefly, adjacent sections were blocked with 3% peroxide in methanol for 10 min at room temperature. Slides were incubated in a mixture containing sodium citrate 0.1%/triton 0.1% for 10 min followed by TUNEL reaction mixture (5 µl TdT enzyme, 5 µl Biotin-dUTP, 90 µl TdT buffer) for 90 min at 37°C. Slides were washed and counterstained with Hoechst (0.001% in PBS) for 10 min at room temperature to facilitate the identification of TUNEL-positive cells.

Immunohistochemistry

Twenty-four hours after the treatments ($n = 7$ per group), oxidative protein modification was detected using polyclonal anti-4-2-hydroxy-2-nonenal (4-HNE) (Alpha Diagnostic International, San Antonio, Texas, USA) and monoclonal anti-3-Nitrotyrosine (Cayman Company, Ann Arbor Michigan, USA) antibodies. Coronal 25 µm sections were incubated with anti-4-HNE or anti-3-NT antibodies (1:200 dilution) for 72 h at 4°C and anti-mouse DyLight 594 or anti-rabbit DyLight 488 (Jackson ImmunoResearch Lab. Inc. West Grove, Pennsylvania, USA, 1:250 dilution) secondary antibodies, for 2 h at room temperature. Three sections per animal were examined and representative images were obtained by confocal microscopy (Leica TCS SP5) using a scanning mode for lasser 488 and 546 nm. As a control for antibody specificity, brain sections were incubated with the secondary antibody in the absence of the primary antibody and immunoreactivity was observed.

LPO levels

Twenty-four hours after the treatments ($n = 7$ per experimental group and $n = 10$ control group), brain homogenates from parietal cortex, hippocampus and striatum were obtained to determine malondialdehyde (MDA) levels using the thiobarbituric acid-reactive substances (TBARS) method as described in Haces et al.[33] Briefly brain tissues were homogenized in 0.5 ml of 1.15% KCL/0.4 mM sodium azide and incubated at 37°C for 20 min. Suspensions were centrifuged at 14,000 rpm, mixed with thiobarbituric acid at 0.75% (Merck, Darmstadt Germany) and incubated at 50°C for 20 min. The protein concentration was determined by Bradford's method and data are expressed as nmol MDA/mg of protein.

Reduced GSH determination

Reduced GSH ($n = 3$–7) was determined using the fluorometric o-phthalaldehyde (OPA) method as

INFORME DE LABORES 2019

described by Senft et al.[34] 12 and 24 h after the treatments. Briefly, parietal cortex, hippocampus and striatum were dissected, weighed and homogenized in detection buffer containing 20 mM HCl, 5 mM DTPA and 10 mM ascorbic acid; samples were rapidly centrifuged at 20,000 rpm for 20 min. For GSH determination, 5% trichloroacetic acid, 7.5 mM N-ethylmaleimide (Sigma-Aldrich, Steinheim, Germany) and 100 µl o-phthaldialdehyde (Sigma-Aldrich, Steinheim, Germany) (used as derivatizing agent to react with GSH) were added to 5 µl supernatant. After mixing, samples were incubated at room temperature for 30 min. Fluorescence was read at 365 nm excitation and 430 nm emission. GSH concentrations were calculated and expressed as nmol/mg tissue based on standard curve.

Behavioral tests

Water maze

Forty-eight hours after the treatments, animals were habituated in an isolated testing room for 30 min. Rats ($n = 7$ per group, 28 total animals) were trained (9:00 a.m.) during five days (five trials per day) in a circular pool divided in four quadrants where a platform was hidden 1 cm under the water at constant temperature (21°C) as described in Delint-Ramírez et al.[35] Twenty-four hours after the last day of training (7 days and 15 days after the SH), the memory test was performed. The platform was removed and animals were allowed to swim during 60 s. The latency and number of crossings through the quadrant where the platform was initially placed were recorded with the Ethovision video tracking.

Contextual fear conditioning

At 48 h after the treatments, different series of animals (treated and non-treated with NAC, $n = 6$–9 per group, 33 total animals) were trained for contextual fear conditioning (9:00 a.m.) and they were tested 24 h later. This was carried out in standard operant chambers (Coulbourn Instruments) located inside sound-attenuating boxes (Med Associates) in an isolated testing room. The floor of the chambers consisted of stainless steel bars that delivered scrambled electric footshock. Between experiments, shock grids and floor trays were cleaned with soap and water, and the walls with wet paper towels as described in Sotres-Bayon et al.[36] On day 1, rats habituated during 5 min to the chamber were immediately followed by fear conditioning to the context consisting of five 2 s, 0.8 mA foot shocks. The interval between successive foot shocks was variable with an average of 2 min. The next day (day 2), rats were tested for contextual fear conditioning memory during 10 min. Behavior was recorded with digital video cameras. Freezing was used as a measure of conditioned fear. Freezing was defined as the absence of all movement except for those related to breathing. The amount of time spent freezing to the context was expressed as a percentage of the total time in the chamber.

Open field

Twenty-four hours after contextual fear conditioning memory test (10:00 a.m.), rats were placed at the center of a wooden open arena (90 cm length × 90 cm width × 60 cm height) with a textured floor illuminated by 22 lux of intensity. Grid lines drawn on the floor of the arena (30 × 30 cm) divided it into a peripheral region (within 60 cm of the walls) and a central region (30 × 30 cm) of approximately equal area. Behavior was recorded for 10 min with a digital video camera and analyzed with commercially available video tracking software (ANY-maze, Stoelting). The total distance traveled (cm) was taken as an index of the locomotor activity and the number of entries to the center of open field as an anxiety index.

Statistical analysis

Data are expressed as mean ± SEM (Standard Error of the mean) and analyzed by one-way ANOVA followed by a Fisher's least multiple comparison test, except for neuronal damage comparisons between NAC-treated and non-treated groups, which were compared by Student's t test. Behavioral tests were analyzed by the Kruskal–Wallis non-parametric test for Water Maze and Tukey for fear conditioning.

Results

Changes in blood glucose and EEG recordings

No significant differences were found in mean basal blood glucose concentration (99.66 ± 1.20 mg/dl) among the different animal groups. In animals exposed to RH blood, glucose declined to 40 mg/dl 30 min after insulin administration and remained between 40 and 45 mg/dl during the following 3 h. Glucose was recovered after food addition (Supplementary Figure 2(a)). The daily mean blood glucose concentration reached during the 3-h period of moderate hypoglycemia was 40 mg/dl (Supplementary Figure 2(b)). In animals exposed to SH alone and to RH/SH, glucose concentration rapidly declined after 30 min insulin administration and remained ≤ 20 mg/dl during the next 2.5–3.0 h up to isoelectricity. It partially recovered 1 h after glucose reperfusion and at 24 h it reached control values in

INFORME DE LABORES 2019

all animals groups (Supplementary Figure 2(a)). Basal cerebral activity was recorded for 30 min before insulin administration and no differences were observed between the groups. After 2–3 h, the EEG characteristic changes of hypoglycemia reported in previous studies were observed.[33] When glucose was close to 20 mg/dl, electrical brain activity slowed and was completely absent during the coma period. Normal brain activity was recovered 1 h after glucose reperfusion (Supplementary Figure 2(c)).

Neuronal death induced by the hypoglycemic coma is exacerbated by previous RH

Figures 1 to 2 show the number of degenerating cells at 24 h and 16 days after the induction of coma. No degenerating cells were observed in animals from the control and RH groups in any of the regions studied (Figures 1(a) and (c) and 2(a)). Twenty-four hours after the animals were exposed to the hypoglycemic coma (9.5 ± 0.54 min) alone (SH), degenerating cells were observed in the parietal cortex and the dorsolateral striatum (Figure 1), while in the hippocampus, degenerating cells were observed only in the crest of DG in 50% of these animals (Figure 2(a), (b) and (d)). Animals examined 16 days after the coma (8.0 ± 0.36 min), showed a lower number of FJB-positive cells in the parietal cortex and the striatum (Figure 1(b) and (d)), while in the crest of the DG, FJB-positive cells were no longer visible (Figure 2(c)).

Animals exposed to coma (9.5 ± 0.20 min) and previously treated with RH (RH/SH), exhibited a significant increase in the number of degenerating cells in the parietal cortex and the striatum as compared to those treated with SH alone at 24 h. This increase was also observed when animals were examined 16 days after RH/SH (7.28 ± 0.42 min of coma) (Figure 1(b) and (d)). Representative micrographs showing FJB-positive

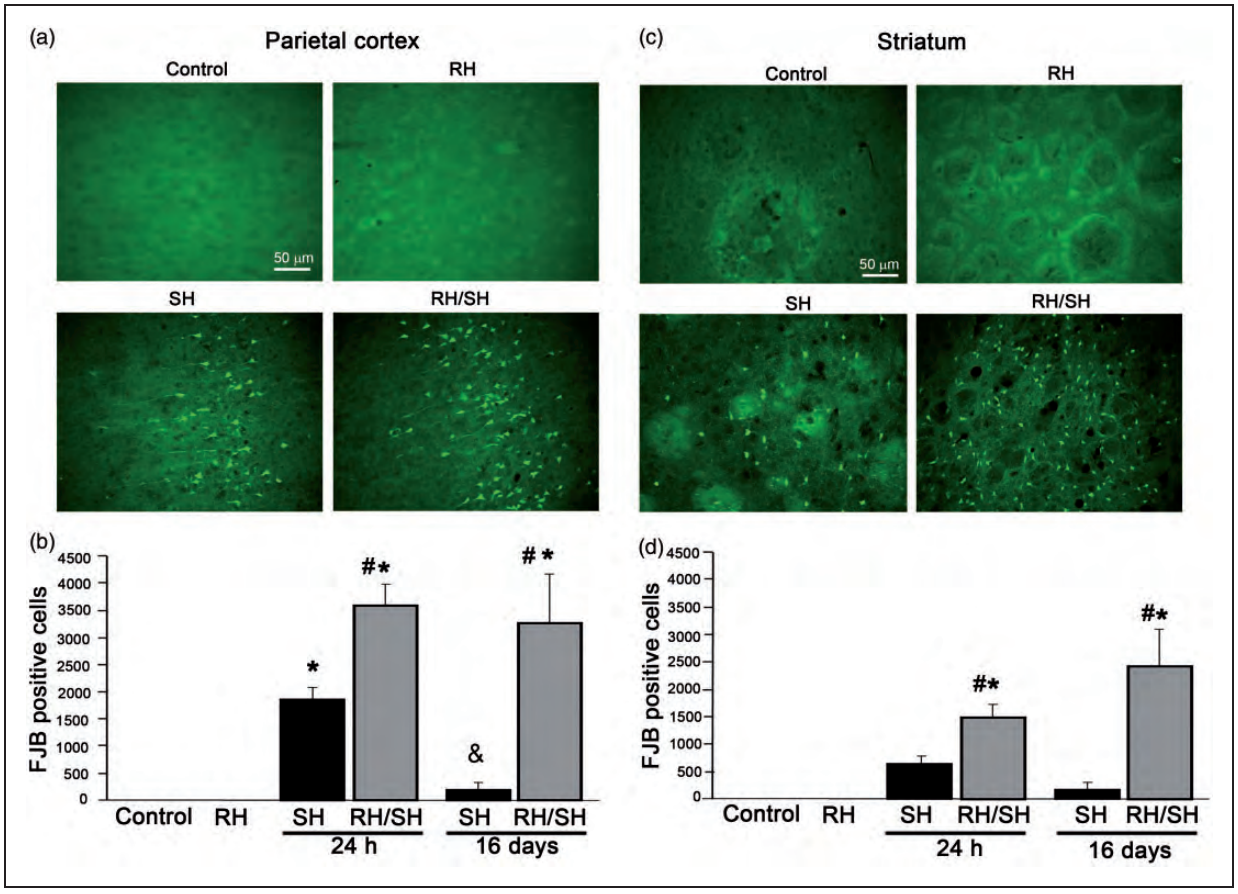

Figure 1. Neuronal death induced by the hypoglycemic coma in the parietal cortex and the striatum is exacerbated by antecedent RH. Neuronal death was evaluated 24 h and 16 days after the treatments and the number of FJB-positive cells was counted. Representative micrographs showing no FJB-positive in control and RH-treated animals and degenerating cells in the parietal cortex (a) and the striatum (c) of animals exposed to SH and RH/SH. (b–d) Cell death was exacerbated in animals exposed to RH/SH at 24 h and 16 days after the treatments. Data are expressed as mean ± SEM from seven animals per group. $^{*}p < 0.0001$ relative to control and RH, $^{\#}p < 0.0001$ relative to SH.

INFORME DE LABORES 2019

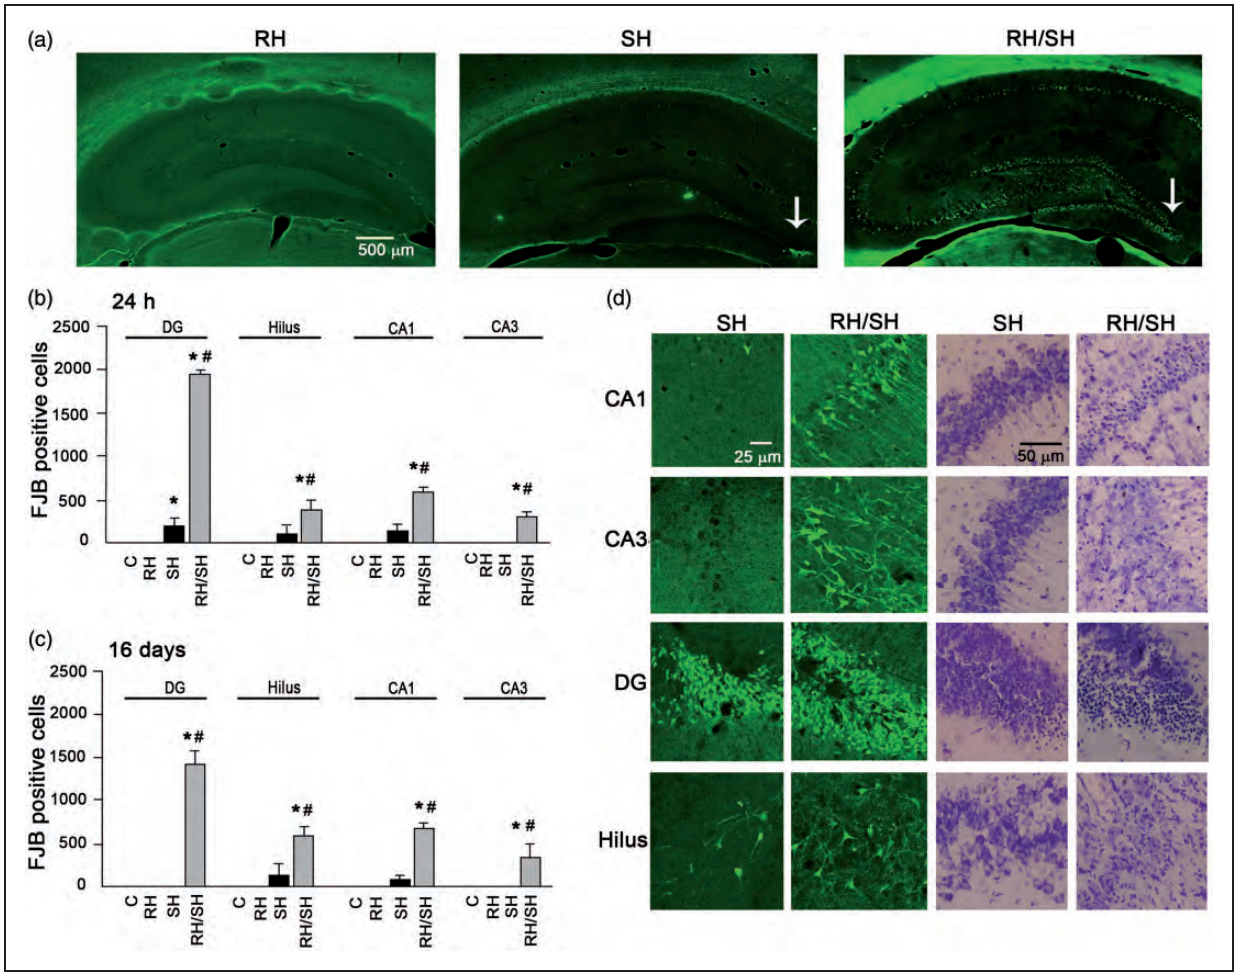

Figure 2. Neuronal death induced by the hypoglycemic coma in the hippocampus is exacerbated by antecedent RH. Neuronal death was evaluated 24 h or 16 days after the different treatments in brain sections stained with Nissl or FJB. (a) Representative micrographs showing degenerating cells only in the crest of the DG of animals exposed to SH and extensive neuronal death in animals from the RH/SH group. (b–c) Quantitative data showing exacerbated neuronal death in animals exposed to RH/SH at 24 h or 16 days. (d) Representative micrographs showing FJB-positive and pyknotic cells in the different hippocampal subregions of rats exposed to the different treatments. Data are expressed as mean ± SEM from seven animals per group. $^{*}p < 0.0001$ relative to control and RH, $^{\#}p < 0.0001$ relative to SH.

cells of animals exposed to the different treatments are shown in Figure 1(a) and (c). Similarly, the hippocampus showed a dramatic elevation in the number of degenerating neurons, which were present not only in the crest of the DG but also in the superior and inferior blades of the DG, the hilus, CA1 and CA3 (Figure 2(a)). This increase was statistically different relative to the SH group at 24 h and 16 days in all hippocampal regions (Figure 2(b) and (c)). These results were corroborated by the quantification of pyknotic cells in Nissl-stained sections (Supplementary Figure 3). Representative micrographs showing degenerating neurons in animals exposed to the different treatments are shown in Figure 2(a) and (d). The presence of pyknotic cells correlated with FJB labeling in the parietal cortex, the striatum (not shown) and the hippocampus (Figure 2(d)). Similarly, TUNEL-positive nuclei, indicative of DNA fragmentation were found in the parietal cortex, the striatum (Supplementary Figure 4) and the hippocampus (Figure 3(a)) of animals of the RH/SH group, while in animals exposed to coma alone, TUNEL-positive nuclei were observed only in the DG (Figure 3(b)). In control and RH groups, no TUNEL-positive nuclei were observed in any region (Supplementary Figure 4). Altogether, these observations indicate that RH increases the vulnerability to neuronal death in the parietal cortex, the striatum and mainly in the hippocampus of animals exposed to a subsequent short period of coma.

INFORME DE LABORES 2019

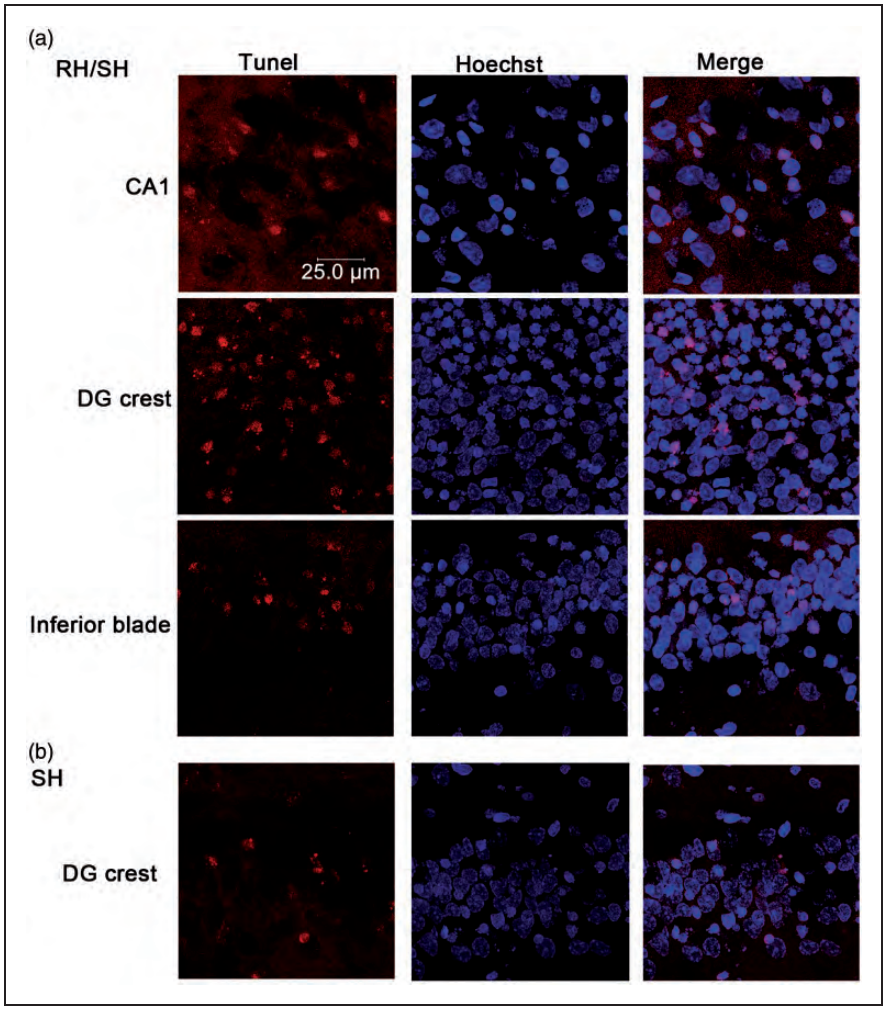

Figure 3. DNA fragmentation induced by the hypoglycemic coma is exacerbated by RH. The presence of DNA fragmentation was examined by the TUNEL assay and Hoechst was used as counterstain. (a) Representative micrographs showing TUNEL-positive cells in CA1 and the DG of rats treated with RH/SH. (b) In rats exposed to SH alone TUNEL-positive were detected only in the crest of the DG.

RH aggravates cognitive impairment induced by the hypoglycemic coma

According to the above-described results, RH notably enhanced neuronal death induced by the hypoglycemic coma in the hippocampus. Therefore, we aimed to test whether animals exposed to RH/SH showed memory impairment using two hippocampal-dependent memory tests. Figure 4(a) shows that during the five days of training in the water maze, the latency to locate the platform decreased similarly in all experimental groups indicating no difference in learning acquisition. At seven days after the coma, the SH and the RH/SH groups exhibited a significant decrease in number of crossings relative to controls, while animals exposed to RH alone showed no significant decrease (Figure 4(b)). At 15 days after the coma, only animals from the RH/SH showed a significant decrease in the number of crossings suggesting a long-term change in spatial memory (Figure 4(c)).

Figure 4(d) shows the performance of animals on the contextual fear conditioning. No statistical differences were found during contextual fear acquisition (day 1) since a similar percent freezing was observed in all groups. In the retrieval test (day 2), only the RH/SH group showed a significant decrease in the percent freezing relative to the control and the RH groups (Figure 4(d) right panel). No changes in locomotor activity and anxiety were found in any of the groups (Figure 4(e) and (f)). These data are in agreement with the spatial memory test and suggest that RH preceding the hypoglycemic coma exacerbates cognitive decline, which correlates with the presence of degenerating neurons in the hippocampus.

INFORME DE LABORES 2019

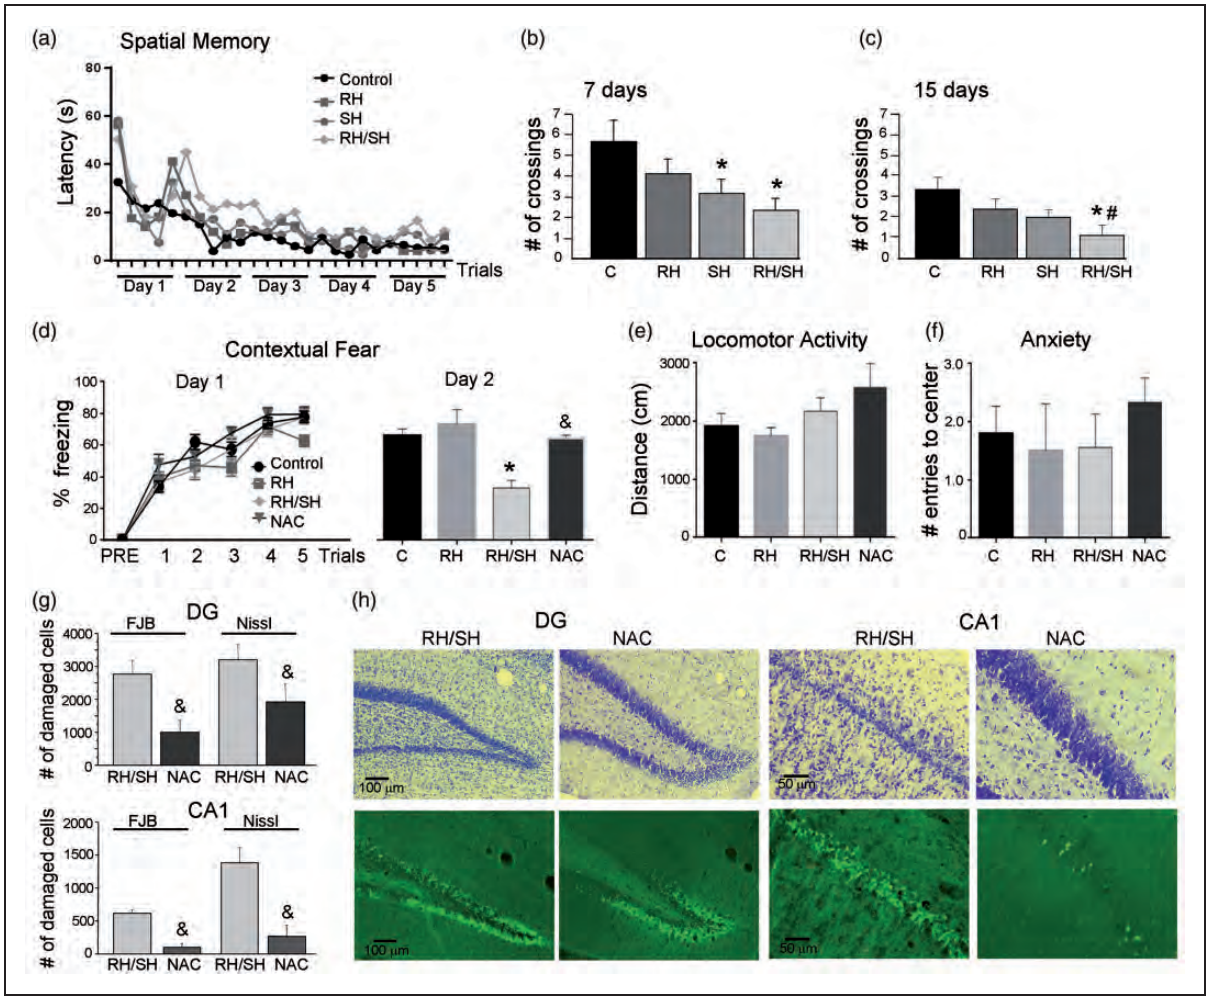

Figure 4. Previous RH aggravates cognitive impairment induced by the hypoglycemic coma. Spatial memory test (Water maze) was performed 7 and 15 days after the treatments. (a) Learning curve of animals exposed to the different treatments. (b) At day 7, animals of the SH and RH/SH groups showed a decrease in the number of crossings. (c) At 15 days, only animals of the RH/SH group showed a significant decrease in the number of crossings. Data are expressed as mean ± SEM from seven animals per group. $^{*}p < 0.01$ relative to control $^{\#}p < 0.05$ relative to SH. Contextual fear conditioning test was performed 48 h after the treatments. (d) No statistical differences between the groups were observed in the acquisition phase (day 1). The RH/SH group showed a significant decrease, while the NAC group showed no change in the percent freezing relative to control and RH groups during retrieval (day 2). Data are expressed as mean ± SEM from six to nine animals per group. $^{*}p < 0.0001$ relative to control and RH $^{\&}p < 0.05$ relative RH/SH. (e) No significant changes were observed between groups in (e) locomotor activity and (f) anxiety tests. (g) Number of damaged cells (FJB-positive group and pyknotic Nissl stained) in the dentate gyrus (DG) and CA1 of animals of the RS/SH and the NAC groups, 24 h after the fear-conditioning test. Data are expressed as mean ± SEM from four to six animals per group. $^{\&}p < 0.002$ relative to RH/SH). (h) Representative images showing the protective effect induced by NAC administration against cell damage (FJB-positive cell and pyknotic cells in Nissl stained section) induced in the DG and CA1 after exposure to RH/SH.

RH preceding the hypoglycemic coma induces oxidative damage

Oxidative stress has been highly implicated in neuronal death induced by the hypoglycemic coma.[12,32,33,37] Therefore, we aimed to evaluate the presence of the LPO product 4-HNE and 3-NT residues in proteins by immunohistochemistry. 4-HNE positive cells were observed in the parietal cortex, the striatum and all hippocampal subregions of animals of the RH/SH group, while in the control, RH and SH groups, 4-HNE inmmunoreactivity was not observed (Figure 5). As shown in the Figure 6, 3-NT-positive cells were observed mainly in the parietal cortex, DG and hilus of animals exposed to RH/SH. In contrast, no 3-NT immunoreactivity was observed in control, and RH groups, and only a few cells were observed in the parietal cortex of some animals of the SH group (Figure 6).

INFORME DE LABORES 2019

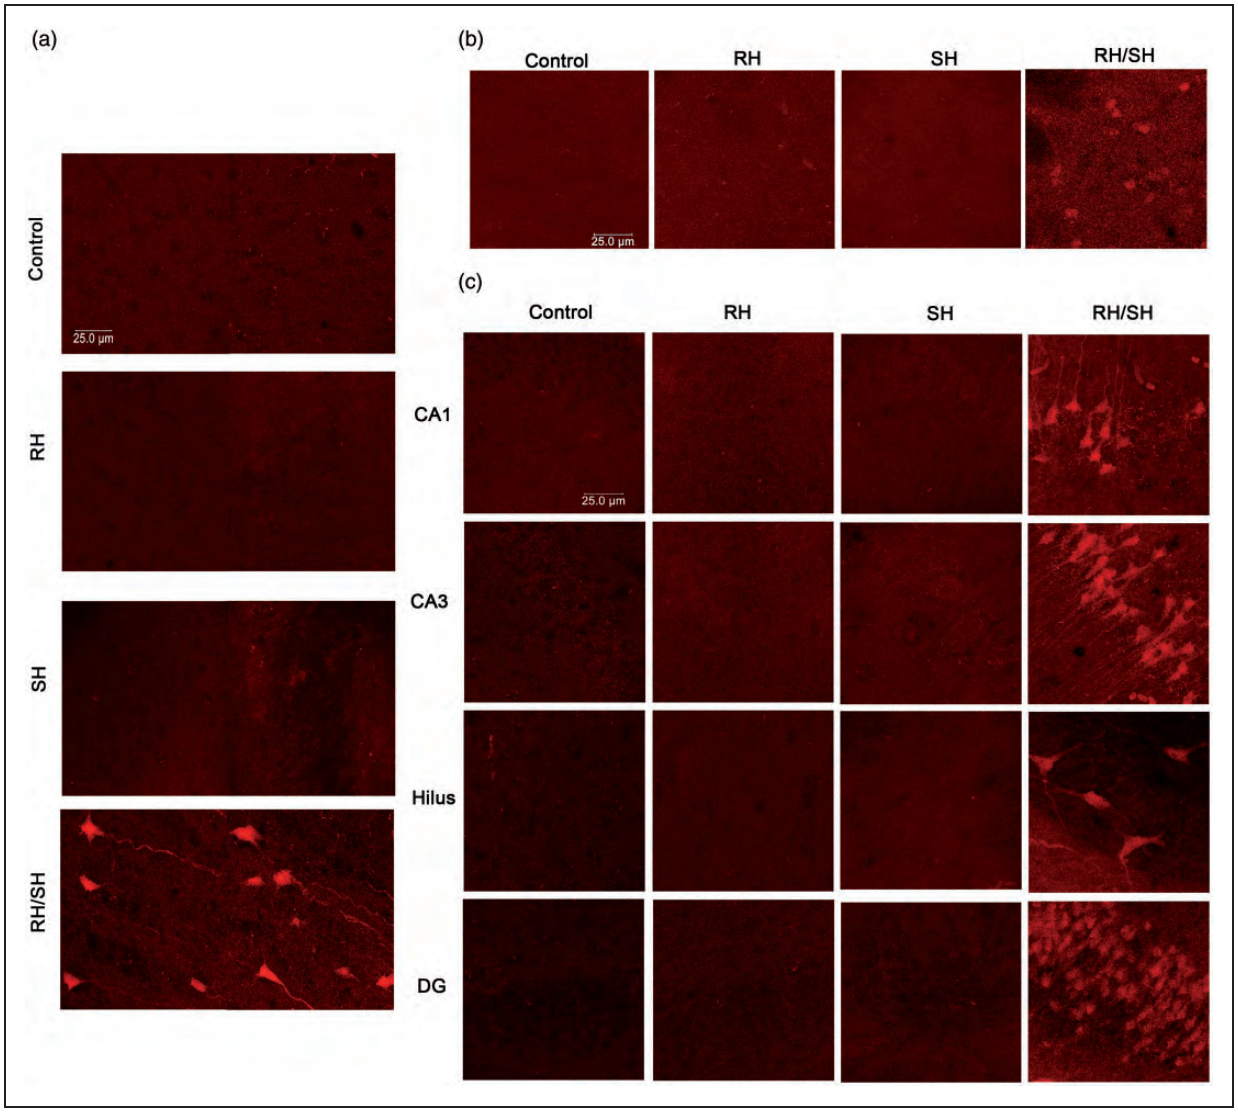

Figure 5. Immunoreactivity to 4-HNE in the brain of animals exposed to RH/SH. Representative fluorescent images showing the presence of 4-HNE-positive cells in (a) parietal cortex, (b) striatum and (c) hippocampus of animals treated with RH/SH. No 4-HNE-positive cells were detected in control, RH and SH groups.

Results suggest that RH facilitates oxidative damage to proteins in animals exposed to a subsequent short period of coma, which correlates with the presence of cell death.

Then we aimed to investigate whether a decrease in reduced GSH, the major antioxidant defense in brain, was involved in oxidative damage observed in animals treated with RH/SH. As observed in Figure 7, RH induced a partial (from 23 to 30%) but significant decrease in GSH, while animals of the RH/SH group showed a further decrease (from 49 to 58%) in GSH in all brain regions, the largest change was observed in the hippocampus (58%). The changes in GSH content were observed at 12 h after the end of treatments and were maintained at 24 h in all regions. These results suggest that a reduction in GSH contributes to enhanced oxidative damage in animals from the RH/SH group. Supporting this hypothesis, we observed that treatment with the antioxidant NAC, completely prevented cognitive decline in the contextual fear conditioning test (Figure 4(d)) and reduced hippocampal neuronal damage (Figure 4(g) and (h)). The number of pyknotic neurons and neurons positive to FJB was significantly reduced in the DG, CA1 (Figure 4(g) and (h)), CA3 and hilus (not shown). In the RH group, a significant increase in LPO was observed in all brain regions studied (Supplementary Figure 5); however, as in the case of GSH, increased LPO did not correlate with oxidative damage in these animals.

INFORME DE LABORES 2019

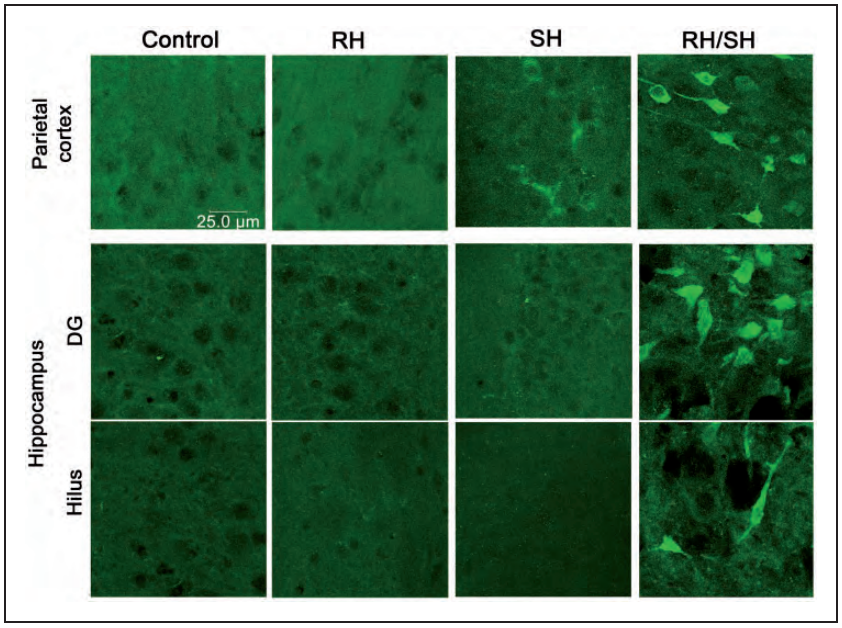

Figure 6. Immunoreactivity to 3-NT in the brain of animals exposed to RH/SH. Representative fluorescent images showing the presence of 3-NT-positive cells in the parietal cortex and the hippocampus of animals treated with RH/SH. No 3-NT-positive cells were detected in control and RH groups and only a few cells were observed in the parietal cortex of animals of the SH groups.

Discussion

TIDM is a long-term disease frequently diagnosed during infancy and a 3–4% annual increase rate in children and adolescents has been estimated in Europe.[3,18] TIDM patients under strict insulin treatment can show one to two episodes per week of moderate hypoglycemia, which increases the risk for SH (one episode per year) due to a blunted counter-regulatory hormonal response and hypoglycemia unawareness.[1–5] Mild to moderate hypoglycemia has been described as blood glucose < 70 mg/dl and > 55 mg/dl without loss of consciousness, while SH is considered when blood glucose falls below 50 mg/dl, is accompanied by seizures, altered consciousness or coma and requires external assistance for treatment with carbohydrates or glucagon.[3,37,38] Hypoglycemic episodes can last for several hours (from 1 to 5 h), as those reported during nocturnal hypoglycemia.[39] TIDM patients are exposed to mild RH for a life-time, and although at moderate levels, hypoglycemia has not been considered a potential threat, its consequences on brain function either alone or when it is followed by an episode of SH, are unknown so far. In the present study, we have addressed this question in a short-term period and as such, the frequency of moderate hypoglycemia was increased to seven consecutive episodes. To mimic T1DM patient's condition, moderate hypoglycemia periods were induced by decreasing blood glucose to 55–40 mg/dl during 2.5–3 h, without loss of consciousness or seizures and spontaneous recovery of euglycemia after food addition. SH was induced by the fall in blood glucose to 20 mg/dl or below accompanied by 7–10 min of EEG isoelectricity (coma state).

The most important finding of the present study is that previous RH exacerbates oxidative damage and neuronal death, leading to memory impairment in animals subsequently exposed to a short period of coma. In previous studies, we have demonstrated that short 5–10 min coma episodes induce neuronal death mainly in the parietal cortex but not in the hippocampus except for the crest of the DG.[32,33] In the present study, we demonstrate that animals exposed to a brief period of coma, which were previously treated with RH, show enhanced neuronal death in the parietal cortex and the striatum, but notably in the hippocampus, where degenerating and pyknotic cells are present in all hippocampal subregions. Degenerating neurons were observed even 16 days after the coma and correlated with deficient spatial memory. Cognitive decline was confirmed by defective performance in the contextual fear-conditioning retrieval test and interestingly we observed that in both spatial and contextual memory tests, mainly the consolidation of memory was impaired. When animals were exposed to coma alone (SH), only a transitory memory decline was present, consistent with the lack of degenerating neurons in the hippocampus, except for a small population of cells in the crest of the DG. Previous studies have implicated oxidative stress in neuronal death after

INFORME DE LABORES 2019

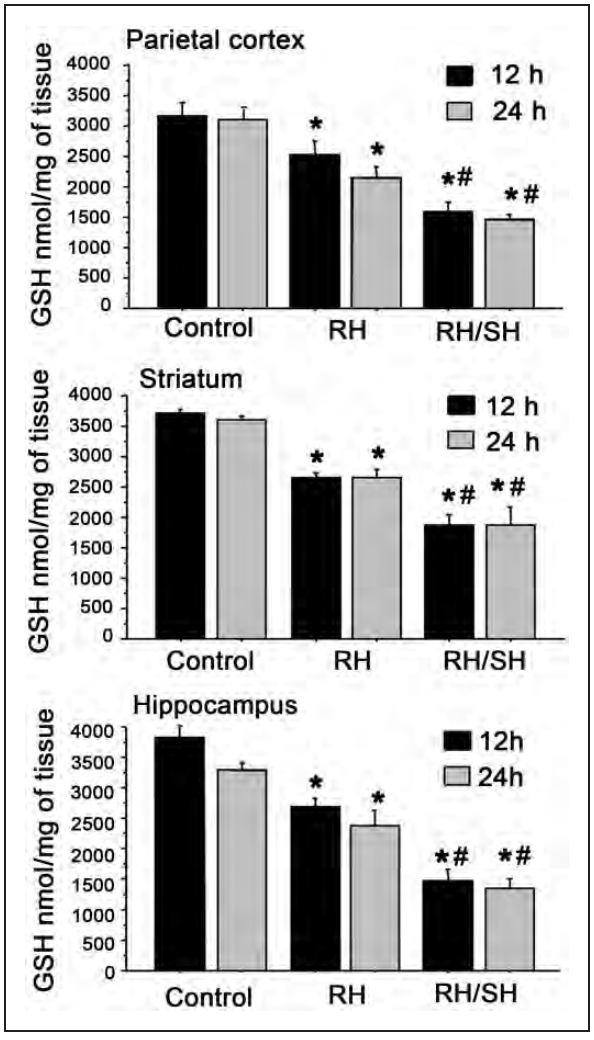

Figure 7. Changes in GSH content after RH and RH/SH. Animals were exposed to the different treatments and 12 and 24 h later reduced GSH levels were measured in different brain regions. Animals exposed to RH show a significant moderate decrease in reduced GSH in all brain regions, which is further decreased in animals from the RH/SH group ($n = 3$–7 animals per group). Data are expressed in means ± SEM. $^{*}p < 0.01$ relative to control; $^{\#}p < 0.01$ relative to RH.

a prolonged period of hypoglycemic coma.[12,13,40,41] In agreement, we observed immunoreactive cells to 4-HNE and 3-NT in brain regions showing dead cells in animals treated with RH/SH. 4-HNE and 3-NT react with proteins altering their function.[42,43] Thus, neuronal death correlates with oxidative alteration of proteins, which might be caused by a deficient antioxidant defense, based on the significant reduction in GSH content in all brain regions. Supporting this conclusion, it was observed that animals treated with NAC showed a significant reduction in the number of degenerating neurons and pyknotic cells in the hippocampus and no memory deficit in the contextual fear-conditioning test. GSH is the main antioxidant defense in the nervous system and its decrease is associated with oxidative stress and cell damage.[44,45] In addition, NAC has been demonstrated to have antioxidant actions and to restore GSH levels in rodents' brain after systemic administration.[46] Furthermore, it was recently reported that treatment with NAC prevents neuronal damage induced by a prolonged period of hypoglycemic coma.[41] Besides a deficient antioxidant defense, decreased glucose brain metabolism might also contribute to exacerbated hypoglycemic neuronal death induced by antecedent RH. A previous study has shown that three consecutive episodes of antecedent hypoglycemia result in decreased glucose oxidation in the brain of animals tested under acute hypoglycemia.[47]

The observed enhancement of hypoglycemic neuronal damage induced by antecedent RH, is in agreement with previous studies showing that exposure to RH in diabetic rats exacerbates brain injury induced by a short period of acute ischemia. This effect correlates with mitochondrial superoxide production implicating oxidative stress.[48] In contrast, a previous study showed that previous RH during three days elicited a preconditioning effect, reducing the number of degenerating neurons and preventing cognitive impairment induced by acute hypoglycemia in non-diabetic animals.[49] However, in that study, the presence of seizures possibly highly contributed to neuronal death, masking the effect of RH on hypoglycemic damage. In addition, a lower number of moderate hypoglycemic periods was used.

Rats treated with RH alone showed a partial decrease in GSH, which correlated with increased LPO but no oxidative damage, cell death or cognitive decline. The absence of neuronal death in this group of animals might result from the lack of glucose infusion since they were allowed to recover euglycemia after food addition. It is well known that glucose reperfusion plays a major role in neuronal death, mainly when blood glucose exceeds physiological levels resulting in hyperglycemia.[40,50,51] Previous data have reported a decrease in GSH content even after a single episode of moderate hypoglycemia,[52] and some studies have shown that RH in healthy animals produces an increase in LPO and 4-HNE immunoreactivity, without leading to significant neuronal death or cognitive decline.[13,19,25] Furthermore, studies have reported that RH in healthy animals can even improve cognitive performance due to synaptic changes and brain metabolic adaptations.[20,21,22,53]

In summary, the present results demonstrate that previous RH can have an adverse effect on subsequent SH in healthy animals, and suggests that this effect is mediated by the decline in the antioxidant defense and oxidative damage. It is expected that the consequences of RH treatment used in the present conditions could

INFORME DE LABORES 2019

be aggravated under diabetic conditions. Recent studies have demonstrated that the effects of RH on oxidative stress and the antioxidant defense are exacerbated in diabetic animals, enhancing cognitive decline.[13,24,25,54] Furthermore, depletion of Nrf2, a major transcription factor regulating the antioxidant defense, exacerbates RH-induced oxidative damage to proteins and cognitive decline in control and diabetic animals.[25]

The present observations demonstrate that RH renders the brain and particularly the hippocampus, more vulnerable to oxidative damage and neuronal death induced by a subsequent episode of hypoglycemic coma, ultimately leading to cognitive dysfunction. These observations highlight the relevance of the history of hypoglycemic episodes in TIDM patients and help us to estimate the consequences of RH on a subsequent episode of SH.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: This study was supported by CB239607 CONACYT grant to LM, CB250870 and 176639 CONACYT grants to FB-R and FS-B. GL was supported by CONACYT fellowship 363968.

Acknowledgements

The authors thank Dr. Ruth Rincón-Heredia for her valuable help in confocal imaging, Gianfranco Chávez Marchetta for his help in Water Maze assays and Francisco Pérez Eugenio for computer facilities. GL performed this study in partial fulfillment of the requirements of the Programa de Doctorado en Psicología at the Universidad Nacional Autónoma de México (UNAM).

Declaration of conflicting interests

The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Authors' contributions

LM and GL conceived the study, analyzed all data and wrote the manuscript. GL performed all experiments; TM performed all hypoglycemic treatments, contributed to data analysis and provided technical assistance; LR-L and FS-B participated in the contextual fear-conditioning experiments, data analysis and results interpretation; IB and FB-R participated in water maze experiments, data analysis and results interpretations; GS-C provided technical assistance and participated in manuscript revision. All authors participated in discussions and critically reviewed the manuscript.

Abstract—Parkinson's disease (PD) is a neurodegenerative illness presenting motor and non-motor symptoms due to the loss of dopaminergic terminals in basal ganglia, most importantly, the striatum. L-DOPA relieves many motor signs. Unfortunately, in the long term, L-DOPA use causes motor disabilities by itself and does not act in comorbid conditions such as depression. These deficiencies have led to search for drugs such as dopamine (DA) receptor agonists (DA-agonists) that allow the reduction of L-DOPA dose. Previously, we have identified the attributes of non-stimulated (resting) and cortical stimulated (active) striatal microcircuits following the activity of dozens of neurons simultaneously using calcium imaging in brain slices. We also have characterized the changes that take place in DA-depleted microcircuits in vitro. In control conditions, there is *low* spontaneous activity. After cortical stimulation (CtxS) sequences and alternation of neuronal ensembles activity occur, including reverberations. In contrast, DA-deprived circuits exhibit *high* spontaneous activity at rest, and a highly recurrent ensemble curtails alternation. Interestingly, CtxS briefly relieves these Parkinsonian signs in DA-depleted tissue. Here we compare the actions of some DA-agonists used in PD therapeutics on the pathological dynamics of DA-depleted microcircuits at rest and with CtxS; taking L-DOPA as reference. D_2-class agonists better reduce the excessive spontaneous activity of DA-depleted microcircuits. All DA-agonists tend to maintain ensemble alternation seen in control circuits after CtxS. However, quantitative analyses suggest differences in their actions: in general, DA-agonists only approximate L-DOPA actions. Nonetheless no treatment, including L-DOPA, completely restores microcircuit dynamics to control conditions. **© 2019 IBRO. Published by Elsevier Ltd. All rights reserved.**

INTRODUCTION

Parkinson's disease (PD) is a neurodegenerative disorder characterized by motor deficits such as tremor, postural instability, rigidity and bradykinesia (Lees et al., 2009; Obeso et al., 2017). Motor signs correlate with the loss of 50–70% of the dopaminergic terminals in the striatum (Burke and O'Malley, 2013). Terminals loss causes alterations on both the direct and indirect pathways of the basal ganglia (Kravitz et al., 2010; Gerfen and Surmeier, 2011; Calabresi et al., 2014; Parker et al., 2018). Even though L-DOPA, as dopamine (DA) replacement therapy, has been the gold standard for PD treatment (Carlsson et al., 1957; Foley, 2000; Mercuri and Bernardi, 2005; Lees et al., 2015; De Deurwaerdère et al., 2017) in the long-term its usage generates motor secondary effects such as dyskinesia (L-DOPA induced dyskinesia), wearing-off and on–off phenomena (Ahlskog and Muenter, 2001; Aquino and Fox, 2015; Sharma et al., 2015; Picconi et al., 2017). In addition, L-DOPA does not improve non-motor conditions of the disease such as depression and cognitive deficits (Millan, 2010). Therefore, there has been a search for adjuvant therapies, including dopaminergic receptor agonists (DA-agonists) whose use has been associated with lower L-DOPA dosage and a lower incidence of motor complications (Sprenger and Poewe, 2013; Jimenez-Shahed, 2016). There are two main classes of DA-agonists: the less selective $D_{1,2}$ receptors agonists such as rotigotine (Jenner and Katzenschlager, 2016; Chen et al., 2017) and the more selective D_2-class receptor agonists such as pramipexole (Mizuno et al., 2014; Shen et al., 2017).

The neurotoxic-based animal models of Parkinsonism have been used for many years, since they mimic many of the pathological and behavioral features of PD in humans, which make them convenient for the development of new therapies (Dunnet and Lelos, 2010; Morissette and Di Paolo, 2018). Recently, calcium imaging in 6-OHDA injured rodents allowed us to compare network activity of dopamine

depleted (DA-depleted) and control microcircuits (Pérez-Ortega et al., 2016; Aparicio-Juárez et al., 2019) with single cell resolution, opening the possibility of in vitro drug testing in brain slice preparations of histological scale to observe changes in microcircuit dynamics. The present study is an initial attempt to do that, using reproducible circuitry properties, easy to observe.

In control non-stimulated resting microcircuits, there is little spontaneous neuronal activity. But after cortical stimulation (CtxS), control microcircuits activity is enhanced showing transient neuronal groups firing together. These neuronal assemblies can alternate with other groups forming sequences or closed cycles (Hebb, 1949; Edelman, 1993; Carillo-Reid et al., 2009; Buzsaki, 2010; Pérez-Ortega et al., 2016). In contrast, non-stimulated DA-depleted microcircuits exhibit enhanced spontaneous activity with respect to the controls and become particularly engaged into a highly recurrent network state with increased synchronization (Liang et al., 2008; Jáidar et al., 2010, 2019; Lemaire et al., 2012; Pérez-Ortega et al., 2016). This state may have a surplus activity of D_2-receptor expressing striatal projection neurons although D_1-receptor expressing striatal projection neurons activity remains important (Parker et al., 2018; Jáidar et al., 2019). The highly recurrent state is dissolved by the action of D_1-agonists, but the enhancement of spontaneous activity is not reversed (Jáidar et al., 2010), in contrast to L-DOPA, which restores spontaneous activity to resting-like conditions (Lemaire et al., 2012; Plata et al., 2013). Interestingly, CtxS in DA-depleted striatal microcircuits, though briefly, also relieves the network from the excessive pathological activity. Addition of L-DOPA to the stimulated microcircuit prolongs this restoration (Aparicio-Juárez et al., 2019).

D_2-class agonist have been used as mono-therapy in the initial stages of PD (Baker et al., 2009) and co-applied with L-DOPA in more advanced phases of the disease (Brooks, 2000; Linazasoro and Spanish Dopamine Agonists Study Group, 2004; Stocchi, 2009; Millan, 2010). D_2-agonists restore the balance between direct and indirect pathways (Ballion et al., 2009), decreasing pathological activity. Here we want to correlate these findings in vitro using the activity of neuronal networks of histological scale. We compare the actions of less selective $D_{1,2}$- agonists with those of more selective D_2-agonists (Hu and Wang, 1988; Wang and Zhou, 2017) under two different conditions pertaining the pathophysiological signatures of parkinsonism (Pérez-Ortega et al., 2016): First, how agonists decrease excessive spontaneous neuronal activity in non-stimulated DA-depleted striatum. Secondly, how they act during network dynamics restoration induced by CtxS (Aparicio-Juárez et al., 2019). The results of this work show that both classes of DA-agonists exhibit subtle differences in spontaneous and stimulated network activity when compared with different metrics during circuit dynamics, a finding that may have clinical relevance. In vitro preparations appear to be potential bioassays to test combinations of adjuvant therapies and new drugs, in addition to cellular, behavioral and clinical tests. Their cost is low and the actions of several drugs can be tested and correlated with other assays.

EXPERIMENTAL PROCEDURES

Research subjects

Protocols were designed and performed as approved by the Institutional Committee for Laboratory Animals Care and Use of the Instituto de Fisiología Celular (IFC), UNAM (NOM-062-Z00–1999; laboratory protocols JBD-59-15) in accordance with the international norms for the ethical use of experimental animals established in the National Institutes of Health Guide for Care and Use of Laboratory Animals Eighth Edition (NIH, 2010). Male and female C57BL/6 mice breaded in the animal facilities of the IFC were used in all experiments. Mice were housed in a temperature controlled, pathogen-free room, on a 12:12 light: dark cycle and allowed food and water ad libitum.

Drugs

6-OHDA (6-Hydroxydopamine hydrochloride, Sigma-Aldrich H4381-100MG) was dissolved in saline solution and injected intracranially (0.1 mg/ml) to obtain hemi-parkinsonian mice. Apomorphine (R-(−)-apomorphine hydrochloride hemihydrate Sigma-Aldrich A4393-250MG) was diluted in saline vehicle and administered via subcutaneous injection to measure rotational behavior in 6-OHDA injected animals. Calcium Orange 8.2 μM (Molecular Probes®, Life technologies, Mexico City, MX) was diluted in dimethyl sulfoxide (DMSO) solution, 0.1% DMSO, 0.67% Pluronic Acid (Pluronic TM F-127, Life Technologies Corporation, Oregon USA, P3000MP) and dissolved in artificial cerebral spinal fluid (ACSF) to be applied to brain slices at 36 °C for 40 min for calcium imaging. NMDA (N-Methyl-D-aspartic acid, Sigma-Aldrich M3262), L-DOPA (3,4-Dihydroxy-L-phenylalanine, Sigma-Aldrich D9628), apomorphine (R-(−)-apomorphine hydrochloride hemihydrate, Sigma-Aldrich A4393), quinelorane (quinelorane hydrochloride, Tocris Bioscience. CAS97548–97-5), pramipexole (pramipexole dihydrochloride, Sigma-Aldrich A1237), ropinirole (ropinirole dihydrochloride, Sigma-Aldrich R2530) and rotigotine (rotigotine hydrochloride, Sigma-Aldrich R9281) were dissolved in ACSF and applied to the bath saline during calcium imaging. Saturating concentrations were employed in all cases reported.

6-OHDA model

The hemi-parkinsonian mouse obtained by 6-OHDA unilateral injections is the most common Parkinsonian rodent model used in research (Ungerstedt and Arbuthnott, 1970). For that purpose 125 mice 25–30 days old were anesthetized intraperitoneally with ketamine (85 mg/kg)-xylacine (15 mg/kg) for stereotaxic surgery. 0.8 μL of 6-OHDA (0.1 mg/ml) were injected intracranially at a 0.2 μL/min rate in −2.6 mm AP, −1.5 mm LM y − 4.7 mm DV from Bregma, targeting the edge of SNc and MFB. Immediately after surgery animals were placed on a heating pad until fully awaken. After 15–30 days recovery period (Postnatal day 45–60), DA-depletion was measured by rotational behavior test, during this period mice received chocolate pellets ad libitum and subcutaneous 100 μL glucose 2% in

saline solution daily injections were administered if more than 20% weight loss was detected. 80% of the injected mice survived (100 mice) until rotational evaluation. For turning behavior evaluation, apomorphine was injected subcutaneously (0.5 mg/kg in saline vehicle with 0.02% ascorbate). Ipsilateral and contralateral rotations to the lesion site were counted with the program RotaCount 2.0 (Omni-Tech, Sioux Falls SD) for at least 50 min. The ratio of contralateral vs ipsilateral rotations was used to identify unilateral DA-depleted mice. Whenever mice presented more contralateral rotations than ipsilateral rotations (ratio ≥ 2) and total contralateral rotations were at least 50 (1 per minute) mice were considered as successfully DA-depleted. Lesion efficacy was 65% as measured by this test (for rotation data see Fig. 1E). This test has previously been reported as effective in detecting about 80% dopamine depletion (Heuer et al., 2012). The lesioned hemisphere used for in vitro experiments is referred to as dopamine depleted (DA-depleted) in the present paper. Not every DA-depleted mouse resulted in experiments reported here since slices with less than 80% cell survival were discarded; this was quantified based on videos with 20 mM KCl application at the end of each experiment. In total, slices from 50 mice were used for calcium imaging experiments.

Immunohistochemistry

Tyrosine Hydroxylase (TH) immunohistochemistry staining was performed as previously reported (Aparicio-Juárez et al., 2019) to confirm DA depletion in some 6-OHDA lesioned mice (Fig.1A-D). Briefly, 8 days after behavioral evaluation, lesioned mice were anesthetized and perfused with phosphate buffer solution 0.1 M (PBS) (NaH_2PO_4 15 mM, Na_2HPO_4 80 mM, NaCl 50 mM, pH 7.4) and 4% paraformaldehyde fixative (PFA) in PBS 0.1 M, pH 8). After brain extraction, 50 µm coronal slices were obtained in a vibratome (PELCO easiSlicer Ted Pella, Redding, CA) and stored in PBS. Slices were blocked with 1% bovine serum albumin (BSA) in PBS and 0.1 M- Tritón 3% for 40 min at room temperature and washed three times in PBS 0.1 M. Primary antibody (Rabbit, anti-Tyrosine Hydroxylase, Chemicon International, 1:500 in PBS 0.1 M- Tritón 3%) was incubated at room temperature for 12 h and washed three times with PBS 0.1 M. Slices were incubated with secondary antibody (Cy3-conjugated Affini Pure Donkey anti-Rabbit, Jackson Immuno Research, Inc. 711–165-152 1:250 in PBS 0.1 M- Tritón 3%) at room temperature for 2 h and washed three times with PBS 0.1 M. Finally, slices were cover slipped with DAPI (Vecta Shield, Vector Laboratories, Inc. H-1200) and images were obtained by confocal microscopy (Zeiss LSM-710, objective: C-Apochromat 10X N.A. 0.45, laser 543 nm). DA fibers in the striatum were quantified as fluorescence intensity compared to the intact side using ImageJ®, while DA somata were manually counted from confocal micrographies. In both cases DA depletion was confirmed to be at least 80%, as illustrated in Fig. 1C-D, across 17 slices taken from different animals. Stereoscopic images were obtained on a Nikon SMZ1500 (HR objective, Apo 1x WD 54).

Calcium imaging

Both controls and DA-depleted mice were anesthetized intraperitoneally with ketamine-xylacine (85 mg/kg-15 mg/kg) and perfused intracardially with chilled sucrose solution (234 mM sucrose, 28 mM $NaHCO_3$, 7 mM dextrose, 4.54 mM pyruvate, 0.28 mM ascorbic acid, 2.5 mM KCl, 7 mM $MgCl_2$, 1.44 mM NaH_2PO_4, 0.4 mM $CaCl_2$, 4 °C). For DA-depleted mice, there was a 14 days delay between rotational behavioral tests and calcium imaging experiments. Once brains were extracted, 300 µm thick para-horizontal slices with a 30° angle were taken (Fig. 1F). in a vibratome (PELCO easiSlicer Ted Pella, Redding, CA) and kept in ACSF (126 mM NaCl, 15 mM dextrose, 26 mM $NaHCO_3$, 0.2 mM thiourea, 0.2 mM ascorbic acid, 2.5 mM KCl, 1.3 mM $MgCl_2$, 1.2 mM NaH_2PO_4 and 2.0 mM $CaCl_2$; pH = 7.4; 300 ± 5 mOsm/L) continually perfused with 95% O_2 and 5% CO_2. Slices from control (Ctr) and lesioned (DA-depleted) animals were used. Since long-term data acquisition was required, a low photobleaching fluorophore (Thomas et al., 2000), Calcium Orange, was chosen. Slices were incubated in a Calcium Orange solution (Calcium Orange 8.2 µM, 0.1% DMSO, 0.67% Pluronic Acid in ACSF) at 36 °C for 40 min and later located in a perfusion chamber with constant ACSF flow under a 20X immersion objective (Olympus XLUMPLFLN Objective, 1.00 NA, 2.0 mm WD). Observation field was 750 × 750 µm. Fluorophore stimulation was carried out with a Lambda LS Illuminator (Sutter Instruments, Petaluma, CA, USA) and a 570/30 nm light filter. Im-Patch© an open source software designed in the LabView environment (National Instruments, Mexico City, Mexico; available at http://Impatch.ifc.unam.mx) was used for fluorescence recordings controlling a CoolSnap K4 camera (Photometrics, Tucson, AZ, USA). Videos were 720–2160 frames long and acquisition rate was 6 frames/ s. To cover long periods, 7–10 videos were taken per experiment, making up to 90 min per experiment.

In order to confirm calcium fluorescence reliability as activity reporter simultaneous calcium and electrophysiological recordings were obtained using whole cell current-clamp configuration. Patch pipettes (3–6 MΩ) were filled with a solution that contains in mM: 115 KH_2PO_4, 2 $MgCl_2$, 10 HEPES, 0.5 EGTA,10 NaCl, 0.2 ATP, 0.2 GTP and 0.03 Calcium Orange salt, the pH was 7.24. As shown in Fig. 1G, the positive derivative $d(\Delta F/F)/dt$ of fluorescence transients coincide in time and duration with cell activity.

Data acquisition

Control striatum slices were compared in two main conditions: spontaneous activity and stimulation-evoked activity. Two stimuli were compared, the previously used pharmacological stimulation consisting in the application of 2 µM NMDA (Carrillo-Reid et al., 2008) and CtxS (Aparicio-Juárez et al., 2019) consisting in 10 pulses, at 40 Hz, 1.1–1.3 mA through a bipolar concentric electrode 50 µm at the tip (FHC, #CBCFE75, Bowdoin, ME, USA) inserted in primary motor cortex (M1) layer V as shown in Fig. 1F. Recordings were obtained in the adjacent dorsal, mostly dorsolateral, striatum in every case. DA-depleted striatum slices were also compared in two conditions: activity altered solely by dopaminergic agonists application (10 µM L-

INFORME DE LABORES 2019

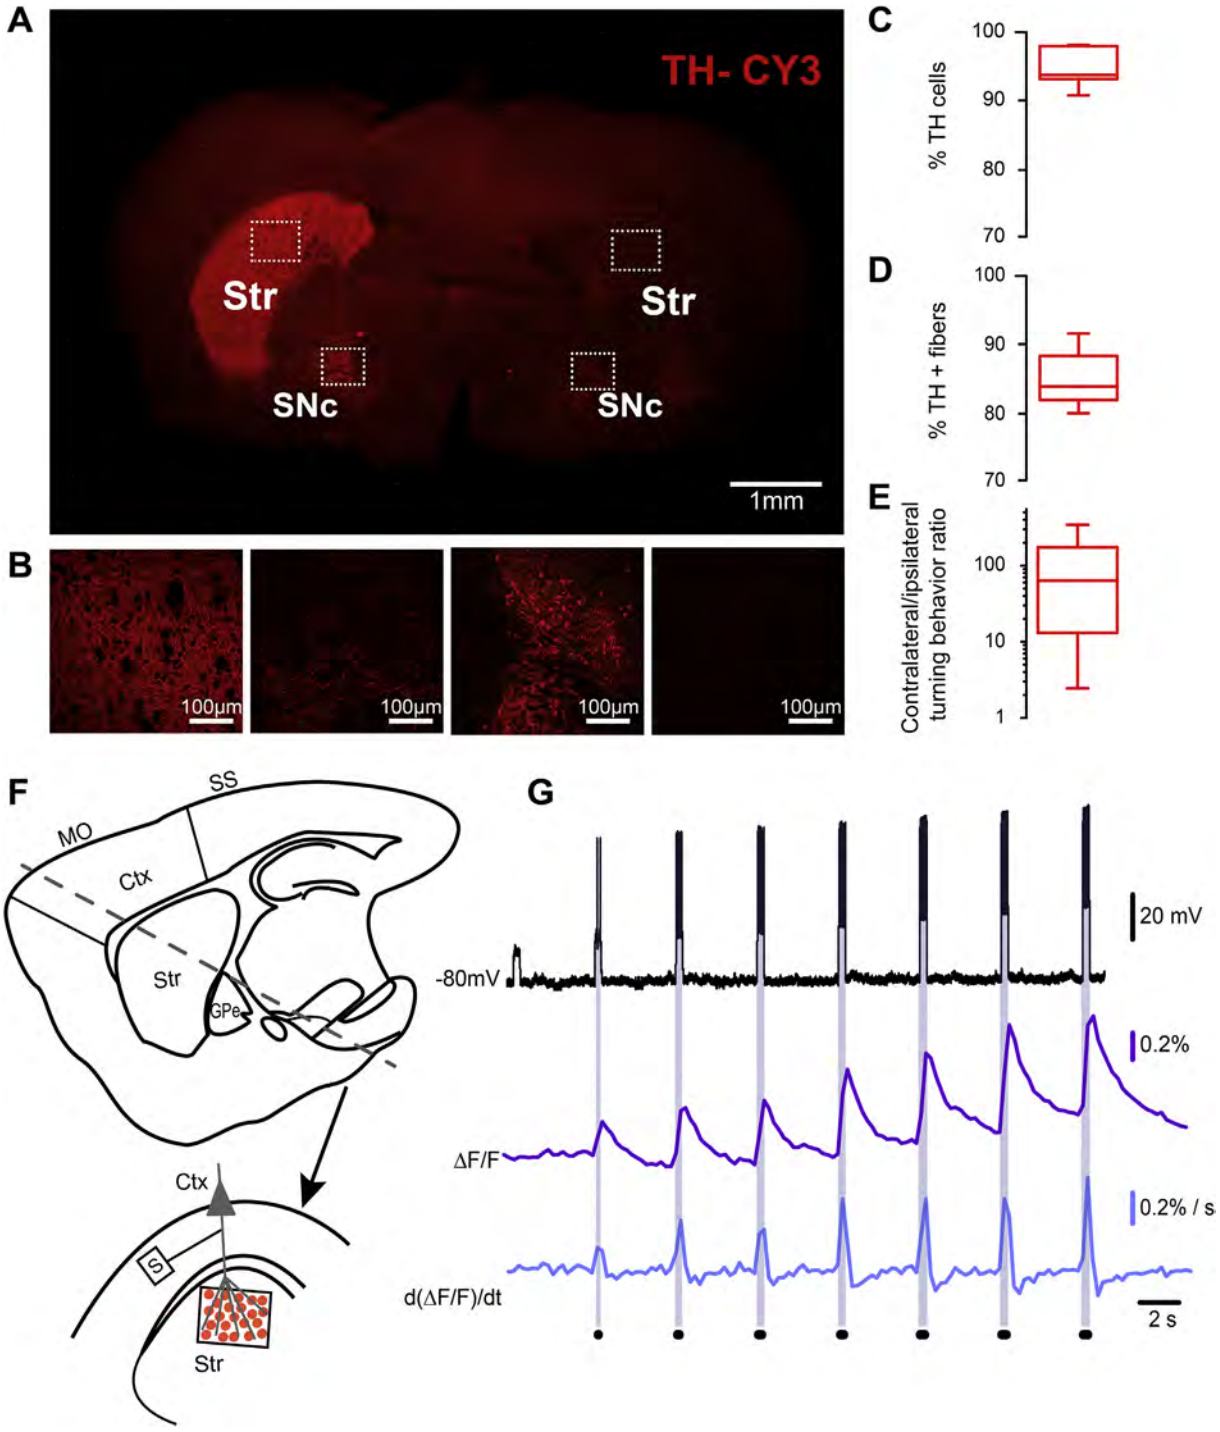

Fig. 1. (A) Stereoscopic fluorescence microscopy showing decreased TH-CY3 on the lesioned hemisphere (right) compared to the intact hemisphere (left) both on striatum (Str) and Substantia nigra compacta (SNc). (D) Percentage reduction of TH-immunoreactive (TH+) fibers (n = 17 mice; fluorescence intensity compared to the non-lesioned side). (E) Box plot showing unbalance in turning behavior evaluated in a sample of experimental animals (n = 65 mice; apomorphine 0.5 mg/Kg). Note variability. (F) Diagram of a sagittal mouse brain slice showing (dotted line) the orientation of a para-horizontal (30°) brain slice (top). Diagram of stimulation and recording sites: mostly motor cortex and dorsolateral striatum, respectively (bottom). (G) Simultaneous electrophysiological (top signal) and calcium imaging recordings (middle) are shown. An intracellular current step of increasing strength was applied to evoke increasing numbers of action potentials and corresponding increases in calcium entry seen as changes in the fluorescence signal (ΔF/F). The positive phase of the time derivative of the calcium transient, d(ΔF/F)/dt, reports the duration of electrophysiological activity (bottom). These durations are denoted with dots in raster plots (bottom).

DOPA, 20 μM apomorphine, 10 μM rotigotine, 10 μM pramipexole, 10 μM ropinirole, 10 μM quinelorane) and activity evoked by cortical stimulation (CtxS) in the presence of one DA-agonist. Spontaneous activity of DA-depleted tissue was always recorded before the addition of any drug to the superfusion system.

Data analysis

Videos were processed with ImPatch©, as previoulsy reported (Aparicio-Juárez et al., 2019). Briefly, cell activity was extracted and transformed into activity matrices were 1 denotes an active frame and 0 an inactive frame for each cell. Whole experiments can be contained in these matrices and expressed as raster plots, where each dot stands for a cell firing in that frame and each row represents the activity of a cell along time (Fig. 1G). The activity of all cells per frame was added to build coactivity histograms. Significant coactivity peaks were determined using several variants of Montecarlo simulations with 10,000 iterations each (see Pérez-Ortega et al., 2016). The significant coactivity peaks were built from the frames in which the threshold was overcome, 12 to 18 frames time bins were used. Coactivity peaks were compared based on a similarity index calculated as the cosine of the angle between vectors obtained with the dot product of each pair of column vectors (Carrillo-Reid et al., 2008), and were associated using hierarchical cluster analysis into groups of neurons that fire together in a time bin, thus defining neuronal ensembles as neurons that transiently fire together and can alternate their activity forming sequences (Carillo-Reid et al., 2009; Buzsaki, 2010; Pérez-Ortega et al., 2016). Ensemble sequences comprise network dynamics (Buzsaki, 2010) which was compared under different conditions: non-stimulated control (Ctr), cortical stimulated controls (Ctr + CtxS or Ctr + NMDA), non-stimulated DA-depleted microcircuits (DA-depleted) and cortical stimulated DA-depleted microcircuits: DA-depleted + CtxS.

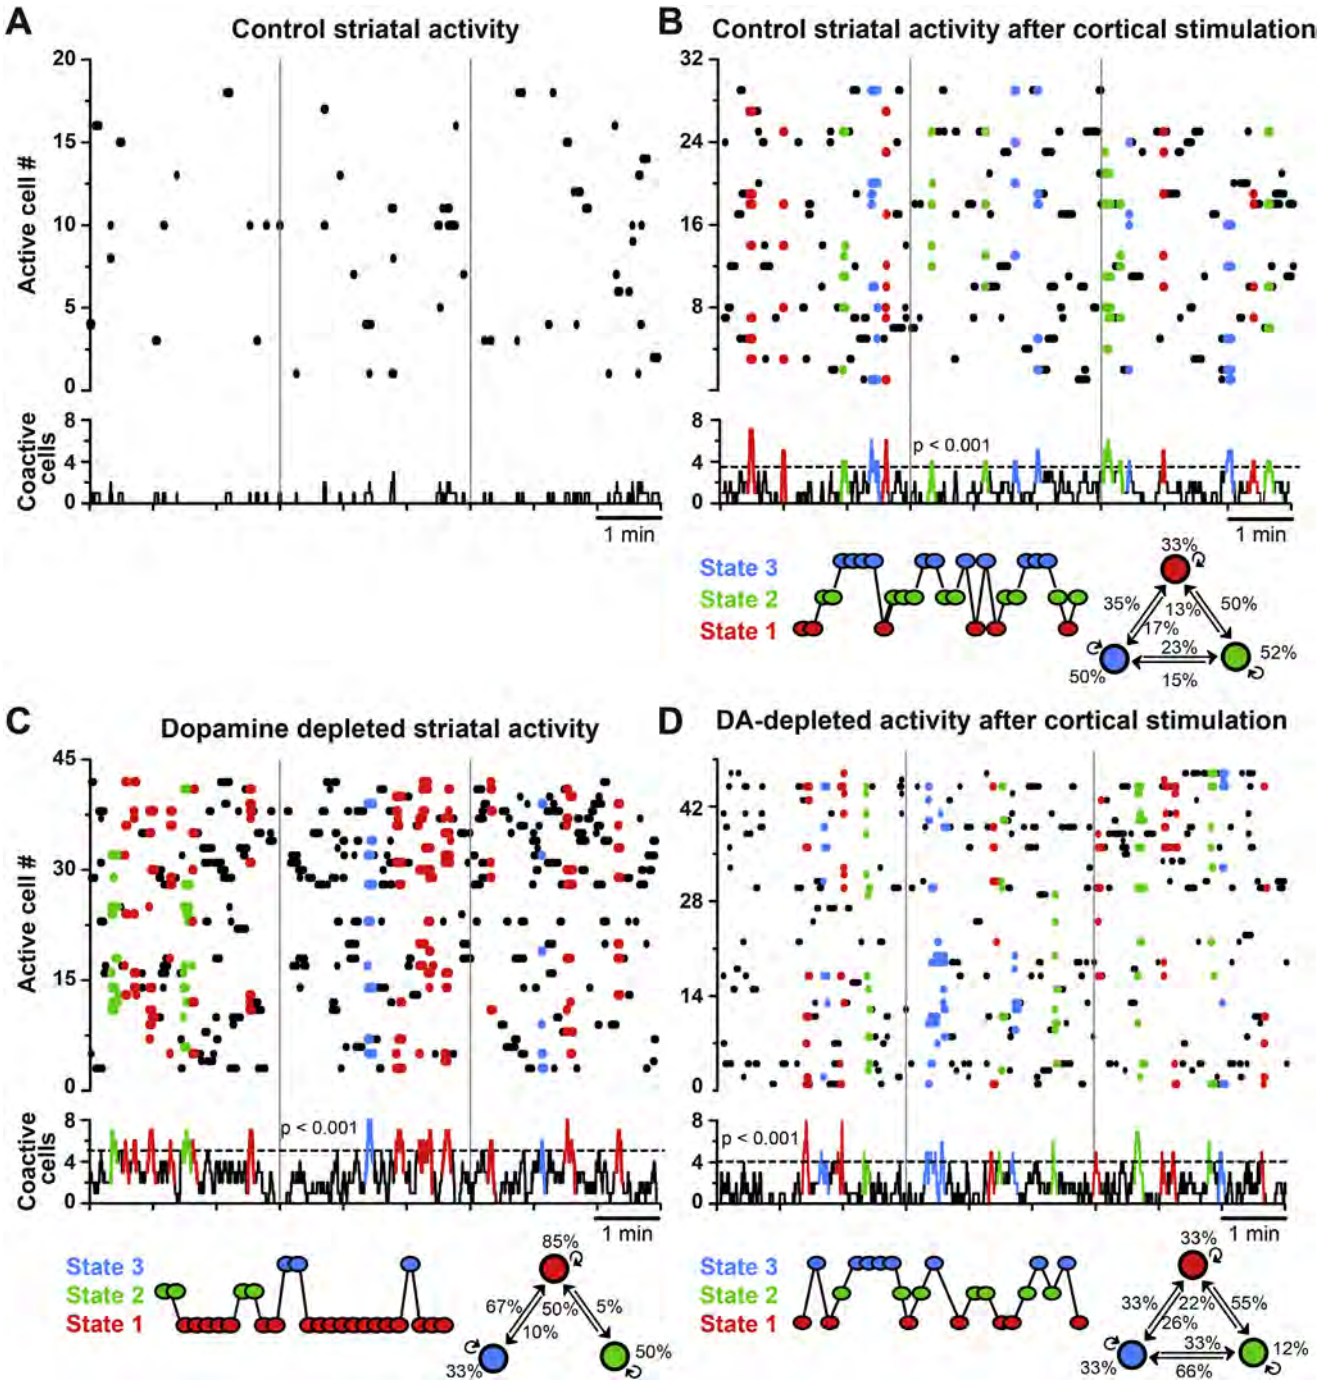
Activity of neurons forming ensembles defined by similarity (see above) are colored differently in raster plots and are symbolized as colored circles in temporal network sequences, allowing to see circuit activity as the transitions between distinct network states. In control conditions these sequences may exhibit closed cycles or reverberations as previously reported (Pérez-Ortega et al., 2016). A reverberation occurs when the transitions between network states generate a closed loop, meaning that every state appeared at least once and the initial state is equal to the last state. To assess significance of coactivity peaks/min, the number of frames in which the coactivity histogram value was greater than the threshold determined by Montecarlo simulations was divided by the total length (min) of the experiment. Numbers of coactivity peaks/min were compared with Wilcoxon matched-paired signed rank tests (Wilcoxon T tests).

Amount of activity per experiment was quantified by cumulative activity plots, which were built by adding activity along time. To consider samples of experiments in the same condition, a linear fit was approximated to cumulative activity plots. Slopes of these fits from samples of neurons were then represented as Tukey box plots. This method was used to compare cell activity in both spontaneous and stimulated conditions. Cumulative activity was compared with Kruskal-Wallis ANOVA corrected for multiple comparisons using the Benjamini-Hochberg procedure (Benjamini et al., 2006) with a false-discovery rate (FDR) of 0.05. To compare individual cells activity trough different sections of a single experiment, activity of each cell was defined as the total number of active frames over the total number of frames. This value was used to compare cellular activity between different microcircuit conditions (see above), with or without a dopamine agonist (+ L-DOPA, + apomorphine, + rotigotine, + pramipexole, + ropinirole, + quinelorane). Cumulative distribution functions (CDFs) were performed for each condition using all neurons of a given sample. CDFs were compared with Kolmogorov–Smirnov tests corrected for multiple comparisons using the Benjamini-Hochberg procedure with a 0.05 FDR.

The DA-depleted microcircuit is characterized by enhanced spontaneous activity with a highly recurrent ensemble (Jáidar et al., 2010; Pérez-Ortega et al., 2016). To quantify its appearance in DA-depleted conditions and in the presence of CtxS and DA-agonists (+ L-DOPA, + rotigotine, + pramipexole, + ropinirole), we calculated a recurrence index for every state with respect to the other states as previously reported. Recurrence is the consecutive repetition of a network state instead of alternation of activity with another state. It is calculated as the total sum of such events whose minimum value is 1 for one state appearance. The recurrence index is the recurrence of a single state divided by the sum of the recurrence of all the other states (Aparicio-Juárez et al., 2019). Network states recurrence was compared using the O'Brien Homogeneity of variance test. Another characteristic of DA-depleted microcircuits is the almost complete absence of closed cycles (recurrence impedes alternation and closed cycles). To measure this, we quantified the number of transitions required to accomplish a closed loop between network states. If a closed loop was not observed during the experiment, the value “infinity” was assigned. The distribution of the number of transitions required to close a loop was presented in pie plots and their underlying distributions were compared with Kolmogorov–Smirnov tests. To assess the transitions required to close a loop, sequences that never closed were excluded and the number of transitions before closure were compared using Kruskal-Wallis tests. All multiple comparisons were corrected using a Benjamini-Hochberg procedure with a 0.05 FDR.

Statistics

The determination of a significance threshold for coactivity peaks has been described previously (see Pérez-Ortega et al., 2016) using custom programs in MATLAB (The Math Works, Inc. Natick, MA). Some statistical tests were run in Graph Prism (GraphPad Software, Inc. La Jolla, CA) for the following purposes: Mann–Whitney tests to compare between samples, Wilcoxon's T test to compare conditions in the same sample, Kruskal-Wallis ANOVA test to compare cumulative activity and transitions to reach closed-loops, and Kolmogorov–Smirnov test to compare distributions of data sets. All multiple comparisons were corrected using a



Benjamini-Hochberg procedure with a 0.05 FDR and recurrence index among different pharmacological conditions were compared using O'Brian Homogeneity of variance test.

RESULTS

DA-depleted microcircuits differ from control striatal microcircuits

Microcircuit activity can be accurately recorded by calcium entry during neuronal firing (see Experimental Procedures and Pérez-Ortega et al., 2016), the positive time derivative of a calcium transient corresponds in time and magnitude with action potentials firing (Fig. 1G). Microcircuit activity can be illustrated in the form of raster plots where rows in the y-axis represent the activity of each neuron in the microcircuit along time, and each dot the activity of a cell in one frame (Fig. 1G). Every raster plot in this work corresponds to a single brain slice taken from a single animal, there are no different experiments coming from the same slice or animal (Videos using calcium orange can be seen in Aparicio-Juárez et al., 2019 and in Video A of the present work).

As previously reported (Carrillo-Reid et al., 2008; Jáidar et al., 2010; Pérez-Ortega et al., 2016), the non-stimulated

control (Ctr) striatal microcircuit has little spontaneous activity (Fig. 2A), similar to that recorded in a resting subject in vivo (Mink, 2003; Parker et al., 2018). In contrast, after cortical stimulation (CtxS; 10 pulses at 40 Hz in cortex layer V see Experimental Procedures), the striatal microcircuit exhibits enhanced activity that may be recorded for a long time after the stimulus (Fig. 2B; see also Aparicio-Juárez et al., 2019), resembling that recorded during motor activity in vivo (Mink, 2003; Cacace et al., 2017; Parker et al., 2018). A similar increase in network activity and motor behavior may be recorded during the administration of NMDA (2 μM), a glutamatergic receptor agonist, into the striatum (data not shown); see also Ossowska and Wolfarth, 1995; Carrillo-Reid et al., 2008). Both cortical stimulation and NMDA generate network dynamics characterized by the alternation or transitions between network states activity.

Histograms of cellular coactivity at the bottom of raster plots show the sum of neuronal activity per frame in each panel (Fig. 2A-D). The threshold to consider a significant peak of coactivity is represented by a dotted line ($P < 0.001$). In control conditions there are no significant peaks of coactivity (Fig. 2A; n = 12 experiments) due to low spontaneous activity; frames with no activity can be recorded. In contrast, after delivering a cortical stimulus (CtxS; Fig. 2B; n = 5; see Aparicio-Juárez et al., 2019), network activity is enhanced and displays significant peaks of neuronal coactivity (Fig. 2B) as compared to non-stimulated controls (cf., Fig. 2A). Similarly, the non-stimulated DA-depleted striatal microcircuit (Fig. 2C; n = 33) exhibits significant spontaneous activity as compared to the non-stimulated controls (cf., Fig. 2A) accompanied by several significant coactivity peaks (histogram below raster plot in Fig. 2C) without any electrical or chemical stimulus. Significant coactivity peaks in a stimulated control (Fig. 2B), non-stimulated DA-depleted microcircuit (Fig. 2C) and stimulated DA-depleted microcircuits (Fig. 2D) are illustrated as colored circles below the histograms (network states). Note that in stimulated control and DA-depleted microcircuits (Fig. 2B and D) network states form chain-like sequences with alternation of activity between network states (Buzsaki, 2010; Pérez-Ortega et al., 2016) including closed ring-like cycles, or reverberations. In contrast, the non-stimulated DA-depleted microcircuit exhibits a sequence of network states in which a highly recurrent state greatly curtails the alternation with other states (Fig. 2C bottom, dominant state colored in red; n = 33), as previously described in rats and mice (Jáidar et al., 2010; Pérez-Ortega et al., 2016; Aparicio-Juárez et al., 2019; Jáidar et al., 2019).

We then compared network activity in these microcircuits. The cumulative activity of every neuron, that is, the area obtained under the histograms of summed activity, was calculated for each experiment, and representative examples are shown in Fig. 3A. Straight lines were fitted to these data and the slope values for each neuron representing activity of each cell along time (active / non-active frames) were graphed as box plots (Fig. 3B). The non-stimulated Ctr microcircuit had significantly less activity than all the other conditions ($P < 0.001$; Kruskal-Wallis ANOVA, FDR correction: Ctr + CtxS, *P = 0.008; Ctr + NMDA, **P = 0.002; non-stimulated DA-depleted striatum, ***P < 0.0001; DA-depleted + CtxS striatum, ** P = 0.0015). Activity levels between stimulated controls ($P = 0.74$) and DA-depleted stimulated microcircuits (Ctr + CtxS, P = 0.96; Ctr + NMDA, P = 0.74) and non-stimulated DA-depleted microcircuits to stimulated conditions (Ctr + CtxS, P = 0.5; Ctr + NMDA, P = 0.8; DA + depleted + CtxS, P = 0.43) showed no significant differences using this test. We conclude that differences between stimulated and non-stimulated DA-depleted microcircuits are not based on the number of active neurons but the dynamics represented by the sequences of network states (Fig. 2, see also Aparicio-Juárez et al., 2019).

We next calculated cumulative distribution functions (CDFs) for cell activity by adding up the cells from all experiments in each condition (Fig. 3C). Extremes of the CDFs are non-stimulated Ctr (n = 449 cells, black trace) and non-stimulated DA-depleted (n = 1258 cells, gray trace). Stimulated controls and stimulated DA-depleted cases stand between both extreme conditions (Ctr + CtxS, n = 173 cells and DA-depleted + CtxS, n = 287 cells). Ctr + CtxS vs. DA-depleted + CtxS were not significantly different, suggesting that stimulation relieves the pathologic state found in the DA-depleted microcircuit (Pérez-Ortega et al., 2016;

Fig. 2. Striatal microcircuit activity in vitro: comparing spontaneous, stimulated, DA-depleted and DA-depleted stimulated conditions. (A-D top) Representative raster plots showing neuronal activity in single experiments of Ca^{2+} imaging recording with single cell resolution (each row in the y-axis shows the activity of a single cell - numbered; x-axis is time in min, in this and other related figures). Each dot in the plot represents firing as the first time derivative of the somatic Ca^{2+} transient from a single cell (Pérez-Ortega et al., 2016). Histograms at the middle in panels A to D show cellular coactivity and significant neuronal coactivity peaks (dotted line denotes significance level). Neurons belonging to the same neuronal ensembles are presented by different colors in their respective coactivity peaks. (A) Control striatal activity without stimulation shows little spontaneous activity (top), intervals without activity, and no significant coactive events (bottom). (B) Administration of an adequate cortical stimulus (CtxS; see Experimental Procedures and Aparicio-Juárez et al., 2019) increases overall activity in the circuit (top) reflected by significant peaks of coactivity (middle) made by different neuronal groups (colored). Each significant coactivity peak is represented by a colored circle at the bottom showing a sequence of activation of network states. The sequence of activation shows alternation between states which may reach closed cycles or reverberations (triangle at bottom right). (C) In contrast to control (panel A), non-stimulated dopamine (DA) depleted striatum shows high overall spontaneous activity (top), without applying any electrical or chemical stimuli. Significant coactivity peaks are also present (middle). However, sequences of network states show that most activity is due to a highly recurrent state (red). This behavior disrupts alternation and reverberations during the time shown (bottom right). (D) Administration of a cortical stimulus in a DA-depleted striatum dissolves the highly recurrent state and more diverse neuronal ensembles reappear as significant peaks of coactivity (middle). The sequence of network states shows again alternation (bottom) and reverberation (bottom right) between network states. Raster-plots are representative examples of samples in each condition (non-stimulated control, n = 12 experiments; Ctr + CtxS, n = 5 experiments; non-stimulated DA-depleted striatum, n = 33 experiments; DA-depleted +CtxS, n = 7 experiments).

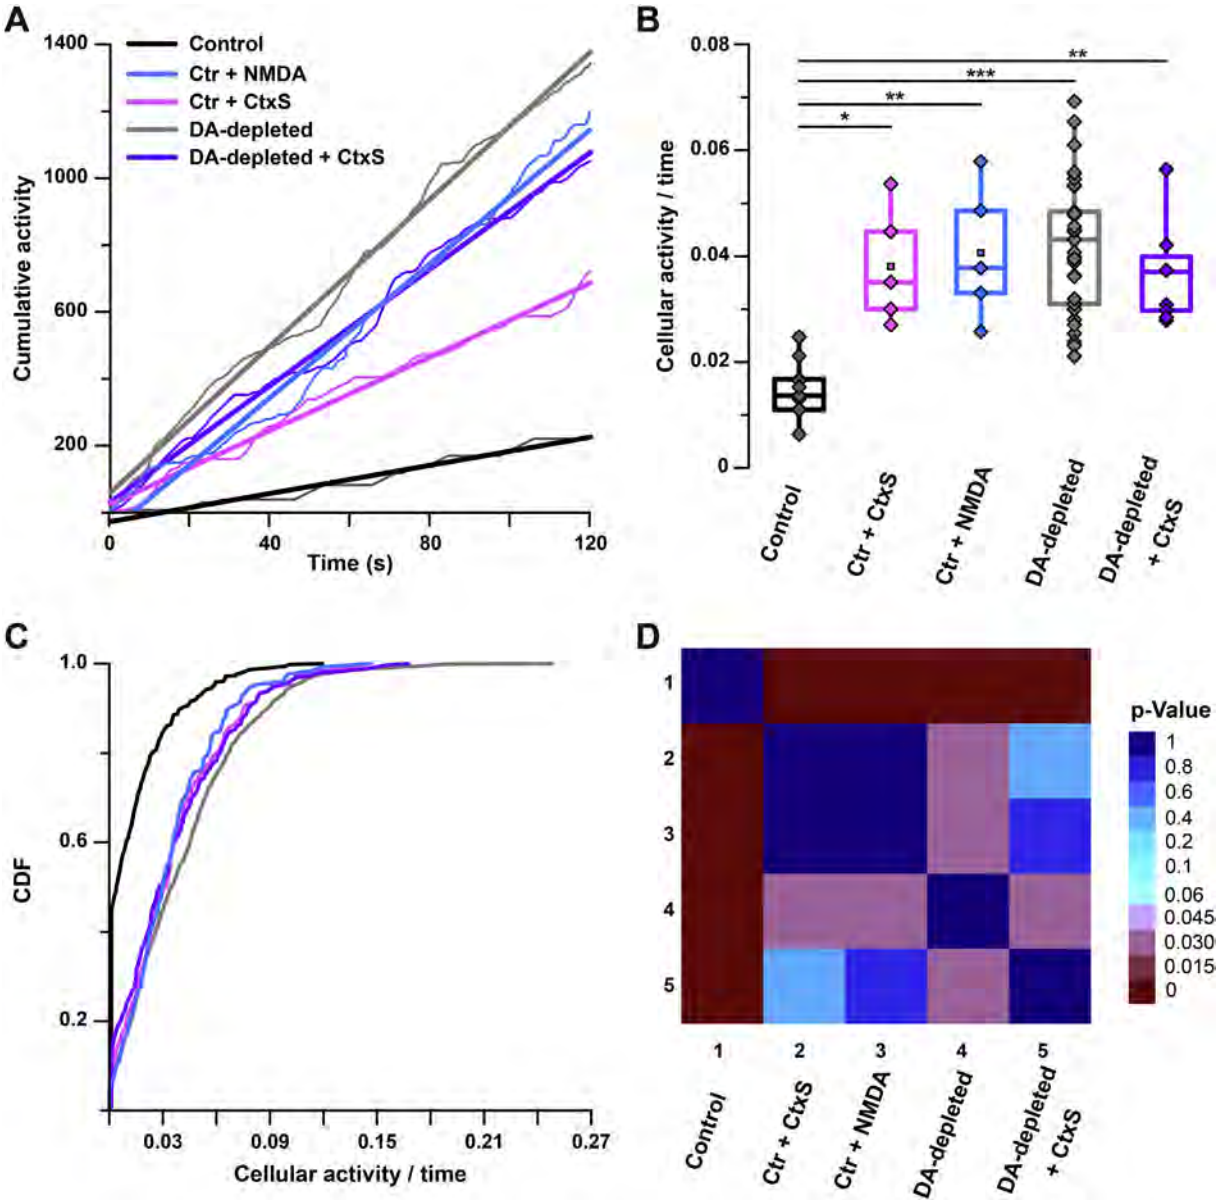


Fig. 3. Measurements of microcircuit activity in different conditions: control (Ctr) without any stimulus, control plus cortical stimulation (Ctr + CtxS), control plus NMDA administration (Ctr + NMDA), non-stimulated DA-depleted tissue (DA-depleted) and cortically stimulated DA-depleted microcircuits (DA-depleted + CtxS). (A) Cumulative activity graphs from single representative experiments as those in Fig. 2 were built adding the areas under activity histograms along time. Straight lines are fitted to the data and the slopes of fitted lines denote cellular activity along time (activity/time). (B) Box and density plots of cellular activity along time in samples of different conditions, each point is a slope obtained as in (A). All conditions are significantly different to the control (Kruskal-Wallis test with post-hoc FDR test; $P < 0.001$) but there are no differences between Ctr + CtxS, Ctr + NMDA and DA-depleted + CtxS with or without stimulation, suggesting that the level of activity is equivalent (Ctr, n = 12 experiments; Ctr + CtxS, n = 5 experiments; Ctr + NMDA, n = 5 experiments; non-stimulated DA-depleted, n = 33 experiments; DA-depleted + CtxS, n = 7 experiments), implying that differences between control and DA-depleted circuits reside in the dynamics and not the level of activity. (C) Still, we built Cumulative distribution functions (CDFs) using all cells from the different experimental samples in each condition: (Ctr, n = 449 cells; Ctr + CtxS, n = 173 cells; Ctr + NMDA, n = 127 cells; DA-depleted, n = 1258 cells; DA-depleted + CtxS, n = 287 cells). For these data, Kolmogorov Smirnov test (with post hoc pair-wise comparisons using FDR (Benjamini et al., 2006)) yielded significant differences between the non-stimulated DA-depleted circuit and stimulated Ctr and DA-depleted circuits. (D) A matrix of the significant P values confirms that control non-stimulated microcircuit differs from all four conditions. The non-stimulated DA-depleted condition shows activity significantly higher to that from Ctr + CtxS, Ctr + NMDA and DA-depleted + CtxS microcircuits. No significant differences between Ctr + CtxS, Ctr + NMDA and DA-depleted + CtxS conditions were found. *denotes statistical significance in this and other figures. FDR stands for false discovery rate correction.

Aparicio-Juárez et al., 2019). A difference with non-stimulated DA-depleted microcircuits and Ctr stimulated circuits was revealed ($P < 0.03$; Kolmogorov Smirnov tests, FDR correction test). A color matrix with post hoc FDR corrected test P-values is shown in Fig. 3D. Note that there are no significant differences between Ctr + NMDA and Ctr + CtxS

INFORME DE LABORES 2019

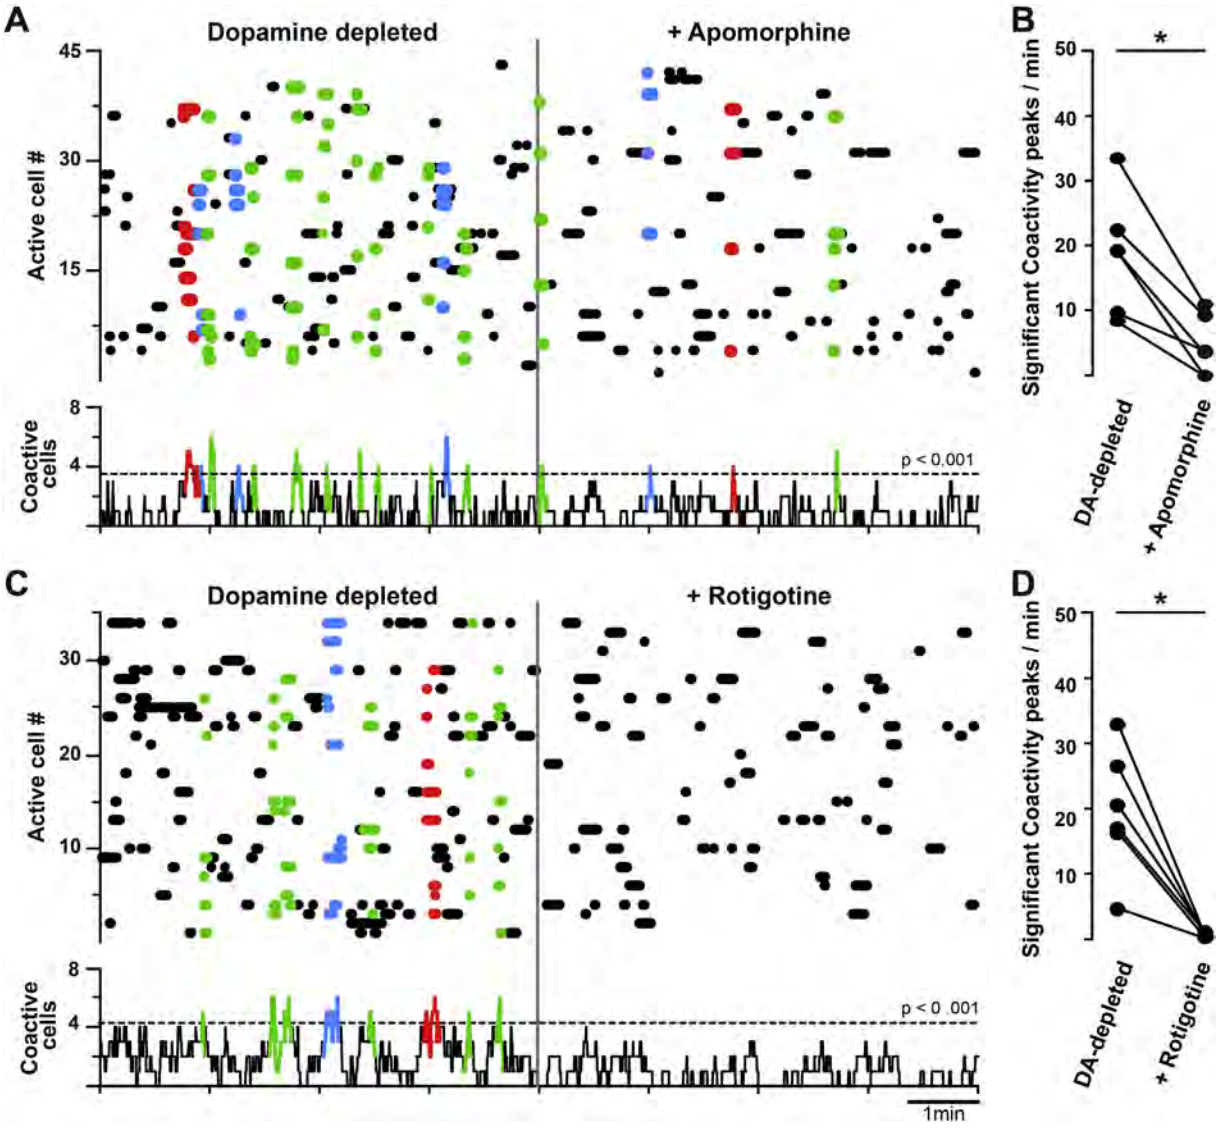

Fig. 4. $D_{1,2}$-class of DA-agonists decrease the spontaneous activity of DA-depleted microcircuits in vitro. Left sections of the raster plots (A and C) show representative non-stimulated DA-depleted microcircuit activity. Notice that in both cases peaks of significant coactivity and a highly recurrent ensemble are evident (green) prior to DA-agonists administration as shown in the histograms bellow. DA-agonists were added after the vertical line. (A) Addition of apomorphine (20 μM) reduces the number of significant coactivity peaks. (B) The reduction of coactivity peaks per minute significantly decreased after apomorphine administration compared with DA-depleted microcircuit without treatment (n = 6 experiments; Wilcoxon matched pairs signed rank test or Wilcoxon T test, P = 0.0313). (C) Addition of rotigotine (10 μM) not only decreased overall activity but also eliminated most significant peaks of coactivity (bottom). (D) This is clear when comparing significant peaks of coactivity per minute before and after rotigotine administration (n = 6 experiments; P = 0.0313; Wilcoxon T test).

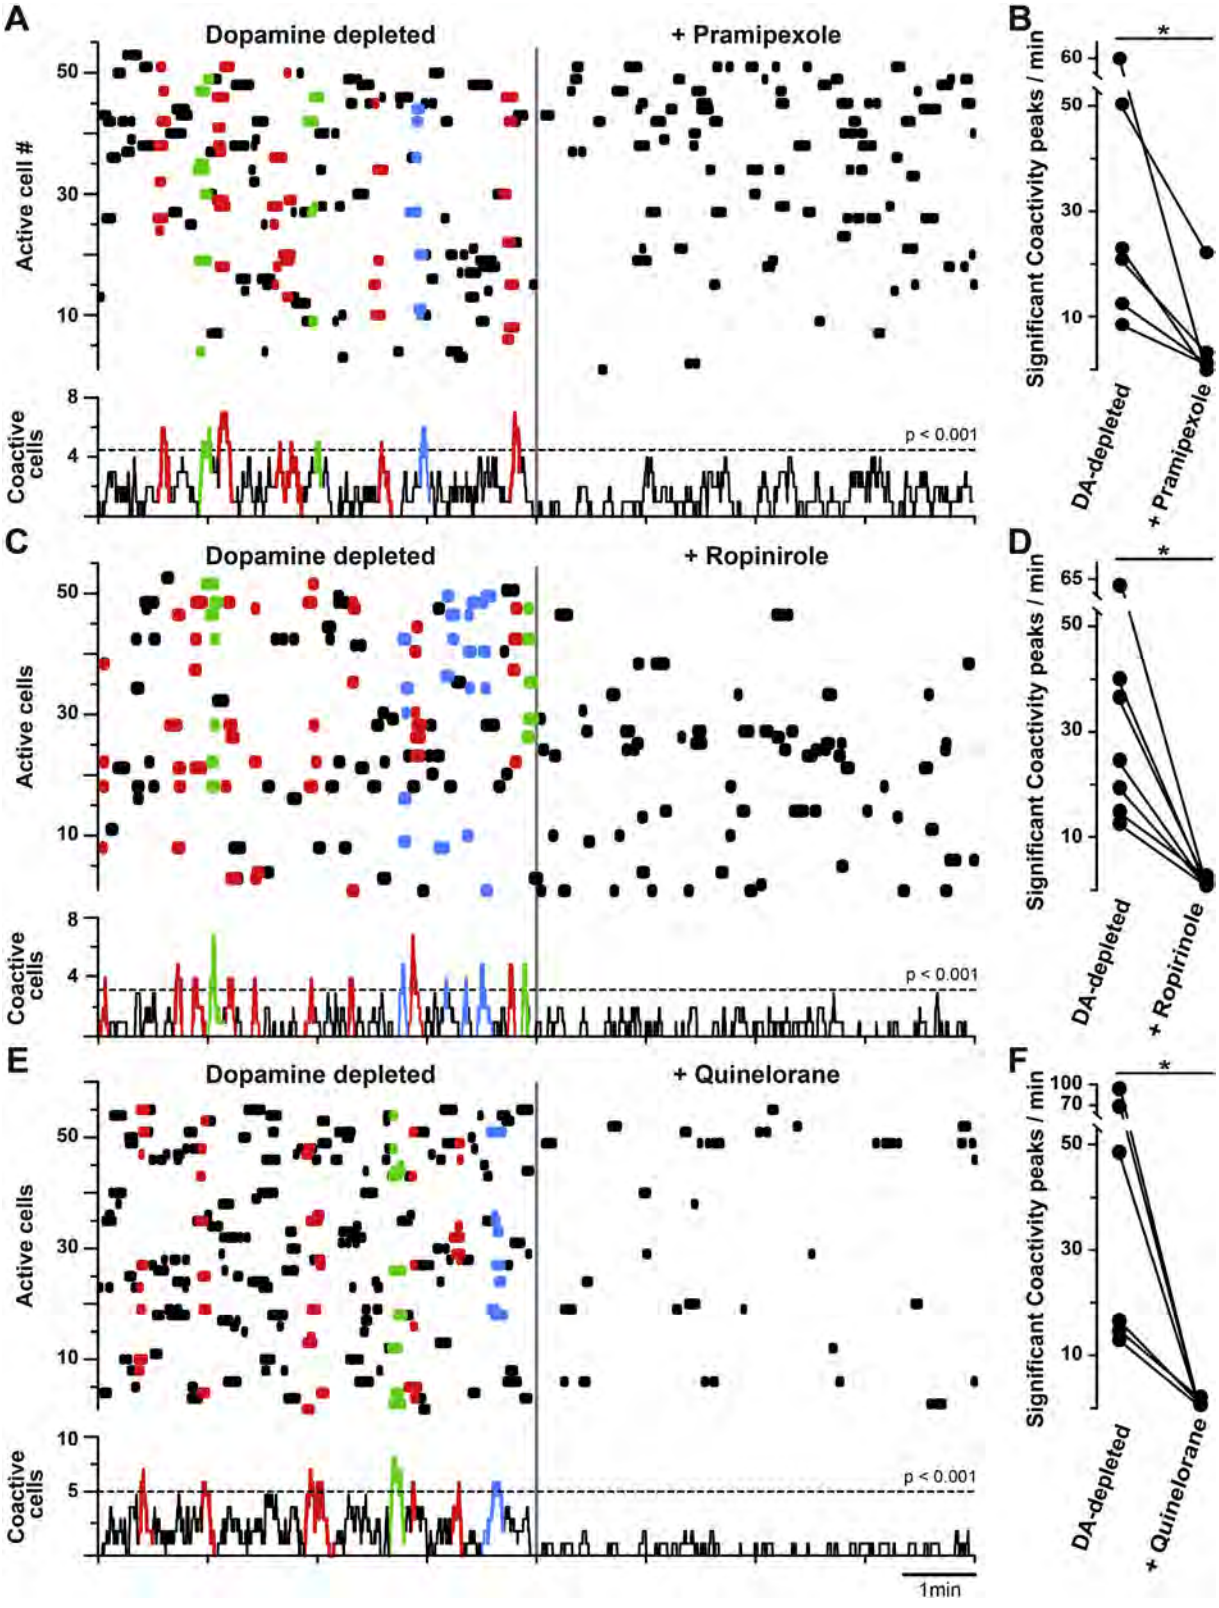
conditions, suggesting that both ways to activate striatal microcircuits are equivalent.



Dopamine receptor agonists reduce enhanced spontaneous activity in the DA-depleted microcircuit

Typically, the DA-depleted microcircuit exhibits an excess of activity compared to non-stimulated controls (cf., Fig. 2A and C). Previously, we demonstrated that the application of L-DOPA reduces spontaneous activity of the DA-depleted microcircuit to control-like levels and that this action is reversible upon washing off L-DOPA (Plata et al., 2013). Now, we compare dopamine receptor agonists (DA-agonists) in the absence of stimulus. First, we tested less selective DA-agonists (Fig. 4), that is, agonists with considerable actions on both D_1 and D_2 receptor classes. The most used in PD treatment are apomorphine and rotigotine, which bind to both D_1- and D_2-class receptors with different affinities.

$D_{1,2}$-class agonists reduced the enhanced spontaneous activity of DA-depleted microcircuits. Both 20 μM apomorphine (Fig. 4A; representative raster; the gray line divides activity before and after administering the drug) and 10 μM rotigotine (Fig. 4B, representative) showed similar effects by reducing microcircuit activity significantly. Coactivity peaks per minute were compared before and after drug administration (Wilcoxon T test), and their reduction was demonstrated

in samples of both apomorphine (Fig.4B, n = 6 experiments; P = 0.0313) and rotigotine (Fig. 4D; n = 6 experiments; P = 0.0313). The assay shows that at therapeutic but saturating concentrations rotigotine performance is better than that of apomorphine.

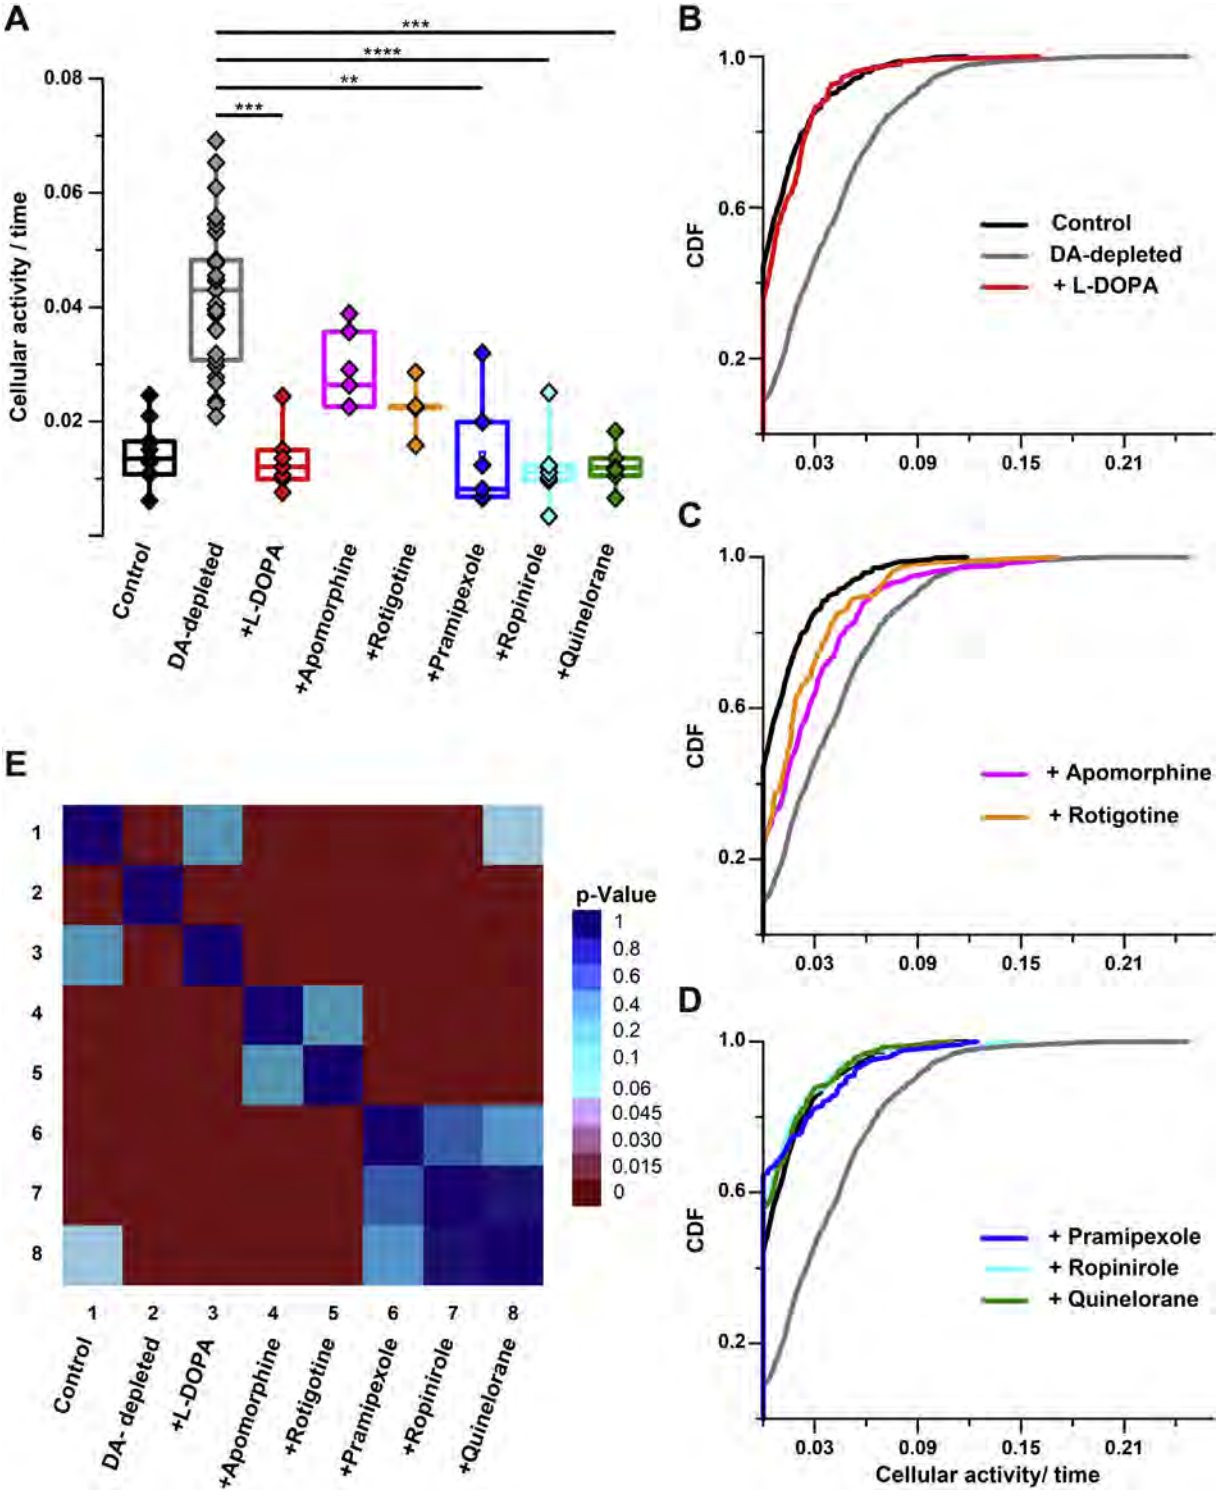
More selective D_2-class ($D_{2/3}$) receptor agonists are also used for the early treatment of PD (Stocchi et al., 2016). To explore the effects of these agonists on the enhanced spontaneous activity of DA-depleted microcircuits, 10 μM pramipexole (Fig. 5A; n = 6 experiments), 10 μM ropinirole (Fig. 5C;

n = 7 experiments) and 10 μM quinelorane (Fig. 5E; n = 6 experiments) were applied. All of them reduced the excess in spontaneous activity of DA-depleted microcircuits (pramipexole: Fig. 5B, P = 0.0313; ropinirole: Fig. 5D; P = 0.0156; quinelorane: Fig. 5F; P = 0.0313; Wilcoxon T tests). To conclude, all DA-agonists tested reduced the pathological spontaneous activity of DA-depleted microcircuits.

D_2-class receptor agonists were more effective in decreasing the spontaneous activity of DA-depleted microcircuits

All DA-agonists reduced the excess in pathological spontaneous activity of non-stimulated DA-depleted microcircuits (see previous section). To better evaluate whether there were differences between the different DA-agonists, a Kruskal-Wallis ANOVA analysis with FDR post hoc correction test between the cumulative cellular activity was made (Fig. 6A). As previously mentioned, spontaneous neuronal activity of the non-stimulated DA-depleted microcircuit was significantly enhanced in comparison with non-stimulated Ctr microcircuit (P < 0.0001; control: n = 12 experiments; DA-depleted microcircuit: n = 33 experiments). Then we compared the activity of DA-depleted microcircuits after a DA-agonist was added with that of non-stimulated DA-depleted microcircuits (Kruskal-Wallis ANOVA, P < 0.0001, post hoc FDR correction test). Activity in non-stimulated DA-depleted circuits was significantly larger than the activity in DA-depleted microcircuits plus L-DOPA (Fig. 6A; P = 0.0004; n = 7 experiments), confirming previous studies (Plata et al., 2013). Surprisingly, however, DA-depleted microcircuits treated with apomorphine or rotigotine were not significantly different from the non-stimulated DA-depleted microcircuits (Fig. 6A; P = 0.99; n = 6 experiments and Fig. 6A; P = 0.5; n = 6 experiments), suggesting that less selective agonists have a more limited action on the spontaneous activity of DA-depleted microcircuits (Jáidar et al., 2010). Nonetheless, when adding more selective D_2-agonists to DA-depleted microcircuits, activity was significantly less than that found in untreated DA-depleted microcircuits, namely: pramipexole (Fig. 6A; P = 0.00015; n = 6 experiments), ropinirole (Fig. 6A; P = 0.0001; n = 8 experiments) and quinelorane (Fig. 6A; P = 0.0001; n = 6 experiments). These results suggest that more selective D_2-class agonists were better than less selective $D_{1,2}$-class agonists in reducing the excess of spontaneous activity observed in non-stimulated DA-depleted microcircuits.

An even more stringent test was performed by comparing cumulative probability distribution functions (CDFs) for each condition using all cells from each experiment (Fig. 6B-D). First, we compared non-stimulated control CDF (n = 449 cells, black trace; Fig. 6B) with that of the non-stimulated DA-depleted microcircuit (n = 1258 cells, gray trace; Fig. 6B), and with the DA-depleted + L-DOPA (n = 232 cells, red trace; Fig. 6B). There was no significant difference between control microcircuit activity and DA-depleted microcircuit plus L-DOPA (P = 0.15; Kolmogorov–Smirnov test with FDR correction), suggesting that in this stage of experimental early Parkinsonism (i.e., "L-DOPA honey moon"), L-DOPA tends to return the microcircuit dynamics to control conditions. As expected, the CDF of the non-stimulated DA-depleted microcircuit was significantly different from these two conditions, its CDF was far right to control and L-DOPA CDFs (Fig. 6B; see graded pseudocolored matrix of paired P-values in Fig. 6E).



Using this stringent test, most DA-agonists employed could not match L-DOPA actions (Fig. 6C and D; see graded pseudocolored matrix of paired P-values in Fig. 6E Kolmogorov–Smirnov test with FDR corrections). However, quinelorane was not significantly different from the non-stimulated control (207 cells, P = 0.06). Every other CDF was significantly different from control CDF: apomorphine = 262 cells, $P = 6.6 \times 10^{-12}$; rotigotine = 139 cells, $P = 5.0 \times 10^{-6}$; pramipexole = 255 cells, P = 0.004; ropinirole = 249 cells, P = 0.006. This analysis showed that apomorphine and rotigotine CDFs were to the right of the control and L-DOPA CDFs (Fig. 6C), while D_2-agonists CDFs superimpose in part with control and L-DOPA CDFs (Fig. 6D). We conclude that D_2-agonists better reduce the excess of spontaneous activity of non-stimulated DA-depleted microcircuits, but no agonist completely emulates L-DOPA actions in this respect. Up to now, we have compared non-stimulated DA-depleted microcircuits before and after addition of L-DOPA or DA-agonists: all DA-agonists reduced spontaneous resting pathological activity when compared one by one. Though, only L-DOPA (and to a minor extent quinelorane) approached the activity of non-stimulated controls. Activity remained significantly different from control microcircuit after the reduction of pathological activity by any of the DA-agonists. It has been previously demonstrated (Aparicio-Juárez et al., 2019, Fig. 2D) that cortical stimulation reduces overall activity restoring neural ensembles sequences similar to control for a limited period of time. Therefore, we asked how DA agonists would interact with this action, perhaps prolonging it. In addition, a comparison between DA agonists actions may suggest which are the more effective.

DA-agonists actions on cortical stimulated DA-depleted microcircuits

To answer the previous questions CtxS was applied to DA-depleted microcircuits previously infused with L-DOPA or other DA-agonists. First, a representative raster plot of L-DOPA is shown in Fig. 7A (top) divided into three different epochs separated by vertical lines. Left epoch shows the

Fig. 5. Comparison of D_2-class receptor agonists effects on DA-depleted microcircuits in vitro. Panels: representative raster plots of spontaneously active DA-depleted microcircuits before and after addition of a dopamine D_2-class receptor agonist (separated by a vertical line). Histograms at bottom show significant peaks of coactive neurons in the same frame. Dotted lines on the histograms show the significance coactivity threshold to record a neuronal ensemble. (A) Representative experiment showing DA-depleted microcircuit spontaneous activity and the reduction of this activity after addition of 10 μM pramipexole. (B) Pramipexole reduced the number of significant peaks of coactivity per min (n = 6 experiments; P = 0.0313; Wilcoxon T test). (C) After the vertical line 10 μM ropinirole was added to the DA-depleted microcircuit. (D) Reduction of coactivity peaks is obvious (n = 7 experiments; P = 0.0156; Wilcoxon T test). (E) When adding 10 μM quinelorane reduction of activity was evident and (F) coactivity peaks were virtually abolished (n = 6 experiments; P = 0.0313; Wilcoxon T test).

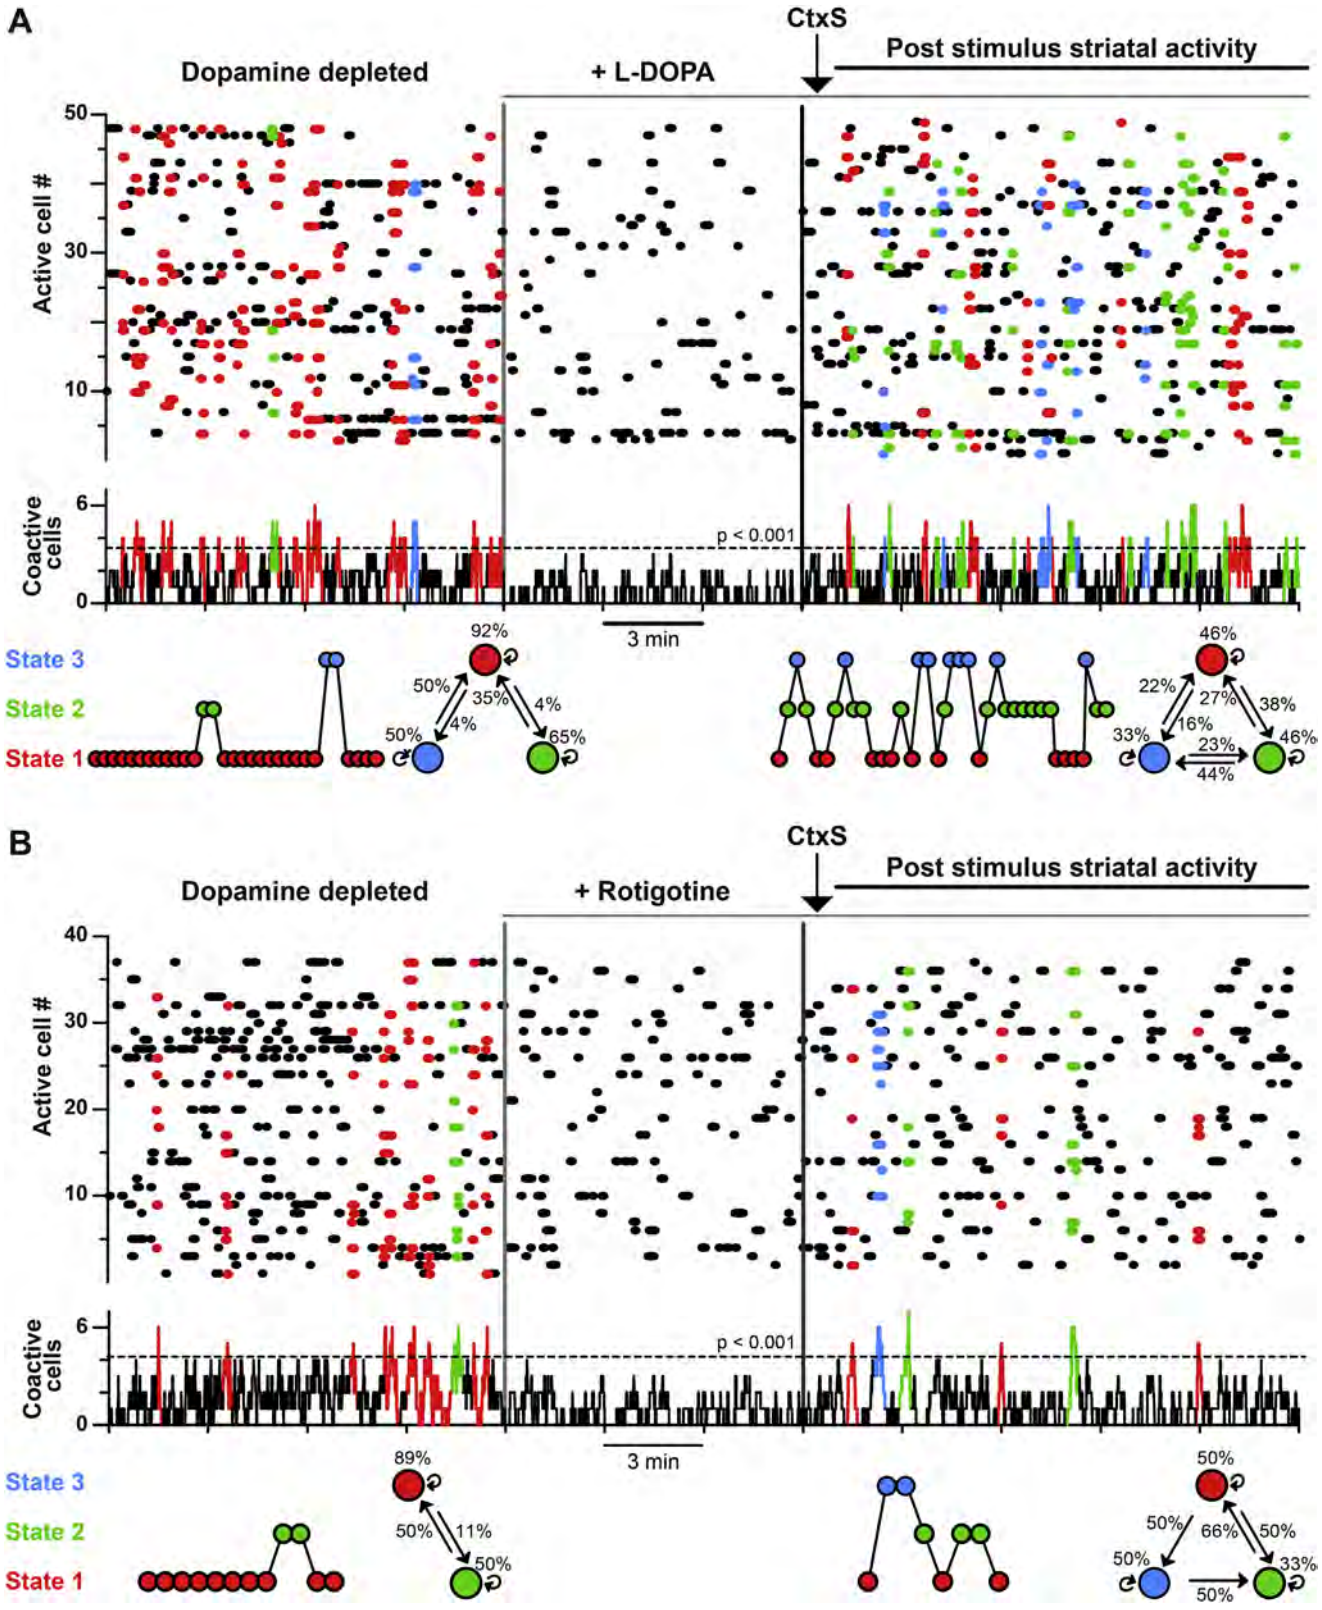
typical spontaneous activity of a DA-depleted microcircuit. Middle epoch shows the decrease of this spontaneous activity due to L-DOPA administration. Right epoch illustrates network activity after cortical stimulation (CtxS) in the continuous presence of L-DOPA, showing that activity is enhanced again. Coactivity histograms and sequences of transitions between network states (below the raster plots) show significant coactivity peaks in the DA-depleted microcircuit both before and after CtxS + L-DOPA. However, a difference is evident: the untreated DA-depleted microcircuit exhibits a highly recurrent network state that impedes reverberation (bottom), while the stimulated DA-depleted microcircuit in the presence of L-DOPA shows a variety of coactivity peaks and alternation between network states including reverberation (bottom; n = 4 experiments, see also Aparicio-Juárez et al., 2019) resembling control activity (see Fig. 2A). In the presence of L-DOPA the DA-depleted microcircuit is able respond to a

cortical command with near control-like dynamics: a sequence of network states. This experimental protocol was then applied to DA-depleted microcircuits when administering rotigotine, a representative $D_{1,2}$-agonist (Fig. 7B), pramipexole, a more selective D_2-agonist ($D_{2,3}$; Fig. 8A) and ropinirole, another D_2-agonist (Fig. 8B). Similar results to the sole administration of L-DOPA were obtained: prior to stimulation a highly recurrent state is impeding alternation and DA-agonists application have a silencing effect. When CtxS was delivered in the continuous presence of DA-agonists, network dynamics became a sequence of alternating network states.

Specifically, rotigotine induced less peaks of coactivity than L-DOPA (Mann–Whitney T test, P = 0.02), although it restored alternation between network states and closed cycles. On the other hand, pramipexole induced a more balanced alternation between network states, although in the experiment shown, closed cycles did not appear (see statistics below). Ropinirole did not restore alternation completely during the sequence of network states, but closed cycles could be present in some cases.

Performance comparison of DA-agonists on cortical activated DA-depleted microcircuits

As shown in Fig. 2, CtxS briefly and transiently recovers control stimulated network dynamics in DA-depleted microcircuits by inducing a sequence of network states activity, similar to that induced in Ctr circuits. However, this change towards control dynamics only lasts approximately 30 min (Fig. 9A top), unless L-DOPA is administered (see Aparicio-Juárez et al., 2019). In that case, a DA-depleted circuit activated by CtxS maintains the alternation of network states for a longer period of time, e.g., 60 min. Therefore, here we compare the actions of CtxS plus the presence of L-DOPA or other DA-agonists (after 60 min), and solely CtxS (30 min), over DA-depleted circuits. First, we used the number of transitions between network states to achieve a closed cycle, a measure of how much alternation between network states is allowed by the circuit (Pérez-Ortega et al., 2016), presented in pie plots (Fig. 9A). A colored scale (at the bottom) shows the number of transitions required to reach a closed cycle, where black color indicates the cases in which a closed cycle was not reached during the time of recording. Even in control conditions (Ctr + CtxS) sequences of neuronal ensembles may not reach a closed cycle during the course of the experiment (12%). When DA-depleted microcircuits receive a cortical stimulus (DA-depleted + CtxS) the highly recurrent state is transiently abolished and microcircuit dynamics resembles that of the Ctr + CtxS microcircuits (Fig. 9A top): where only a minority of sequences do not reach closed cycles (18%; P = 0.206; Kolmogorov–Smirnov test with post hoc FDR correction). This confirms that cortical stimulation briefly (30 min) relieves the microcircuit from the highly recurrent state as previously reported (Aparicio-Juárez et al., 2019). The maintenance of control-like network dynamics in stimulated DA-depleted microcircuits for longer time, e.g., 60 min, requires the action of L-DOPA (Aparicio-Juárez et al., 2019). Therefore, here we compared to what extent different DA-agonist could prolong the action of CtxS in terms of network alternation sequences and closed cycles (Pérez-Ortega et al., 2016).



It was found that, even if L-DOPA induces alternation of network states in the stimulated condition, a higher percentage of non-closed cycles, 36%, is revealed as compared with Ctr + CtxS (P = 0.007; n = 4 experiments; Kolmogorov–Smirnov test with post hoc FDR correction in this and next comparisons of this section). Still, most sequences had closed cycles. Using the same test other agonists yield: rotigotine (P = 0.002, n = 4 experiments), pramipexole (P = 0.016, n = 4 experiments) and ropinirole (P = $1X10^{-9}$, n = 4 experiments). The results suggest that even when active DA-depleted circuits exhibit sequences of network states. However, no DA-agonist, including L-DOPA, is capable of completely resembling the Ctr + CtxS circuit.

Since all active DA-depleted circuits exhibit several closed cycles we asked how many transitions between network states were needed to reach them, excluding the instances in which there were no closed cycles during recording time. Fig. 9B shows this comparison with density plots: Ctr + CtxS distribution was compared (Kruskal-Wallis

Fig. 6. D_2-class receptor agonists were more effective in decreasing the excess of spontaneous activity in DA-depleted microcircuits. (A) As in Fig. 3B, cellular activity over time was compared among the different experimental conditions (experiments/condition: non-stimulated control (Ctr) = 12, non-stimulated DA-depleted = 33, non-stimulated DA-depleted + L-DOPA = 7, + apomorphine = 6, + rotigotine = 6, + pramipexole = 6, + ropinirole = 8, + quinelorane = 6). As previously mentioned, activity over time of the non-stimulated DA-depleted microcircuit is significantly larger than that of the non-stimulated control microcircuit (P < 0.0001). DA-depleted microcircuit activity significantly decreased (Kruskal-Wallis ANOVA, P < 0.0001, with FDR correction) after administration of L-DOPA (P < 0.0004), and D2-class agonists, namely: pramipexole (P = 0.00015), ropinirole (P = 0.0001) and quinelorane (P = 0.0001). However, $D_{1,2}$-class agonists: apomorphine (P = 0.99) and rotigotine (P = 0.5) failed to differ from the DA-depleted microcircuit. (B) Cumulative distribution functions (CDFs) of cell activity from: non-stimulated control (n = 449 cells; black trace); non-stimulated DA-depleted (n = 1258 cells; gray trace) and DA-depleted + L-DOPA (n = 232 cells; red trace) microcircuits. Note that when adding L-DOPA to the DA-depleted microcircuit its CDF greatly resembles the one from control microcircuit (P = 0.15; Kolmogorov–Smirnov test with FDR correction). Non-significant differences with non-stimulated controls predicts a good therapeutic effect. (C) In this respect, CDFs from DA-depleted microcircuits after the addition of apomorphine (n = 262 cells; P = $6.6X10^{-12}$) and rotigotine (n = 139 cells; P = $5.0X10^{-6}$) showed significant differences with non-stimulated controls, that is, less selective DA-agonists did not approach the control; these DA-agonists stay in between non-stimulated Ctr and non-stimulated DA-depleted circuits. (D) In addition, compared to control CDF, CDFs from DA-depleted microcircuits after the addition of D_2-class selective DA-agonist were also significantly different to non-stimulated Ctr: pramipexole (n = 255 cells; P = 0.004), ropinirole (n = 249 cells; P = 0.006) and quinelorane (n = 207 cells; P = 0.06). However, the CDFs of these DA-agonists are nearer to control CDF (black line). (E) A matrix of P-values from pairwise comparisons, based on CDFs (Kolmogorov–Smirnov test with FDR corrections) shows that only the action of L-DOPA was not statistically different from control activity. All DA-agonists statistically differ from the control using this stringent test. D_2-agonists do not differ much among them.

ANOVA with post hoc FDR correction) with: DA-depleted microcircuits plus CtxS at 30 min (P = 0.149), and with DA-depleted microcircuits plus CtxS and DA-agonists at 60 min: L-DOPA (P = 0.736), rotigotine (**P = 0.003), pramipexole (P = 0.199) and ropinirole (***P = 0.001). These results suggest that L-DOPA and pramipexole have a better performance than rotigotine and ropinirole in DA-depleted microcircuit dynamics.

In order to unveil drugs' efficacy while making a hierarchical scale between them we used the recurrence index test

(Aparicio-Juárez et al., 2019), a measure of how much a pathological microcircuit has a highly recurrent network state that curtails alternation between neuron groups. Using this metric, all DA-agonists were significantly similar to control stimulated circuits (O'Brien homogeneity of variance test): DA-depleted + CtxS (30 min) P = 0.073, and at 60 min: L-DOPA + CtxS (P = 0.186); rotigotine + CtxS (P = 0.079); pramipexole + CtxS (P = 0.214); ropinirole + CtxS, P = 0.071). These results suggest that clinically available DA-agonists help maintaining microcircuit dynamics away from the typically highly recurrent dominant state network seen in DA-depleted conditions, even if they fail to completely preserve CtxS effects along time.

DISCUSSION

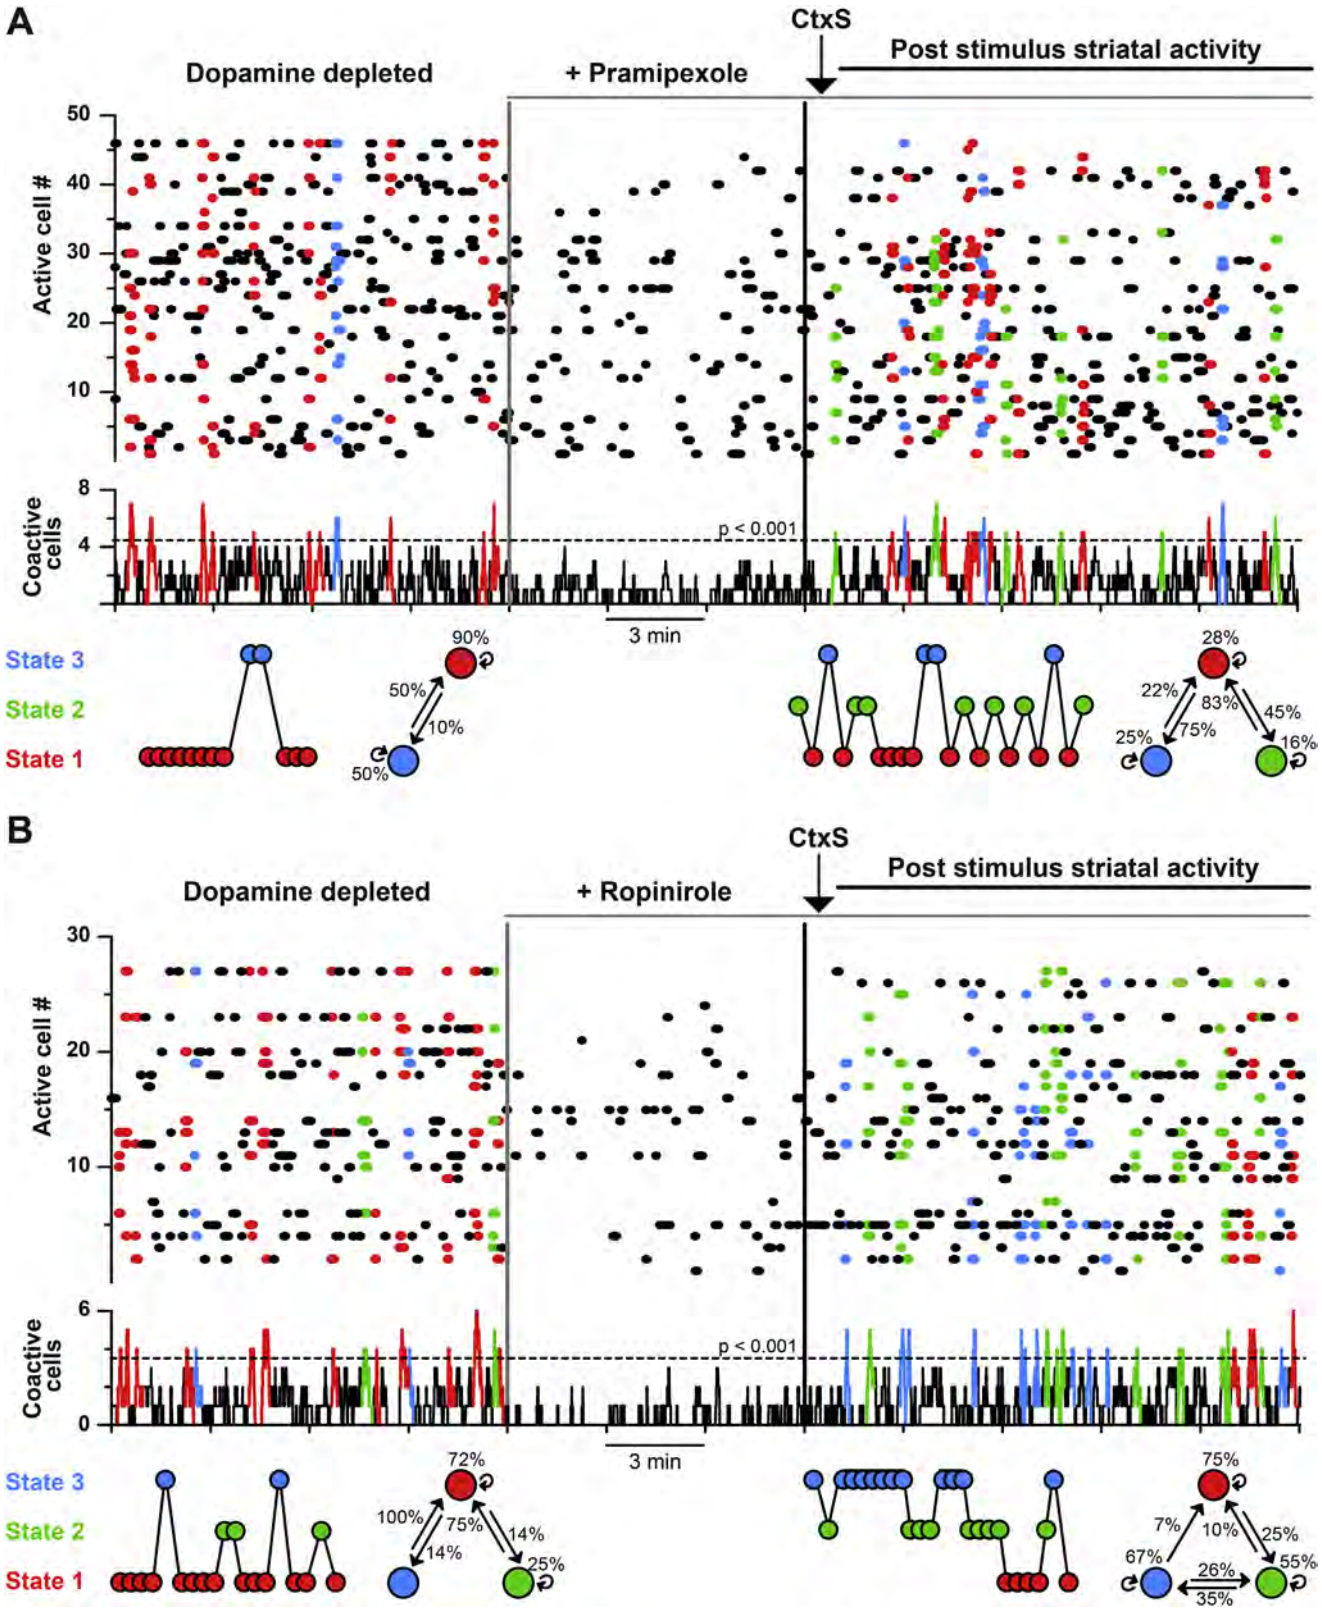
Previously, we have described some properties of the striatal microcircuit at histological scale (dozens of neurons) in vitro, to compare controls with DA-depleted microcircuits (Carrillo-Reid et al., 2008; Jáidar et al., 2010; Carrillo-Reid et al., 2011; López-Huerta et al., 2013; Pérez-Ortega et al., 2016). Because between molecular-cellular studies (Millan, 2010) and in vivo animal models (Liang et al., 2008; Dunnet and Lelos (2010) or clinical studies (Lam, 2000), there is a gap: pharmacological tools or studies at the microcircuit level in vitro, where drug concentrations can be controlled. The present work intends to use some previously described striatal microcircuit properties in vitro to compare antiparkinsonian agents used in PD therapeutics.

Spontaneous striatal activity

As seen in vitro, non-stimulated control striatal microcircuits at a histological scale show little activity (Plata et al., 2013; Aparicio-Juárez et al., 2019), similar to the activity seen in resting subjects in vivo (Mink, 2003; Parker et al., 2018). In contrast, striatal microcircuits depleted of dopamine show a significantly enhanced spontaneous activity, mainly consisting of a highly recurrent network state (Liang et al., 2008; Jáidar et al., 2010; Pérez-Ortega et al., 2016; Jáidar et al., 2019), with both indirect and direct pathway striatal projection neurons (Parker et al., 2018; Jáidar et al., 2019). Because the non-stimulated microcircuit behaves differently in control and after DA-depletion, exhibiting different functional network architectures (Pérez-Ortega et al., 2016), here we considered the non-stimulated and stimulated microcircuits separately.

The present results show that pramipexole, ropinirole and quinelorane, more selective D_2-class DA-receptor agonists ($D_{2,3}$-types), greatly decrease the enhanced spontaneous activity of non-stimulated DA-depleted microcircuits. Less selective $D_{1,2}$-agonists such as apomorphine and rotigotine were not that good in decreasing this enhanced spontaneous activity. L-DOPA was better in suppressing this enhanced spontaneous activity than any other DA-receptor agonist, suggesting that when a Parkinsonian subject is at rest, D_2-class DA-agonists signaling would better control rigidity and resting tremor, the clinical correlates of this enhanced activity.

Cortical stimulated striatal microcircuits



Striatal microcircuit activity in vitro can be elicited in control conditions by chemical or electrical stimulus. Low concentrations of NMDA (2 μM in mice) maintains in vitro microcircuits activated for long periods of time (Fig. 3, see also Carrillo-Reid et al., 2008), as well as, electrical cortical stimulation (Control + CtxS). Activation of control microcircuits significantly above spontaneous activity can last about half an hour or more (Fig. 2B, Aparicio-Juárez et al., 2019), resembling in vivo microcircuits during movement (Mink, 2003; Cui et al., 2014; Parker et al., 2018). The mechanism by which the striatal microcircuit remains active long after the stimulus is unknown. A working hypothesis is that spontaneously active excitatory interneurons, such as cholinergic interneurons (Goldberg and Wilson, 2005; Tepper et al., 2018; Surmeier et al., 2011) may ignite microcircuit activation.

Once activated, striatal microcircuits are characterized by sequences of significant and transient coactivity peaks, given by different neuronal groups or ensembles (Hebb, 1949; Edelman, 1993; Carrillo-Reid et al., 2008; Buzsaki, 2010; Carrillo-Reid et al., 2017; Klaus et al., 2017), composed of functionally connected neurons (Buzsaki, 2010; Carrillo-Reid et al., 2015). Different neuronal groups show alternation between them (Carrillo-Reid et al., 2008, 2009; 2017), reflecting behavioral stages in vivo (Klaus et al., 2017; Owen et al., 2018; Parker et al., 2018). In contrast, alternation between ensembles is restricted in DA-depleted microcircuits in which a highly recurrent network state which correlates with in vivo locked or disturbed locomotion, and reduced encoding specificity (Parker et al., 2018). Changes in synaptic plasticity after DA-depletion have been reported (e.g., Calabresi et al., 2006; Gerfen and Surmeier, 2011; Barroso-Flores et al., 2015; Deffains and Bergman, 2015) and those might underlie the lack of alternation between ensembles.

Interestingly, in CtxS DA-depleted microcircuits, the highly recurrent state disappears temporarily, mitigating

Fig. 7. Cortical stimulation activates DA-depleted microcircuits similarly to control stimulated circuits when $D_{1,2}$-class dopamine receptor agonists are present. Representative raster-plots are divided by vertical lines into three epochs. 1) Non-stimulated DA-depleted spontaneous activity, 2) Addition of 10 μM L-DOPA (A) or 10 μM rotigotine (B) to the microcircuit, and 3) Activity after cortical stimulation (CtxS) in the presence of DA-agonists. Histograms bellow each raster plot show significant coactivity events, which are colored according to network states. In both cases (A and B) non-stimulated DA-depleted microcircuits show a highly recurrent state (colored in red) and less alternation, confirmed by the sequence of network states which fail to form closed loops. Both L-DOPA (A) and rotigotine (B) eliminate significant coactivity peaks and decrease spontaneous activity. In that condition, cortical stimulation reignites activity in the DA-depleted circuit in the presence of the DA-agonists. Microcircuits exhibit several and alternating significant peaks of coactivity (histogram and sequences at bottom). Activation sequences now allow reverberations during recording time. At glance, peaks of coactivity are less likely to occur after cortical stimulation in the presence of rotigotine as compared to L-DOPA.

pathological network dynamics (Figs. 2, 3). There are no significant differences when comparing Ctr + CtxS with DA-depleted + CtxS circuits within 30 min of stimulation (in early Parkinsonism). However, after 30 min the highly recurrent state is reestablished. L-DOPA administration prolongs the improvement (e.g., 60 min), which in in vitro activated circuits is seen as a recovery of network states alternations (Aparicio-Juárez et al., 2019). We used different statistical analyses to compare the actions of different DA-agonists in DA-depleted + CtxS microcircuits 60 min

INFORME DE LABORES 2019

after the stimulus, using the property of alternation between ensembles activity. We focused on the actions of the most used DA-agonists in PD therapeutics (Blandini and Armentero, 2014; Stocchi et al., 2016). Future work will test other drugs (Millan, 2010).

Dopamine receptor agonists actions on cortical stimulated striatal microcircuits

At a first glance (see statistical comparisons below), all DA-agonists had an action similar to that of L-DOPA on DA-depleted + CtxS microcircuits (Figs. 7, 8): alternation between network states and closed cycles during the time of recording were recovered. The highly recurrent network state was dissolved (Jáidar et al., 2010; Aparicio-Juárez et al., 2019).

However, we quantitatively compared the actions of DA-agonists with different metrics. First, distributions of the number of transitions required to close a cycle were compared (pie plots in Fig. 9A black color indicates that no cycle was closed during recording time; Kolmogorov–Smirnov tests with post hoc FDR corrections). Within the first 30 min after the stimulus, DA-depleted + CtxS circuits yielded a distribution that was not significantly different than that from Ctr + CtxS circuits ($P = 0.206$). In contrast, all DA-agonists tested 60 min after CtxS in DA-depleted circuits had distributions of the number of transitions required to close a cycle significantly different than Ctr + CtxS circuits, suggesting that no DA-agonist, including L-DOPA, is capable of maintaining CtxS effects.

Thereafter, we excluded the cases with unclosed cycles. The measurements showed that L-DOPA and pramipexole produce a better performance than rotigotine and ropinirole, suggesting that L-DOPA and pramipexole will better improve movement in Parkinsonian subjects.

Finally, the presence of a highly recurrent network state is another signature of in vitro DA-depleted microcircuits. The presence of this condition may be measured with a recurrence index (Aparicio-Juárez et al., 2019). This is shown in box plots as increased variance (Fig. 9C; O'Brien homogeneity of variance test). A comparison of DA-agonists in DA-depleted + CtxS circuits after 60 min of stimulation showed that all DA-agonists have some benefit on stimulated DA-depleted circuits.

Correlations

The present work aims to show that the use of behavioral tests in animal models of PD (Liang et al., 2008; Dunnet and Lelos, 2010) as well as molecular and cellular studies (Millan, 2010) to investigate neurological therapies may be assisted with in vitro bio-assays that record several neurons during microcircuit dynamics. The theoretical framework to find circuit features to measure quantitatively posits that vertebrate neurons work together forming neuronal ensembles or groups (e.g., motoneurons pools) and that a microcircuit of histological scale can be seen as a temporal sequence of neuronal ensembles (Hebb, 1949; Edelman, 1993; Carrillo-Reid et al., 2008; Buzsaki, 2010; Carrillo-Reid et al., 2017; Klaus et al., 2017). In addition, synaptic plasticity abnormalities during PD have been described (Calabresi et al., 2006; Gerfen and Surmeier, 2011), as well as the connections within an ensemble (Carrillo-Reid et al., 2017) and closed cycles or reverberations (Carrillo-Reid et al., 2008). Moreover, sequences of neuronal ensembles have been correlated with motor actions in vivo (Klaus et al., 2017; Owen et al., 2018; Parker et al., 2018), showing the crucial role of interneurons (Owen et al., 2018).

By using this framework, we provide circuitry correlates to the usefulness of D_2-class agonists as initial mono-therapy in early PD, evidencing insufficient performance in the case of ropinirole, and supporting L-DOPA as the leading option in advanced PD (Rascol et al., 1998; Reichmann, 2000; Radad et al., 2005; UK PD MED Collaborative Group, 2014; Zesiewicz et al., 2017). Further, we show a poorer performance of the less selective $D_{1,2}$ DA-agonists. Not expected in the logic that occupancy of both receptors may be thought to prevent the disarray in their signaling, but consistent with previous results showing that bath application of a selective D_1-agonist (SKF81297) does not revert the enhanced spontaneous activity in non-stimulated DA-depleted microcircuits (Jáidar et al., 2010). Microcircuit results support previous multivariate binding analyses that show that these two classes of agonists belong to different pharmacological families (Millan, 2010). In addition, a subtle difference between pramipexole and ropinirole was disguised. In the present bio-assay the chosen DA-agonists were administered continuously and for a short period of time, in contrast to a pulsatile activation for a very long time (Fabbrini et al., 1988). Long-lasting and dramatic reduction in motor complications have been observed in advanced PD patients when the treatment is not pulsatile (Nutt et al., 2000; Devos and DUOPOPA Study Group, 2009). Therefore, our results support the development of an oral long-acting form of L-DOPA (Olanow and Stocchi, 2017) since all DA-agonists were below L-DOPA performance. At the

Fig. 8. Cortical stimulation activates DA-depleted microcircuits similarly to the control stimulated circuit when D_2-class dopamine receptor agonists are present. Representative raster-plots are divided by vertical lines into three epochs. 1) Non-stimulated DA-depleted spontaneous activity, 2) Addition of 10 μM pramipexole (A) or 10 μM ropinirole (B) to the microcircuit, and 3) activity after cortical stimulation (CtxS) in the presence of DA-agonists. Histograms bellow each raster plot show coactivity events, and significant peaks are colored according to network states. In both cases (A and B) non-stimulated DA-depleted microcircuits show a highly recurrent state (colored in red) and less alternation, confirmed by the sequence of network states which fail to form closed loops. Both pramipexole (A) and ropinirole (B) are sufficient to abolish significant coactivity peaks. Finally, cortical stimulation reignites activity in the DA-depleted circuit in the presence of DA-agonists. Stimulated network activity now exhibits different significant coactivity peaks (histogram and sequences at bottom) that alternate their activity forming sequences. In these cases, pramipexole better reduced activity of the highly recurrent network state, however, in this case closed cycles did not appear during recording time (A), on the other hand, ropinirole shows less alternation between network states but closed cycles or reverberations were commonly completed.

INFORME DE LABORES 2019

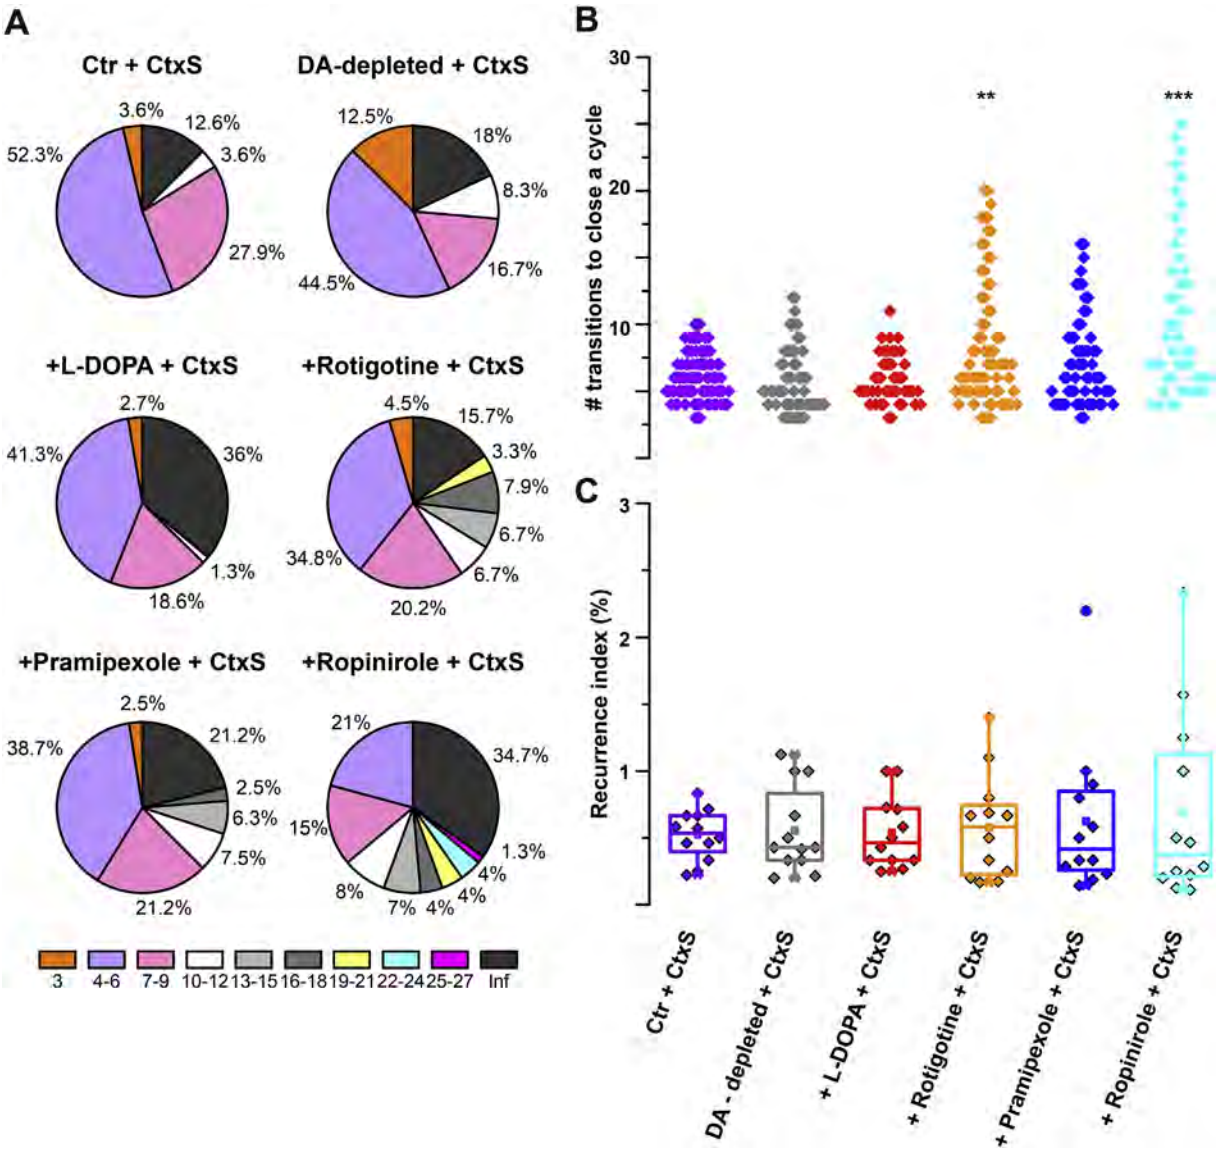


Fig. 9. Performance comparisons of DA-agonists on cortical activated DA-depleted microcircuits. (A) Pie plots show number of network state transitions necessary to close a cycle (see color scale below), including the cases in which there were no closed cycles during recording (in black). Top: the first 30 min after cortical stimulation of the DA-depleted microcircuit in absence of any drug (n = 4 experiments) was compared with control stimulated microcircuits (n = 5 experiments): there is no significant difference (Kolmogorov–Smirnov test with post hoc FDR correction, P = 0.206). Then, actions of DA-agonists on DA-depleted + CtxS circuits were compared with CtxS control circuits 60 min after stimulation (Aparicio-Juárez et al., 2019). In this condition, we compared different DA-agonists to find which one was not statistically different (resembled more) to control activated circuits: L-DOPA (P = 0.007, n = 4 experiments), rotigotine (P = 0.002, n = 4 experiments), pramipexole (P = 0.016, n = 4 experiments) and ropinirole ($P = 1X10^{-9}$, n = 4 experiments). The results of this stringent test were that no DA-agonist, including L-DOPA, is capable to completely resemble the control activated (Ctr + CtxS) circuit. (B) To see if these results were due to the number of incomplete cycles, we excluded them from the analyses and simply looked at the number of transitions required to close a cycle (when they could be closed during recording time). These data are displayed in density plots: Ctr + CtxS distribution was compared (Kruskal-Wallis ANOVA with post hoc FDR correction) with: DA-depleted + CtxS at 30 min (P = 0.149) and with CtxS plus a given DA-agonist at 60 min: L-DOPA + CtxS (P = 0.736), rotigotine + CtxS (**P = 0.003), pramipexole + CtxS (P = 0.199) and ropinirole + CtxS (***P = 0.001). This metric shows that L-DOPA and pramipexole produce a better microcircuit performance than rotigotine and ropinirole after CtxS. (C) A third metric was the recurrence index (Aparicio-Juárez et al., 2019) which indicates the appearance of a highly recurrent network state, shown in Tukey box plots as increased variance, and compared with the O'Brien homogeneity of variance test. In this perspective, DA-depleted + CtxS (30 min) P = 0.073 was not significantly different. While DA-agonists + CTxS compared at 60 min yield: L-DOPA + CtxS (P = 0.186); rotigotine + CtxS (P = 0.079); pramipexole + CtxS (P = 0.214); ropinirole + CtxS, P = 0.071), showing that all DA-agonists have some positive effect on active stimulated DA-depleted circuits, maintaining them out of a complete Parkinsonian dynamics after being activated by CtxS.

same time we confirm that no drug, including L-DOPA, completely restores circuitry function. However, new drugs and drug combinations (Millan, 2010) can also be tested with the present preparation. In addition, the action of CtxS to the DA-depleted circuit suggests that a combination of electrical plus pharmacologic stimulation may be helpful.

In conclusion, the present results show that microcircuit properties can be used to compare different drugs used in

neurological disorders, in particular, Parkinson's disease. By using calcium imaging with single cell resolution and recording dozens of cells simultaneously we found different effectiveness of DA-agonists in reversing pathological network dynamics in both, the resting non-stimulated tissue and the active stimulated one. A hierarchy in agonists performance was found: L-DOPA > selective D_2-class agonists > less selective $D_{1,2}$-class agonists. Paralleling cellular, behavioral and clinical studies (Baker et al., 2009; Bello et al., 2017; Blandini and Armentero, 2014; UK PD MED Collaborative Group, 2014).

Abstract: Hyperpolarization-activated cationic HCN channels comprise four members (HCN1–4) that control dendritic integration, synaptic transmission and action potential firing. In the kidney, HCN1, HCN2 and HCN3 are differentially expressed and contribute to the transport of sodium, potassium (K^+) and ammonium into the nephrons. HCN3 is regulated by K^+ diets in the kidney. In this work we performed a proteomic analysis of HCN3 expressed in human embryonic kidney cells (HEK293 cells). More than 50% of the interacting proteins belonged to mitochondria. Therefore, we explored the presence of HCN channels in kidney mitochondria. By immunoblotting and immunogold electron microscopy HCN3 protein expression was found in rat kidney mitochondria; it was also confirmed in human kidney. Patch-clamp recordings of renal mitochondria and mitochondria from HEK293 cells overexpressing HCN1, HCN2 and HCN3 channels, stained with MitoTracker Green FM, indicated that only HCN3 could produce inwardly K^+ currents that were inhibited by ZD7288, a specific blocker of HCN channels. Furthermore, ZD7288 caused inhibition of the oxygen consumption coupled to ATP synthesis and hyperpolarization of the inner mitochondrial membrane. In conclusion, we show for the first time that pacemaker HCN channels contribute to K^+ transport in mitochondria facilitating the activity of the respiratory chain and ATP synthesis by controlling the inner mitochondrial membrane potential.

Keywords: mitochondria; kidney; mitochondrial potassium channel; hyperpolarization-activated cyclic nucleotide-gated cationic HCN channels in mitochondria; potassium transport in mitochondria; mitochondria uncoupling

1. Introduction

The large number of mitochondria in the kidney provides the energy required to remove waste products and maintain electrolyte balance. Mitochondria are important organelles for cell viability,

INFORME DE LABORES 2019

since they produce ATP via oxidative phosphorylation (OXPHOS) and play an active role in calcium homeostasis, reactive oxygen species (ROS) production and apoptosis. The electron transport system (ETS) and the ATP synthase are located in the inner mitochondrial membrane (IMM) and are essential components for the generation and preservation of energy metabolism [1]. The high negative value of the IMM potential ($\Delta\Psi m$) required for oxidative phosphorylation is a powerful driving force for potassium (K^+) uptake. Therefore, dynamic regulation of mitochondrial K^+ flux in vivo is necessary to maintain the structural and functional membrane integrity for oxidative phosphorylation. To avoid swelling and lysis, the ion leakage in the mitochondria has to be balanced by extrusion of ions against the electrical gradient and this mechanism is accomplished by the mitochondrial K^+ cycle [2].

The electrogenic transport of K^+ into the mitochondrial matrix is strictly ion-channel-dependent. Activation of mitochondrial K^+ channels is a hallmark of cell death and plays a central role in cardiomyocytes and neuron protection [3–5]. Mitochondrial K^+ channels, such as the ATP-regulated (mitoKATP) channel, the Ca^{2+}-activated K^+ (mitoKCa) channel, the voltage-gated Kv1.3 (mitoKv1.3) channel and the two-pore domain TASK-3 (mitoTASK) channel, have been documented at the IMM of different organs, tissues or glioma cell lines. IMM K^+ channels contribute to the regulation of the matrix volume, to establish $\Delta\Psi$ and ΔpH, to calcium influx and to ROS production [6,7]. Activation of IMM K^+ channels favors an uncoupling effect that could in turn decrease energetic efficiency [8]. So far only an ATP-sensitive K^+ transport pathway has been documented in the rat kidney mitochondria [9].

The hyperpolarization-activated cyclic nucleotide-gated cationic (HCN) channels comprise four members termed HCN1–4 [10]; they have a pacemaker activity in excitable tissues controlling excitability, establishment of the resting membrane potential, dendritic integration, synaptic transmission and action potential firing [11,12]. Previously, we found that HCN channels transport ammonium (NH_4^+) in addition to Na^+/K^+ in the acid-secretory type-A intercalated cells of distal nephron segments of the kidney [13], contributing to the acid-base balance. Among HCN channel subtypes only HCN1, HCN2 and HCN3 are expressed and differentially distributed in the proximal convoluted tubule, the thick ascending limb of Henle, connecting tubule and collecting ducts of the rat kidney [14]. Due to the wide and abundant distribution of HCN3 in the kidney, in this work we performed a proteomic analysis of HCN3 overexpressed in HEK293 cells. Analysis of the proteomic data revealed interaction of HCN3 with mitochondria proteins. By immunoblotting, immunogold electron microscopy, patch-clamp recordings, oximetry and $\Delta\Psi$ measurements, we confirmed this prediction and determined that HCN channels behave as open K^+ channels in the kidney mitochondria, contributing to oxygen consumption, ATP synthesis and $\Delta\Psi$ establishment.

2. Results

2.1. Proteomic Analysis of HCN3 Channel

HCN3 is differentially expressed in the rat kidney: proximal tubules and thick ascending limb of Henle and its protein abundance is regulated by K^+ metabolism [14]. In this study, proteomics and bioinformatics analyses were performed to establish a protein-protein interaction network (interactome) associated with HCN3. For this purpose, HCN3 protein was immunoprecipitated from transfected HEK293, electrophoretically separated and analyzed by mass spectrometry. Mitochondrial proteins were the most prominent protein family identified (Table 1).

The resulting candidate proteins had a percentage ≥95% of reliability (Protein AutoCurate green), highlighting the robustness of the analytical method. * Proteins identified with at least one Gene Ontology (GO) term related with mitochondria (www.geneontology.org, www.pantherdb.org and www.string-db.org) and these proteins are listed in the actual version of the MitoProteome database (www.mitoproteome.org).

2.2. Identification of HCN Potassium Channels in Kidney Mitochondria

To investigate HCN3 expression in mitochondria, we performed immunoblot analysis with mitochondria isolated from the renal cortex. Immunoblotting of all HCN subtypes revealed very low amounts of HCN2 and abundant expression of HCN3 in kidney mitochondria. α-tubulin and VDAC were used as negative and positive controls of mitochondria abundance, respectively (Figure 1a). Therefore, we proceeded to study HCN3 protein expression in HEK293 cells. Before the transfection

INFORME DE LABORES 2019

assay with each member of the HCN family (HCN1–4) in HEK293 ells, we analyzed and confirmed the expression of endogenous HCN1, HCN2 and HCN3 (Figure 1b). However, only HCN3 was detected in the mitochondrial fraction. In contrast, overexpression of HCN1–4 channels in HEK293 cells showed that HCN3 and HCN4 could be trafficked to mitochondria (Figure 1b,c).

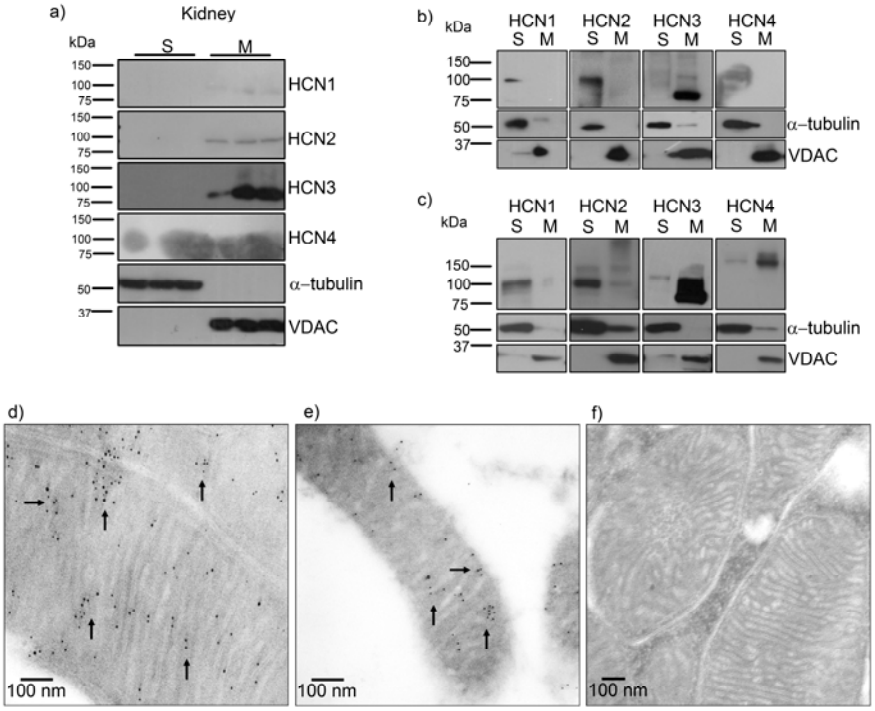

Figure 1. HCN3 channel expression in mitochondria isolated from renal cortex and HEK293 cells. (**a**) Immunoblotting of HCN1, HCN2, HCN3 and HCN4 with polyclonal antibodies detected only HCN2 (~94 kDa) and HCN3 (~86 kDa) in renal mitochondria. α-tubulin (~50 kDa) and voltage dependent anion channel (VDAC, ~31 kDa) were used as negative and positive controls of mitochondria abundance, respectively. (**b**) Immunoblotting of HCN1, HCN2, HCN3 and HCN4 in supernatant (S) and mitochondria (M) of control HEK293 cells. (**c**) Immunoblotting of HEK293 cells transfected with HCN1, HCN2, HCN3 and HCN4 in supernatant (S) and mitochondria (M). Only HCN3 (86 kDa) and HCN4 (160 kDa) were observed in HEK293 mitochondria. Immunogold electron microscopy localization of HCN3 (arrows) in the inner mitochondrial membrane of mitochondria from (**d**) rat (renal cortex) and (**e**) human kidney. (**f**) Negative control was performed in the absence of the primary antibody.

HCN3 immunogold labeling was developed in rat and human renal tissue and examined by electron microscopy. HCN3 was localized specifically in the IMM in rat and human (Figure 1d,e). Human mitochondria looked smaller than rat mitochondria since they were recovered from formalin-fixed paraffin-embedded tissues.

2.3. Functional Characterization of HCN Channels in Mitochondria

We aimed to study HCN3 functional expression in mitochondria isolated from the renal cortex (Figure 2a–c). To identify clearly mitochondria and separate them from cell debris, we incubated the isolated mitochondria with the mitochondria-selective fluorescent label MitoTracker Green FM (Figure 2a). Patch clamp recordings obtained from isolated mitochondria (whole-mitochondria recordings) evidenced the presence of hyperpolarization-activated K^+ currents (Figure 2b,c) that were inhibited by the HCN-specific inhibitor, ZD7288 (Figure 2b,c). Based on immunoblotting assays (Figure 1a) and the time constant of activation (τ) at −100 mV of 1120 ± 450 ms (n = 17), the currents observed in kidney mitochondria were produced mostly by HCN3 channels (Figure 1a) since HCN2 displays a fast activation (τ = 562 ± 198) [15].

INFORME DE LABORES 2019

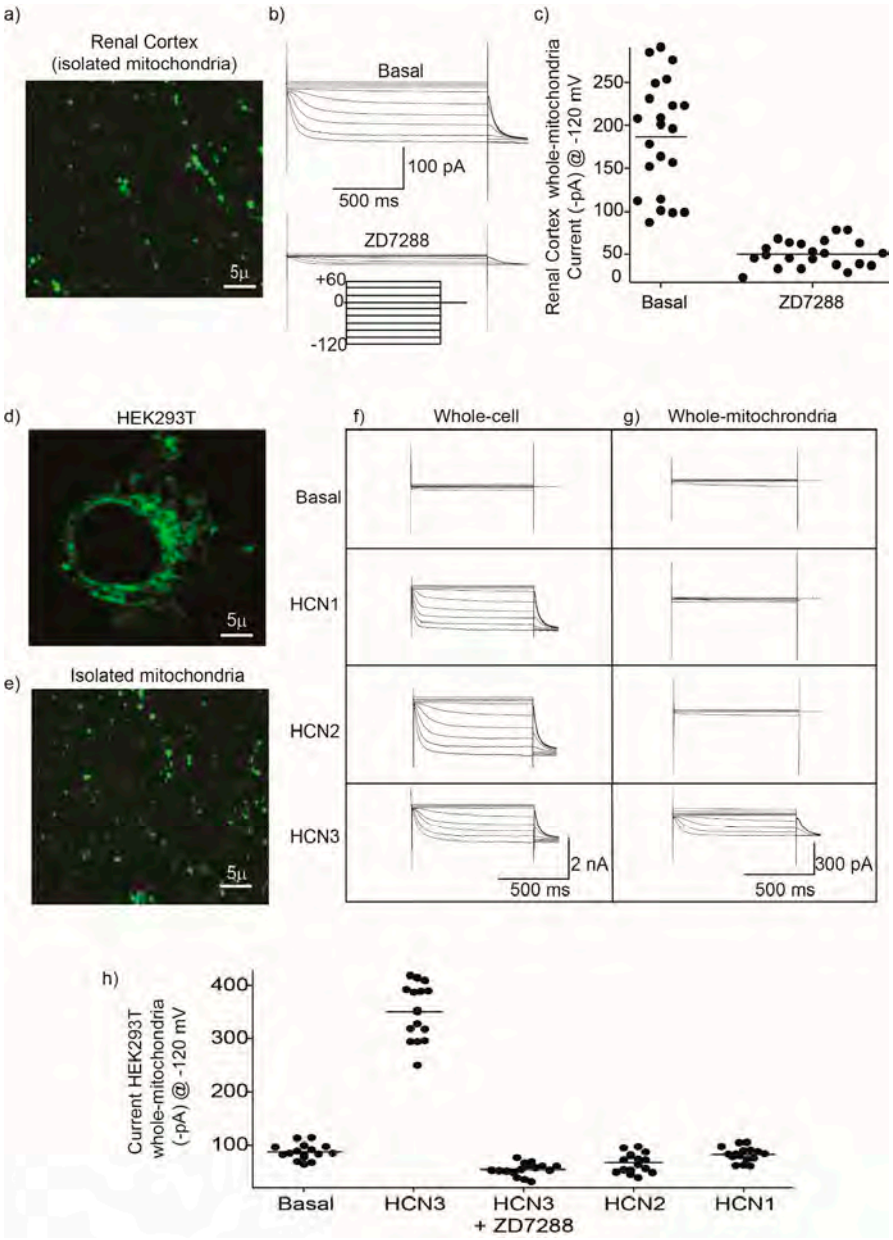

Figure 2. Inwardly potassium (K^+) currents recorded in isolated mitochondria from the renal cortex and HEK293 cells correspond to HCN3. (**a**) Fluorescence microscopy imaging from isolated mitochondria obtained from the renal cortex. Mitochondria were incubated for 10 min with 5 µM of the fluorescent indicator MitoTracker Green FM. Excitation was 490 nm and emission collected at 525 nm. By fluorescence microscopy it was possible to separate mitochondria from debris during patch clamp experiments. (**b**) Whole-mitochondria voltage clamp currents were recorded with 20 mV steps from −120 mV to +60 mV and a holding potential of 0 mV. Basal shows a representative family of HCN currents obtained from a single mitochondrion and the same family of currents after 2 min of incubation with 50 µM of the inhibitor ZD7288. (**c**) Currents obtained at −120 mV from different independent mitochondria under basal conditions and after addition of ZD7288. Each filled circle represents a single measurement and the horizontal line indicates the mean value. (**d**) HEK293T cells labeled with the fluorescent indicator MitoTracker Green FM. (**e**) Isolated mitochondria from HEK293 cells labeled with MitoTracker Green FM. (**f**) Family of currents obtained in whole-cell configuration and (**g**) in whole-mitochondria, under basal conditions and from cells overexpressing HCN1, HCN2 and HCN3. (**h**) Currents recorded at −120 mV from mitochondria isolated from HEK293 control cells (Basal) and cells overexpressing HCN1, HCN2, HCN3 and HCN3 + ZD7288. Each filled circle represents a single measurement and the horizontal line indicates the mean value.

INFORME DE LABORES 2019

We proceeded next to explore the presence of HCN currents in HEK293 cells comparing whole-cell currents with currents from isolated mitochondria (whole-mitochondria recordings). Firstly, we labeled mitochondria with MitoTracker Green FM in intact living HEK293 cells (Figure 2d) and isolated mitochondria (Figure 2e). As illustrated in the Figure, MitoTracker Green FM labeled selectively mitochondria in culture cells and also in isolated mitochondria. Transfecting of all HCN1–3 plasmids resulted in whole-cell currents associated with each channel (Figure 2f). These results indicated that although each HCN channel subtype is expressed and localized at the plasma membrane of HEK293 cells (therefore identified by whole-cell recordings), only HCN3 produced functional currents in isolated mitochondria (Figure 2g,h).

2.4. ZD7288 Decreased the Mitochondrial Respiratory Control Index and ΔΨm

To elucidate the functional role of HCN3 in mitochondria, the effect of ZD7288 was evaluated on isolated mitochondria from the renal cortex and HEK293 cells transfected with HCN3. It is well established that activation of NADH quinone oxidoreductase (Complex I) in respiratory state 2 (S2), increases hyperpolarization of the IMM by the electron transport chain proton pumping. Also, the addition of ADP or state 3 (S3) stimulates oxygen consumption due to ATP synthesis; this effect is inhibited by oligomycin (S4o). ZD7288 did not affect S2 and S4o. In contrast, ZD7288 drastically reduced oxygen consumption in S3 from 1202 ± 166.6 pmol O_2 s^{-1} mg^{-1} to 330.4 ± 29.72 pmol O_2 s^{-1} mg^{-1} (Figure 3a). As a consequence, mitochondrial coupling decreased: the respiratory control index (RCI) changed from 6.71 ± 0.70 to 2.09 ± 0.27 with ZD7288 (Figure 3b). Therefore, ZD7288 reduced the mitochondrial OXPHOS capacity. Interestingly, ΔΨm measured with safranin O diminished progressively from S2 to S3 to S4 with ZD7288. This effect was exacerbated in S3. Furthermore, ΔΨ in S4o also diminished with respect to the control group (Figure 3c).

Cationic dyes preferentially accumulate in the mitochondrial matrix because of the higher ΔΨ (−120 to −160 mV) with respect to plasma membrane ΔΨ (−60 to −90 mV) [16]. To further estimate the contribution of HCN3 to ΔΨm, JC-1 assays were performed in control and transfected HEK293 cells with HCN3. As expected, ΔΨm was significantly lower in cells transfected with HCN3 than in control cells, which is consistent with the reduction in both routine and leak respiration observed in HEK293 transfected cells. Strikingly, addition of CCCP did not further diminish ΔΨ of the transfected cells, confirming the strong uncoupling effect of recombinant HCN3 K^+ channel in the mitochondria (Figure 4a,b).

Each merge image of Figure 4a corresponds to one representative experiment captured during four to eight independent assays performed for each experimental condition. Therefore, conclusions were extracted from the statistical analysis of the values plotted in Figure 4b.

It is well known that not all potential energy in mitochondria is transformed into ATP, as some processes like substrate transport and thermogenesis also depend on ΔΨm. Therefore, cell respiration in vitro is regulated by aerobic ATP demand but also by mitochondria processes that are required for cell growth, such as mitochondrial anabolism, and by processes that reduce mitochondrial coupling such as proton leak, electron leak and electron slip. So, cells incubated in the corresponding culture medium maintain this "basal (or routine) respiration". The oxygen consumption of all mitochondrial processes that do not produce ATP can be evaluated by the oligomycin induction of the non-phosphorylating resting state (an uncoupled state) known as "leak respiration". According to our results, endogenous HCN3 in kidney mitochondria and in mitochondria from HEK292 cells reduce ΔΨm. In fact, a stronger ΔΨm reduction effect was observed by overexpressing HCN3 in HEK293 cells (Figure 4b). Therefore, we performed an additional experiment in an attempt to explain the origin of this effect. In general, overexpression of HCN3 lowers "routine respiration" but also reduces "leak respiration" (Figure 5a,b). Although the value of respiration attributable to oxidative phosphorylation (P) decreased (Figure 5c), recombinant HCN3 did not change the respiratory control (RCI) (Figure 5d). Together these findings indicated that although mitochondrial ATP production decreased with channel overexpression, this was not due to a lower efficiency of mitochondrial function, but rather to a lower activity of all

INFORME DE LABORES 2019

mitochondrial processes in the HCN3 group. A possible explanation could be a decrease in the mitochondrial mass since both groups produced ATP with equal efficiency (RCI did not change). In summary, the fact that both routine and leak respiration decreased with HCN3 overexpression seems to indicate fewer mitochondria. This hypothesis should be confirmed in the future.

3. Discussion

The kidney is, after the heart, the organ with the highest resting metabolic rates, mitochondrial content and oxygen consumption. The kidney contains abundant mitochondria to provide the energy necessary to recover or eliminate nutrients from the filtrated blood (amino acids, glucose, urea, electrolytes) and maintain the acid-base balance. Furthermore, healthy mitochondria are essential for the Na^+-K^+-ATPase activity and to generate the electrochemical gradients across the plasma membrane of epithelial cells.

The development of quantitative high-throughput assays for identification of candidate proteins that interact with membrane proteins represents a powerful approach for biomarker discovery. In this work, targeted proteomics provided a sensitive assay to develop the hypothesis of the presence of the HCN3 channel in the kidney mitochondria.

The HCN family has been widely studied in the brain and heart, where they play a key role in the initiation and regulation of the electrical rhythmic activity [17,18]. In the mammalian heart and nervous system HCN channels contribute to spontaneous beating in pacemaker cells [17]. In nonpacing cells, inward cationic currents carried by HCN channels facilitate the establishment of the resting membrane properties by limiting the fluctuation of membrane potentials [18]. Although HCN channels form

cationic non-selective channels, they display a higher selectivity for K^+ over NH_4^+ and Na^+. Our assays of ΔΨm helped to determine that HCN channels are K^+ channels in the IMM and that their topology seems to be a mirror of the HCN channels in the plasma membrane but facing the cytosol instead of the extracellular side.

Previously we found that HCN channels are differentially distributed along the rat nephron. In particular HCN3 is observed near luminal membranes and the cytosol in the proximal convoluted tubule and towards basolateral membranes of the medullary thick ascending limb of Henle [14]. HCN3 has been found in the bladder and the junction of renal pelvis and has been implicated in ureteral peristaltic activity [19,20].

In this work we demonstrated for the first time and through several approaches that HCN channels, mostly HCN3, are located in mitochondria of the rat and human kidney by immunogold-labeling. Remarkably, by transfecting each HCN subtype in HEK293 cells, we observed that only HCN3 and HCN4 subtypes could be trafficked to mitochondria. In fact, we predicted these finding by proteomic analysis of HCN3 in HEK293 cells (Table 1).

Mitochondria HCN3 functional expression was confirmed by patch-clamp recordings in rat kidney and HEK293 mitochondria. The magnitude of HCN inward K^+ currents (100–300 pA) that were recorded by patch-clamp (Figure 2) should correspond to the electrical activity of several fused mitochondria. This experiment confirmed not only the presence of HCN K^+ currents in the kidney mitochondria but, by HCN1–3 subtype transfection in HEK293T cells, that only HCN3 could be trafficked to these organelles. In the distal NH_2 and COOH termini exist multiple regions specific to each of the four vertebrate HCN paralogs. These multiple regions of variable length and sequence confer isoform-specific properties. For example, in the COOH terminus of the HCN1, HCN2 and HCN4 isoforms, there is a block of residues conserved immediately downstream of the cyclic nucleotide binding domain [21,22]. Even when HCN3 subtype lacks this conserved block of residues, this would not explain HCN3 targeting to mitochondria since HCN4 is also trafficked to this organelle (Figure 1c). Further experiments should be performed to identify the targeting signals of HCN3 and HCN4 to mitochondria that have not been identified for other mammalian mitochondrial K^+ channels.

Since patch-clamp recordings of HCN channels in the whole mitochondria does not allow to distinguish between the outer and the IMM, we evaluated the effect of the HCN channel blocker ZD7288 on the mitochondrial oxygen consumption and ΔΨm on isolated renal mitochondria. Oxygen consumption by the respiratory chain in S2 or when ATP synthesis was inhibited with oligomycin in S4o was not affected by ZD7288. In contrast, oxygen consumption during ATP synthesis in S3 decreased to basal conditions with ZD7288. These results suggested that HCN3 K^+ channel participates in the respiratory chain activity, especially during ATP synthesis. The effect of ZD7288 on the respiratory control index (RCI) confirmed this conclusion. It is important to underline that the control group is defined as the assay in the absence of ZD7288. States 2 and 4o (induced by oligomycin) must not be considered as basal respiration; these states are bioenergetic parameters determined according to the protocol followed in oxygraphic experiments with isolated mitochondria. Briefly, state 2 corresponds to the respiration due to the added substrates: sodium pyruvate, malate and glutamate in the absence of exogenous ADP. Later, ADP is added to achieve a stationary state of maximum oxygen flux triggered by oxidative phosphorylation (OXPHOS) or state 3. Finally, oligomycin is added to inhibit ATP synthase developing a non-phosphorylating stationary state (state 4o) when oxygen flux is maintained to compensate proton leak [1,3]. The difference between state 2 and state 4o is that in state 2 an ATPase residual activity may cause a recycling of ATP to ADP and, therefore, a residual activation of respiration. In contrast, in state 4o oligomycin inhibition of ATP synthase eliminates this contribution. Oxygen consumption in S3 is mostly determined by OXPHOS and depends highly on changes in ΔΨm [1]. Therefore, small changes in ΔΨm more severely affect the respiration rate in S3 than in S2 or S4o, where OXPHOS is not present. In conclusion, our results support that inhibition by ZD7288 affects OXPHOS more than it does leak states of respiration.

Regarding ΔΨm, changes in safranine O fluorescence were more sensitive to inhibition of HCN3 by ZD7288 than oximetry assays: safranine O fluorescence in states 2, 3 and 4o diminished by about 20%, 40% and 50%, respectively, with respect to basal conditions (Figure 3c). These results supported that HCN3 is an open K^+ channel and its blockade by ZD7288 provoked a higher IMM polarization (i.e., a more negative ΔΨm). Therefore, HCN3 represents a K^+ leak towards the mitochondrial matrix in resting conditions.

To further confirm the effect of HCN3 channel on the polarization of the IMM, assays were carried out with culture control HEK293T cells and HEK293T cells transfected with HCN3, using the lipophilic cationic dye JC-1. JC-1 forms aggregates with intense red fluorescence in healthy mitochondria with high ΔΨm (hyperpolarization) and monomers with green fluorescence when ΔΨm diminishes (depolarization). The higher the ratio of red to green fluorescence, the higher the polarization of the IMM [23]. The red to green fluorescence intensity ratio is not dependent on the mitochondrial size, density and shape. Therefore, JC-1 can be used both as qualitative and quantitative measure of ΔΨm. ZD7288 more than doubled JC-1 the fluorescence ratio with respect to control cells, supporting that endogenous expression of HCN3 enhances mitochondrial K^+ fluxes with a mild uncoupling effect. Moreover, enrichment of mitochondria with HCN3 revealed a stronger uncoupling effect similar to that obtained with CCCP. In these circumstances, 50 μM ZD7288 reverses partially the uncoupling effect of overexpression of mitochondrial HCN3 since most probably not all HCN3 channels were blocked.

The fact that recombinant HCN3 did not change the respiratory control (RCI) indicated that, although mitochondrial ATP production decreased with channel overexpression, this was not due to a lower efficiency of mitochondrial function. A decrement in the mitochondrial mass might be implied since mitochondria of both groups were equally efficient producing ATP. Furthermore, these results help to explain why ΔΨm is lower with HCN3 overexpression compared to ΔΨm in control HEK293 cells.

Only an ATP-sensitive K^+ transport has been identified in kidney mitochondria [9]. In contrast to this ATP-K^+ channel (KATP), which is inhibited by ATP, HCN channels are constitutively open in the mitochondria. Interestingly, voltage-gated mitochondrial K^+ channels documented so far are closed in physiological conditions, for example: the maxi-conductance K^+ channel (BKCa) and voltage-gated Kv1.3 channel. TWIK-related acid-sensitive K^+ channel 2 (TASK3) regulates mitochondrial morphology, membrane potential and aldosterone production in adrenal cortex [24]. All K^+ channels have been involved in the regulation of mitochondrial respiration, ΔΨm and ROS production within mitochondria. Opening of mitochondrial K^+ channels has been associated with cytoprotection, while closed K^+ channels may facilitate cell death [6,7]. The IMM K^+ channels identified so far comprise BKCa [25], intermediate-conductance K^+ channel (IKCa) [26], small-conductance K^+ channel (SKCa) [27], Kv1.3 [28], KATP channel [29], two-pore TASK-3 [30], Kv1.5 [31], ROMK2 and Kv7.4 [32].

The proton pumps of the respiratory chain maintain ΔΨm in the range of −150 to −180 mV in the IMM. While Δp (combination of both ΔΨm and the mitochondrial pH gradient, ΔpH_m) provides the bioenergetic driving force for and regulates ATP production, ΔΨm provides the charge gradient required for mitochondrial Ca^{2+} sequestration and production of reactive oxygen species (ROS) [33]. The opening of K^+ channels provokes depolarization (uncoupling effect) while their blocking induces hyperpolarization in the IMM [34].

The mitochondrial electrochemical equilibrium is continuously maintained by the coupling of K^+ channels and K^+ efflux mediated by exchangers [35]. Mitochondrial swelling occurs after continuous K^+ entry, caused by osmotic entrance of water through aquaporins and triggers the blockade of mitochondrial functions, favoring the release of cytochrome c. To avoid osmotic volume changes and mitochondrial depolarization, the positive K^+ influx is counterbalanced by the efflux of protons (H^+) through the activities of the respiratory chain complexes and by the K^+/H^+ antiporter (i.e., K^+ "futile cycle") [36].

4. Materials and Methods

4.1. Reactives, Antibodies and Plasmids

Antimycin A, adenosine diphosphate (ADP), (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) (HEPES), fat-free bovine serum albumin (BSA), carbonyl cyanide m-chlorophenylhydrazone (CCCP), D-sucrose, ethylenediaminetetraacetic acid (EDTA), ethylene glycol-bis(2-aminoethylether)-N,N,N′,N′-tetraacetic acid (EGTA), K-lactobionate acid, mannitol, magnesium chloride ($MgCl_2$) tetrahydrate, oligomycin, rotenone, safranin O, sodium phosphate dibasic (Na_2HPO_4), sodium phosphate monobasic (NaH_2PO_4), sodium glutamate, sodium malate, sodium pyruvate, taurine, polylysine, mannitol and anti-α-tubulin (t9026) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Dulbecco's Modified Eagle Medium (DMEM, 31600-083) Optimem (22600-134) were purchased from Gibco, Life Technologies. Dynabeads protein G (10003D), MitoTracker Green FM, NuPAGE® LDS buffer 4×, NuPAGE (NP0007) 10% Bis-Tris protein gels, MOPS sodium dodecyl sulfate (SDS) buffer, 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolylcarbocyanine iodide (JC-1, T3168), anti-green fluorescent protein (GFP, clone 3E6) HindIII and kpnI were purchased from Invitrogen by Thermo Fisher Scientific. Fetal Bovine Serum was purchased from Biowest (S1650). Normal mouse IgG (sc-2025) and polyethyleneimine (PEI, sc360988A) were purchased from Santa Cruz Biotechnology (Dallas, TX, USA). Bio-safe Coomassie G250 was purchased from Bio-Rad (Hercules, CA, USA). Polyclonal voltage-dependent anion channel (VDAC, ab34726) was purchased from Abcam (Cambridge, UK) and Immobilon Western Chemiluminescent horseradish peroxidase (HRP) substrate was from Millipore (Mexico City, México). Anti-HCN1, anti-HCN2, anti-HCN3 and anti-HCN4 were purchased from Alomone (Jerusalem, Israel). cOmplete™ Protease Inhibitor Cocktail Roche, Mexico. ZD7288 was purchased from Tocris (Minneapolis, MN, USA). pcDNA3-mHCN1, pcDNA3-mHCN2, pcDNA3-hHCN4 and pEGFP·C3 were provided by Luis Vaca. pcDNA3-mHCN3 was provided by Andreas Ludwig.

4.2. DNA Constructs

pcDNA3-mHCN3 was subcloned into eukaryotic expression vector pEGFP·C3 using HindIII and KpnI. After subcloning, the sequence was confirmed by restriction assay and DNA sequencing analysis using an automated DNA sequencing technique.

4.3. Cultures and Transfection of HEK293 Cells

Human embryonic kidney cells (HEK293T cells) were grown in DMEM supplemented with 100 U/mL penicillin, 100 mg/mL streptomycin and 10% fetal bovine serum at 37 °C in a humidified atmosphere with 5% CO_2. HEK293T cells were grown in tissue culture and transfected at 80% confluence using 1 mg/mL PEI and Optimem. Briefly, 1 μg of each plasmid pcDNA3-mHCN1, pcDNA3-mHCN2, pcDNA3-mHCN3 and pcDNA3-hHCN4 were diluted in low serum medium Optimem and mixed with the transfection reagent PEI, incubated at room temperature for 20–25 min and added to cultures. HEK293 cells were washed with cold phosphate buffer saline (PBS). For IP, 5 μg of GFP-HCN3 was transfected in HEK cells.

4.4. Proteomic Assays

For GFP-HCN3 immunoprecipitation from HEK293T cells lysate, 5 μg of anti-GFP and 50 μL of Dynabeads protein G were mixed and incubated at 4 °C for 2 h. Then, 2 mg/mL of sample was added to the antibody-beads complex and incubated at 4 °C for 2 h. As control we used 2 μg/mL normal mouse IgG. Sample was extensively washed with radioimmunoprecipitation (RIPA) buffer with Protease Inhibitor Cocktail. NuPAGE LDS buffer was added and boiled for 7 min to separate the beads. The supernatant (30 μL) was loaded on NuPAGE 10% Bis-Tris protein gels in MOPS SDS buffer. Electrophoresis was run at 150 V for 20 min and the gel was stained with Bio-safe Coomassie G250. Samples from gel were enzymatically digested according to the modified protocol from [37]. Then, 4 μL

per sample were loaded into Symmetry C18 Trap V/M precolumn (Waters, MA, USA); 180 µm × 20 mm, 100 Å pore size, 5 µm particle size desalted using as a mobile phase A, 0.1% formic acid (FA) in H_2O; and mobile phase B, 0.1% FA in acetonitrile; under the followed isocratic gradient: 99.9% mobile phase A and 0.1% of mobile phase B at a flow of 5 µL min^{-1} for 3 min. After, peptides were loaded and separated on a HSS T3 C18 Column 75 µm × 150 mm (Waters); 100 Å pore size, 1.8 µm particle size; using an UPLC ACQUITY M-Class (Waters) with the same mobile phases under the following gradient: 0 min 7% B, 30.37 min 40% B, 32.03–35.34 min 85% B, 37–47 min 7% B at a flow of 400 nL min^{-1} and 45 °C. The spectral data were acquired in a mass spectrometer with electrospray ionization (ESI) and ion mobility separation (IMS) Synapt G2-Si (Waters) using data-independent acquisition (DIA) approach by $HDMS^E$ mode (Waters). The tune page for the ionization source was set with the following parameters: 2.60 kV in the sampler capillary, 30 V in the sampling cone, 30 V in the source offset, 70 °C for the source temperature, 0.6 bar for the nano flow gas and 120 L h^{-1} for the purge gas flow. Two chromatograms were acquired (low- and high-energy chromatograms) in positive mode in a range of m/z 50–2000 with a velocity of 0.5 scans s^{-1}. No collision energy was applied to obtain the low-energy chromatogram, while for the high-energy chromatograms, the precursor ions were fragmented in the transfer using a collision energy ramp of 19–55 V. Generated raw files containing MS and MS/MS spectra were deconvoluted and compared using ProteinLynx Global SERVER (PLGS) v3.0.3 software Waters [38] against a reversed *Homo sapiens* database (downloaded from Uniprot, 71,785 protein sequences, last modification 1 December 2017). Workflow parameters were as follows: trypsin as a cut enzyme and one missed cleavage allowed; carbamidometh©(C) as a fixed modification and amidation (N-term), deamidation (N,Q), oxidation (M), Phosphoryl (S,T,Y) as variable modifications. Automatic peptide and fragment tolerance, two minimum fragment ion matches per peptide, five minimum fragment ion matches per protein, one minimum peptide match per protein and a false discovery rate (FDR) ≤4%. All identifications had a percentage of reliability ≥95% (Protein AutoCurate green). Synapt G2-Si was calibrated with [Glu^1]-Fibrinopeptide, $[M + 2H]^{2+}$ = 785.84261 at ≤ 1 ppm.

4.5. Isolation of Kidney and HEK293 Cell Mitochondria

Male Wistar rats (200–250 g) were anesthetized by intraperitoneal administration of pentobarbital sodium (50 mg/Kg). Kidney cortex was excised and cooled by immersion in isolation buffer (225 mM D-mannitol, 75 mM sucrose, 1 mM EDTA, 5 mM HEPES, 0.1% fatty acid-free BSA, pH = 7.4) at 4 °C and then cut in small pieces. The isolation procedure was performed at 4 °C. The kidney capsule was removed; tissues were washed with isolation buffer to remove blood, were cut and homogenized with three up/down strokes in a glass Potter-Elvehjem homogenizer with a Teflon@ pestle with 2 mL of isolation buffer. The homogenates were centrifuged at 4000× *g* for 5 min to precipitate debris and unbroken tissue. The supernatant was transferred to new tubes and centrifuged at 12,500× *g* for 15 min without centrifuge brake. The supernatant was recovered as control and the mitochondrial-enriched fraction (bottom) was gently resuspended in 1 mL of BSA-free isolation buffer and centrifuged at 10,000× *g* for 10 min. Finally, the pellet was gently resuspended in 180 µL of BSA-free isolation buffer. Isolation of HEK293 cells mitochondria for immunoblotting was prepared as previously described [39] with minor modifications. Briefly, HEK293 were collected in cold PBS and centrifuged at 700× *g* for 10 min at 4 °C. The cell pellet was resuspended and homogenized in a mitochondrial isolation buffer (MIB; 200 mM sucrose, 10 mM Tris/MOPS pH 7.4, 1 mM EGTA/Tris), using a Teflon pestle attached to a drill at medium speed for three passes. Homogenized cells were passed through two syringes (18 gauge 1 $\frac{1}{2}$ inch and 27 gauge $\frac{1}{2}$ inch). To isolate the mitochondria, the homogenate was centrifuged at 600× *g* for 10 min at 4 °C. The supernatant was transferred to a new tube and centrifuged at 10,000× *g* for 10 min at 4 °C. The mitochondrial pellet was washed 2× with MIB, centrifuged at 10,000× *g* for 10 min at 4 °C, and resuspended with RIPA buffer. For purification of mitochondria for patch-clamp assays, the supernatant obtained from either HEK293T cells or renal cortex was mixed with Percoll to form an 8% (v/v) solution that was stratified with a 15% (v/v) Percoll solution carefully added through the walls. Tubes were centrifuged at 12,500× *g* for 10 min without centrifuge brake. The supernatant

INFORME DE LABORES 2019

was discarded and the mitochondrial-enriched fraction (bottom) was gently resuspended in 1 mL of BSA-free isolation buffer and centrifuged at 10,000× *g* for 10 min. Finally, the pellet was resuspended in 100 µL of BSA-free isolation buffer. All procedures were performed at 4 °C. The protein content was measured by the Lowry method.

4.6. Immunoblotting

For SDS-PAGE electrophoresis, the samples were mixed with loading buffer and boiled for 5–8 min. Proteins were separated in 10% acrylamide gels and transferred to 0.2 mm PVDF membrane. Blots were blocked for 1 h at room temperature (RT) in Tris-buffered saline with 0.1% Tween-20 (TBST) containing 5% blotting-grade dry milk, incubated overnight with primary antibody diluted in blocking buffer at 4 °C and washed 3× for 10 min in TBST. Then were incubated with secondary antibody horseradish peroxidase-conjugated for 1h at RT and washed 3× for 10 min in TBST. Dilution of primary antibodies applied to blots from transfected HEK293T cells and isolated mitochondria was 1:1000 for anti-HCN1–3, and 1:1200 for anti-HCN4. As positive control of mitochondrial purification we used polyclonal anti-VDAC and as negative control, anti-α-tubulin. Immunoreactivity was detected using Immobilon Western Chemiluminescent HRP Substrate.

4.7. Immunogold Electron Microscopy

For immunogold labeling, adult Wistar rats were euthanized with intraperitoneal Pentothal, both kidneys were immediately removed, thin tissue slices were obtained and immersed into Karnovsky fixer solution (4% paraformaldehyde and 1.5% glutaraldehyde). Animals were treated in accordance to "Technical specifications for the production, use and care of laboratory animals" (NOM-062-ZOO-1999), and experiments approved by the School of Medicine UNAM, Committee on Animal Research and Ethics (86-2008, date of approval 8 September 2008). The kidney cortex was selected and sectioned in small tissue fragments that were deposited into glass tubes and fixed by immersion in the same fixer solution during 4 h at 20 °C, dehydrated and infiltrated with LR-White hydrosoluble resin. Ultrathin sections of 60–70 nm were placed on nickel grids and incubated overnight at 4 °C with specific anti-HCN-3 (1:100) rabbit antibodies followed by a 2-h incubation at room temperature with goat anti-rabbit IgG conjugated to 5-nm gold particles. The grids were contrasted with uranyl acetate and examined with FEI Tecnai G2 Spirit transmission electron microscope (Hillsboro, OR, USA). The human sample was from a transplant donor and was recovered from formalin-fixed paraffin-embedded tissues; later it was fixed for a day in formaldehyde at 10% in PBS buffer. These conditions did not help to preserve the sample for electron microscopy.

4.8. Patch-Clamp Recordings of Whole-Cell and Whole-Mitochondria

HEK293T cells expressing the different constructs described in Figure 2 were placed on coverslips coated with polylysine. Cells were studied between 24–48 h post-transfection. Coverslips were mounted on an open perfusion chamber (TIRF Labs, Cary, NC, USA). The patch clamp amplifier used for whole-cell recordings was the EPC-10 (HEKA Electroniks, Lambrecht Germany). The patch clamp pipettes were prepared from Corning 7052 glass and had a resistance of 5–10 MΩ when filled with the pipette solution (see below). Pipette tip diameter under these conditions was smaller than 1 micron which was sufficiently small to patch large mitochondrion. An Ag/AgCl electrode was utilized to attain electrical continuity and was connected to the bath solution via a KCl-agar bridge. Whole-cell currents were studied in the whole-cell mode with cells expressing the different constructs carrying HCN channels. The pipette solution was: KCl 150 mM, EGTA 5 mM, HEPES 10 mM, pH 7.2. The bath solution contained: KCl 150 mM, glucose 30 mM and HEPES 10 mM, pH adjusted to 7.2. Osmolarity of both solutions was adjusted to 310 mOsm with mannitol. The voltage protocol consisted of 20 mV steps from −120 mV to +60 mV with a holding potential of 0 mV with a duration of 2 s.

For whole-mitochondria currents, mitochondria were isolated either from HEK293 cells expressing the different HCN channels indicated in Figure 2, or from the renal cortex. Isolated mitochondria were

identified using fluorescence microscopy to separate mitochondria from cellular debris. Mitochondria were incubated for 3 min with 5 μM of the fluorescent indicator MitoTracker Green FM. Mitochondria were identified under fluorescence microscopy using the emission filter 525/50 nm (peak emission for MitoTracker Green FM is 516 nm). Excitation was produced using a 490 nm, 205 mW LED from Thorlabs (excitation peak for MitoTracker Green FM is 490 nm). Whole-cell and whole-mitochondria currents were imported into Igor pro v. 7 (Wavemetrics, Tigard, OR, USA) for further analysis and plotting. Final figures were created with Adobe Illustrator (Adobe Systems).

4.9. Mitochondrial Oxygen Consumption

Mitochondrial oxygen consumption rates were evaluated with a high resolution respirometry (oxygraph O2k, OROBOROS, Innsbruck, Austria) at 37 °C. Isolated mitochondria were loaded into the chamber with 2 mL of MiR05 respiration buffer (0.5 mM EGTA, 3 mM $MgCl_2$, 60 mM K-lactobionate, 20 mM taurine, 10 mM KH_2PO_4, 20 mM HEPES, 110 mM sucrose and 1 g/L essentially fatty acid free BSA). The mitochondrial electron transfer system (ETS) was started by addition of complex I (CI) linked substrates: 5 mM sodium pyruvate, 2 mM malate and 10 mM glutamate. After stabilization, the corresponding inhibitor (100 μM ZD7288) or vehicle (water) was added and respiration in state 2 (S2) was determined. Respiration in state 3 (S3) was stimulated by the addition of 2.5 mM ADP, later 2.5 μM oligomycin was used to induced state 4 (S4o) respiration. All the above parameters were corrected by residual respiration (ROX), which was obtained by addition of 0.5 μM rotenone (complex I inhibitor) and 2.5 μM antimycin A (complex III inhibitor). The respiratory control index (RCI) was defined as the S3/S4o ratio. All values were normalized by total protein content measured by the Lowry method.

Oxygen consumption in HEK293 cells was performed using 2 mL of culture medium. Each experiment was initiated by addition of the cells. The respiratory parameters were: 1. Routine respiration defined as oxygen consumption by the cells; 2. Leak of the respiration, corresponding to oxygen consumption in the presence of 5 μM oligomycin; 3. Respiratory control index (RCI) corresponding to the ratio basal/leak; 4. Respiration attributable to oxidative phosphorylation (P) was calculated by the formula: Routine minus Leak. All parameters were corrected by subtracting the non-mitochondrial respiration, obtained by the addition of 1 μM rotenone, 5 μM antimycin A, and normalized by the number of cells determined by trypan blue.

4.10. Mitochondrial Membrane Potential (ΔΨm) Monitored by Safranin O and JC-1 Staining

ΔΨm was determined in tandem with the oxygen consumption assays using an O2k-Fluorometer module (OROBOROS). Briefly, the changes in safranin O fluorescence (3 μM) in MiR05 medium were used to monitor changes in ΔΨm. To stimulate complex I linked respiration, 5 mM sodium pyruvate, 2 mM malate and 10 mM glutamate were added. ΔΨm in S2 was obtained after addition of the corresponding inhibitor or vehicle (see above); ΔΨm in S3 was estimated by addition of 2.5 mM ADP and in S4o 2.5 μM oligomycin was added. Finally, 0.5 μM rotenone and 2.5 μM antimycin A were used to completely dissipate ΔΨm and correct by non-specific interactions. Calibration curves of safranin O were employed to ensure the linearity of the assay and the ΔΨm sensibility to CCCP was employed to confirm the veracity of the assay. Results were expressed as the percent of changes in the measurable concentration of safranin O of the sample with respect to the control change. To measure ΔΨm potential by JC-1, 7000 cells were cultured into wells of 96-well plate. Cells were transfected with pcDNA3 (control) or pcDNA3-HCN3 (see above, transfection of HEK cells). After transfection, cells were incubated with 8 μg/mL JC-1 for 60 min on non-supplemented medium. To remove excess probe, cells were washed three times with PBS; fresh supplemented medium was placed on cultures. Depolarized-related (green) fluorescence was measured at 525 nm and polarized-related (red) signal was read at 590 nm, both emissions were obtained at 488 nm excitation. ZD7288 and CCCP were used at 50 μM. Data and representative images were obtained with a Cytation 5 Cell Imaging Multi-Mode reader (BioTek Instruments, Winooski, VT, USA), with GFP and RFP filters. JC-1 fluorescence was

calculated as the ratio of red fluorescence and green fluorescence and were normalized with HEK cells (control) without inhibitor.

5. Conclusions

HCN3 constitutes a novel mitochondrial K^+ channel in the kidney that is coupled to the respiratory chain and ATP synthesis. HCN3 produces a mild uncoupling effect in renal mitochondria and therefore would alter the rate of ROS production and be protective in the kidney. HCN pacemaker channels in the kidney mitochondria contribute importantly to the bioenergetic field and open a new route to the understanding of mitochondrial diseases and new therapeutic avenues. Finally, our study predicts that mitochondria from other organs like heart, brain and liver should also express HCN3 and HCN4 channels.

Thrombin induces Ca^{2+}-dependent glutamate release from RPE cells mediated by PLC/PKC and reverse Na^{+}/Ca^{2+} exchange

Edith López, Irene Lee-Rivera, Alejandro Alvarez-Arce, Ana María López-Colomé

Department of Molecular Neuropathology, Instituto de Fisiología Celular, UNAM, Ciudad Universitaria, México City, CdMx, Mexico

Purpose: We analyzed the molecular mechanisms leading to glutamate release from rat primary cultures of RPE cells, under isosmotic conditions. Thrombin has been shown to stimulate glutamate release from astrocytes and retinal glia; however, the effect of thrombin on glutamate release from RPE cells has not been examined. Our previous work showed that upon the alteration of the blood–retina barrier, the serine protease thrombin could contribute to the transformation, proliferation, and migration of RPE cells. In this condition, elevated extracellular glutamate causes neuronal loss in many retinal disorders, including glaucoma, ischemia, diabetic retinopathy, and inherited photoreceptor degeneration.
Methods: Primary cultures of rat RPE cells were preloaded with 1 µCi/ml ^{3}H-glutamate in Krebs Ringer Bicarbonate (KRB) buffer for 30 min at 37 °C. Cells were rinsed and super-perfused with 1 ml/min KRB for 15 min. Stable release was reached at the 7th minute, and on the 8th minute, fresh KRB containing stimuli was added.
Results: This study showed for the first time that thrombin promotes specific, dose-dependent glutamate release from RPE cells, induced by the activation of protease-activated receptor 1 (PAR-1). This effect was found to depend on the Ca^{2+} increase mediated by the phospholipase C-β (PLC-β) and protein kinase C (PKC) pathways, as well as by the reverse activity of the Na^{+}/Ca^{2+} exchanger.
Conclusions: Given the intimate contact of the RPE with the photoreceptor outer segments, diffusion of RPE-released glutamate could contribute to the excitotoxic death of retinal neurons, and the development of thrombin-induced eye pathologies.

The RPE is the predominant component of the outer blood–retina barrier (BRB), and plays an essential role in the maintenance of the functional and structural integrity of the neural retina required for visual function. The RPE is involved in the trans-epithelial transport of nutrients, the storage and metabolism of vitamin A derivatives, the renewal of photoreceptor outer segments, and the release of trophic compounds, cytokines, chemokines, and growth factors required for the proper function of the neural retina [1,2].

As a main component of the epithelium that separates the inner eye from the bloodstream, the RPE also contributes to establishing the immune privilege of the eye. Under pathological conditions, which alter the BRB, such as rhegmatogenous retinal detachment, contact with blood-contained thrombin may contribute to the induction of the epithelial-mesenchymal transition (EMT) of RPE cells [3-5], which, in turn, results in the death of retinal neurons and the loss of vision [6-8]. Within the eye, several pathological insults which disrupt the BRB may induce RPE cells to undergo EMT, which has been identified in several proliferative ocular diseases [9]. Among these ailments, the pathogenesis of proliferative vitreoretinopathy (PVR), a major cause of failure in retinal surgery aimed to the correction of retinal detachment or severe ocular trauma, includes a fibrotic reaction leading to the formation of contractile membranes on both retinal surfaces formed mainly by transformed RPE and glial cells [9]. This process involves EMT through which RPE cells become fibroblastic, proliferate, and acquire the ability to migrate [10].

In addition to the well-known role in hemostasis, the proinflammatory serine protease thrombin, activated upon tissue injury, is involved in the regulation of cell proliferation, invasiveness, and tumor growth [11]. Through the activation of distinct signaling cascades, thrombin may provide cytoprotective effects or lead to cell degeneration [12,13]. Thrombin is present in the brain during primary cerebral hemorrhage, ischemia, or after trauma episodes which disrupt the blood–brain barrier [14,15]. Thrombin also seems to be involved in neurologic complications in HIV [16], and it is accumulated in Alzheimer senile plaques [17]. Despite this evidence, information concerning the signaling mechanisms mediating thrombin actions in the retina is scarce.

Cell responses to thrombin occur via the protease-activated receptors 1, 3, and 4 (PARs) [18], coupled to members of the G-protein families, particularly Gq, Gi,

INFORME DE LABORES 2019

and $G_{12/13}$. Through this interaction, thrombin elicits various downstream signaling cascades [12,19]. Thrombin effects are direct, mediated by the activation of PAR signaling, or indirect, triggered by the release of chemokines, growth factors, neurotransmitters, and angiogenic factors [20]. In RPE cells, thrombin activation of PAR-1 induces the release of epidermal growth factor (EGF) [21] and the stimulation of monocyte chemoattractant protein 1 (MCP1) and GRO chemokine expression and release [22].

Glutamate (Glu) has been shown to regulate the proliferation, migration, and survival of several cell types within the nervous system [23,24], and to play a key role in synaptic plasticity and gene expression [25]. However, the excessive release of glutamate is an early and critical event in the Ca^{2+}-mediated death of neurons implicated in neurodegenerative processes associated with ischemia, epilepsy, and other neuropathological conditions [26,27].

Glutamate is the main excitatory neurotransmitter in the radial signaling pathway of the vertebrate retina from photoreceptors to ganglion cells, acting at ionotropic and metabotropic glutamate receptors (GluRs) [28]. Stimulation of GluRs has been shown to induce the release of glutamate from the retina [29], and to promote the excitotoxic death of retinal neurons [30]. In such a system, any additional factor enhancing glutamate efflux from retinal cells will exacerbate the excitotoxic damage.

Retinal photoreceptors lie between the inner retina and the RPE. Efficient photoreceptor function depends on short- and long-term support from the RPE [31]. The apical membrane of the RPE is separated from the plasma membrane of the photoreceptor outer segments by an extracellular space of only 10–20 nm [32]. Thus, glutamate released by RPE cells may influence synaptic transmission at the main signaling pathway of the retina. Although glutamate release from photoreceptors to inner retinal neurons has been extensively documented, the role of glutamate in communicating the RPE with the neural retina is largely unexplored. Thrombin has been shown to stimulate glutamate release from astrocytes and retinal glia in response to ATP and osmotic stress [33-35]. In turn, glutamate promotes ATP release and RPE cell proliferation acting through N-Methyl-D-aspartic acid (NMDA) and metabotropic receptors [31,36,37]. Thus, the autoactivation of glutamate receptors may contribute to the induction of RPE cell transformation and the development of PVR. However, the effect of thrombin on glutamate release from RPE cells is unexplored. We demonstrated that thrombin-induced activation of PAR-1 glutamate release from RPE is protein kinase C (PKC)-regulated and calcium-dependent.

METHODS

Reagents: All reagents used were cell culture grade. Dulbecco's modified Eagle's medium (DMEM), Opti-MEM, Hanks' balanced salt solution (HBSS), trypsin-EDTA, fetal bovine serum (FBS), penicillin, streptomycin, and dispase were obtained from Invitrogen (Carlsbad, CA). Bovine serum albumin (BSA) was from Equitech-Bio Inc. (Kerrville, TX). Thrombin, hirudin, KN-93, and Ro-32–0432 were from EMD Millipore (Burlington, MA). Ser-Phe-Leu-Leu-Arg-Asn-amide trifluoroacetate salt (SFLLRN), aminooxyacetic acid (AAOA), L-methionine sulfoximine, EGTA, ryanodine, dantrolene, and wortmannin were obtained from Merck KGaA (Darmstadt, Germany). L-trans-2, 4-L-trans-Pyrrolidine-2,4-dicarboxylic acid (PDC), U73122, U0126, and KB-R7943 were from Tocris Bioscience (Bristol, UK). 1,2-Bis(2-aminophenoxy)ethane-N,N,N',N'-tetraacetic acid tetrakis(acetoxymethyl ester) (BAPTA AM) was obtained from Molecular Probes (Eugene, OR). D-Phenylalanyl-prolyl-arginyl Chloromethyl Ketone (PPACK) was from Enzo Life Sciences (New York, NY).

Cell culture: RPE cells were isolated as previously described [36]. Briefly, 8- to 10-day-old Long Evans rats (RRID:RGD_2308852) were anesthetized with pentobarbital (100 mg/kg) and euthanized following the Animal Care and the Guidelines for Animal Care of the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research and Mexican NOM-062-ZOO-1999. Eyes were enucleated, rinsed in DMEM, containing 100 U/ml penicillin and streptomycin, and incubated in DMEM containing 1% v/v dispase for 30 min at 37 °C. The RPE was detached from the neural retina, the choroid, and the sclera in calcium- and magnesium-free HBSS. The tissue was then incubated in the presence of 0.1% trypsin–EDTA, for 5 min at 37 °C. The cells were mechanically dissociated using a Pasteur pipette. Trypsin digestion was stopped with the addition of 4% FBS. Cells were separated with centrifugation at 195 ×g for 5 min, suspended in Opti-MEM containing 4% FBS, and seeded onto six-well culture plates at 2×10^5 cells/cm^2 density. After 4 days in the presence of FBS, the medium was replaced with serum-free Opti-MEM for 24 h to synchronize the cells. All experiments were performed in confluent, passage 1 cultures 2 weeks after seeding.

Immunocytochemistry: RPE cells from the primary cultures were seeded on 22 mm glass coverslips and allowed to reach confluence for 2 weeks with the medium (Opti-MEM containing 4% FBS) changed every 4 days. Cells were fixed in 4% paraformaldehyde for 10 min, washed with PBS (137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4), and permeabilized with 0.1% Triton X-100 for 5 min,

Molecular Vision 2019; 25:546-558 <http://www.molvis.org/molvis/v25/546> © 2019 Molecular Vision

and then blocked for 1 h with either PBS-Tween-0.05%, FBS 10% (for zonula occludens 1 [ZO-1]), PBS-Tween-0.05%, FBS 10%, 1% BSA (for RPE), and PBS-casein 0.5%-saponin 0.1% (for CRALPB). Primary antibody was incubated overnight at 4 °C in blocking buffer. For ZO-1 (Santa Cruz, Santa Cruz, CA, Cat No sc33725), the antibody was diluted 1:50, RPE65 (Novus Biologicals, Centennial, CO, Cat No NB100355) 1:250, and CRALPB (Abcam, Cambridge, UK, Cat No 15051), 1:50. Fluorescein isothiocyanate (FITC)-labeled secondary antibodies were incubated in blocking buffer 1:100 for ZO-1 and cellular retinaldehyde-binding protein (CRALBP); 1:500 for RPE65. The cells were washed three times with PBS for 5 min. Samples were mounted with Dako Fluorescence Mounting Medium (Dako North America, Inc., Carpinteria, CA), and visualized using a microscope Eclipse TE 2000-U. Images were acquired with a DXM1200F camera and 40X objective (0.6 NA) using ACT-1 software (All from Nikon, Tokyo, Japan).

Release experiments: Cultures of rat RPE cells were incubated in the presence of the glutamate decarboxylase inhibitor amino-oxyacetic acid (1 mM), methionine sulfoximine (0.5 mM), and reuptake inhibitor 1-transpyrrolidine-2,-4-dicarboxylic acid (trans-PDC) 50 µM for 30 min before loading with 1 µCi/ml ^{3}H-glutamate in Krebs Ringer Bicarbonate (KRB; 118 mM NaCI, 4.7 mM KCI, 2.5 mM $CaCl_2$, 1.2 mM KH_2PO_4, 1.17 mM $MgSO_4$, 25 mM $NaHCO_3$, 5.6 mM glucose, pH 7.4) solution for 30 min at 37 °C. Cells were rinsed and superfused with KRB, and samples of 1 ml were collected every minute for 10–15 min. Once stable release was attained, stimulus was applied in fresh KRB. The values in the bar graphs represent the percentage of ^{3}H-Glu released on the first minute following stimulation, compared to the value in an unstimulated control. The results in the line graphs represent the percentage of ^{3}H-Glu released each minute compared to the total ^{3}H-Glu incorporated in the cells. When inhibitors were used, they were included 30 min before thrombin or SFLLRN stimulation.

Statistical analysis: The paired Student *t* test was applied for statistical analysis, using the Prism V7.0 program (GraphPad Prism, RRID:SCR_002798). Results are expressed as the mean ± standard error of the mean (SEM) of at least three independent experiments.

RESULTS

RPE cell morphology and identity: RPE cells in culture are considered a suitable model in which dedifferentiation and proliferation of these cells can be studied [38]. Previous studies conducted by our group showed some of the biochemical features of cultured RPE cells in response to thrombin and the glutamate receptors expressed by these cells [22,36]. To confirm the identity of the cultured cells, we tested the expression of RPE65. RPE-specific 65 kDa protein (RPE65) is a critical enzyme in the vertebrate visual cycle that catalyzes the conversion of all-trans-retinyl esters to 11-cis-retinol during phototransduction. RPE65 expression is considered a hallmark of RPE cells [39], and as shown in Figure 1A, it is widely expressed in these cultures. CRALBP also plays an important role in the visual cycle, and it is considered a marker for RPE cells [39]. As shown in Figure 1E, CRALBP was negative in these cells, suggesting that they were not mature RPE cells. However, the RPE cultures showed a typical epithelial morphology, with the presence of melanosomes (Figure 1B,D,E). The tight junction (TJ) protein ZO-1 is a membrane-associated TJ adaptor protein that plays a key role in cell-cell adhesion and epithelial function, particularly in BRB function. Figure 1C shows that ZO-1 expression is restricted to the cell membrane, and reveals a polygonal structure characteristic of differentiated RPE. However, it is noticeable that not all cells express ZO-1. These results suggested that although these cultures have many features of differentiated RPE cells, they are probably not fully mature cells, and could resemble RPE cells transitioning into PVR cells.

Thrombin induces ^{3}H-glutamate release from RPE cells: Our previous work showed that thrombin activation of PAR-1 signaling promotes RPE cell transformation, proliferation, and migration, characteristic of fibroproliferative eye pathologies [22]. In addition to these effects directly derived from PAR signaling, Glu release from RPE may induce RPE proliferation by stimulating Glu receptors on the same RPE cells [36], which may contribute to excitotoxicity through diffusion to the inner retina [29]. To assess this possibility, we tested the effect of thrombin (2 U/ml) on the release of ^{3}H-glutamate from rat RPE cells in primary culture, and showed that the inclusion of 2 U/ml thrombin stimulated Glu release by about 40% over control, which was increased to 60% upon preincubation with the glutamate metabolism inhibitor AAOA and the Glu reuptake inhibitor PDC (Figure 2A). Thrombin-induced Glu release was fast, attained 1 min after the addition of thrombin. Glu release was shown to be specifically prevented by the thrombin inhibitors hirudin (4 U/ml) and PPACK (10 µM; Figure 2B).

Thrombin-induced Glu release is dose-dependent, mediated by the activation of PAR-1: The dose–response curve for thrombin stimulation of glutamate release from 1 pM to 20 nM concentration showed that glutamate release was evident from 100 pM, and reached a saturation value at 10 nM thrombin (Figure 3A). These results indicated that thrombin

INFORME DE LABORES 2019

concentration in plasma [40] suffices for the induction of glutamate release upon RPE exposure to blood due to disruption of the BRB.

To determine if the thrombin effect is mediated by the activation of PAR-1, RPE cells were stimulated with the highly specific PAR-1 agonist peptide SFLLRN. Figure 3B shows that PAR-1 activation induces the dose-dependent release of glutamate, with the maximum effect (100% stimulation over control) attained at 10 µM SFLLRN concentration. This result demonstrated that thrombin-induced Glu release is mediated by activation of PAR-1.

PAR-1-induced glutamate release requires calcium increase from intra- and extracellular stores: Thrombin has been shown to increase intracellular calcium through PAR-1 activation. To investigate if PAR-1-mediated Glu release is calcium-dependent, RPE cells were stimulated with 10 µM SFLLRN in nominally calcium-free medium. As shown in Figure 4A, SFLLRN-induced release was decreased by

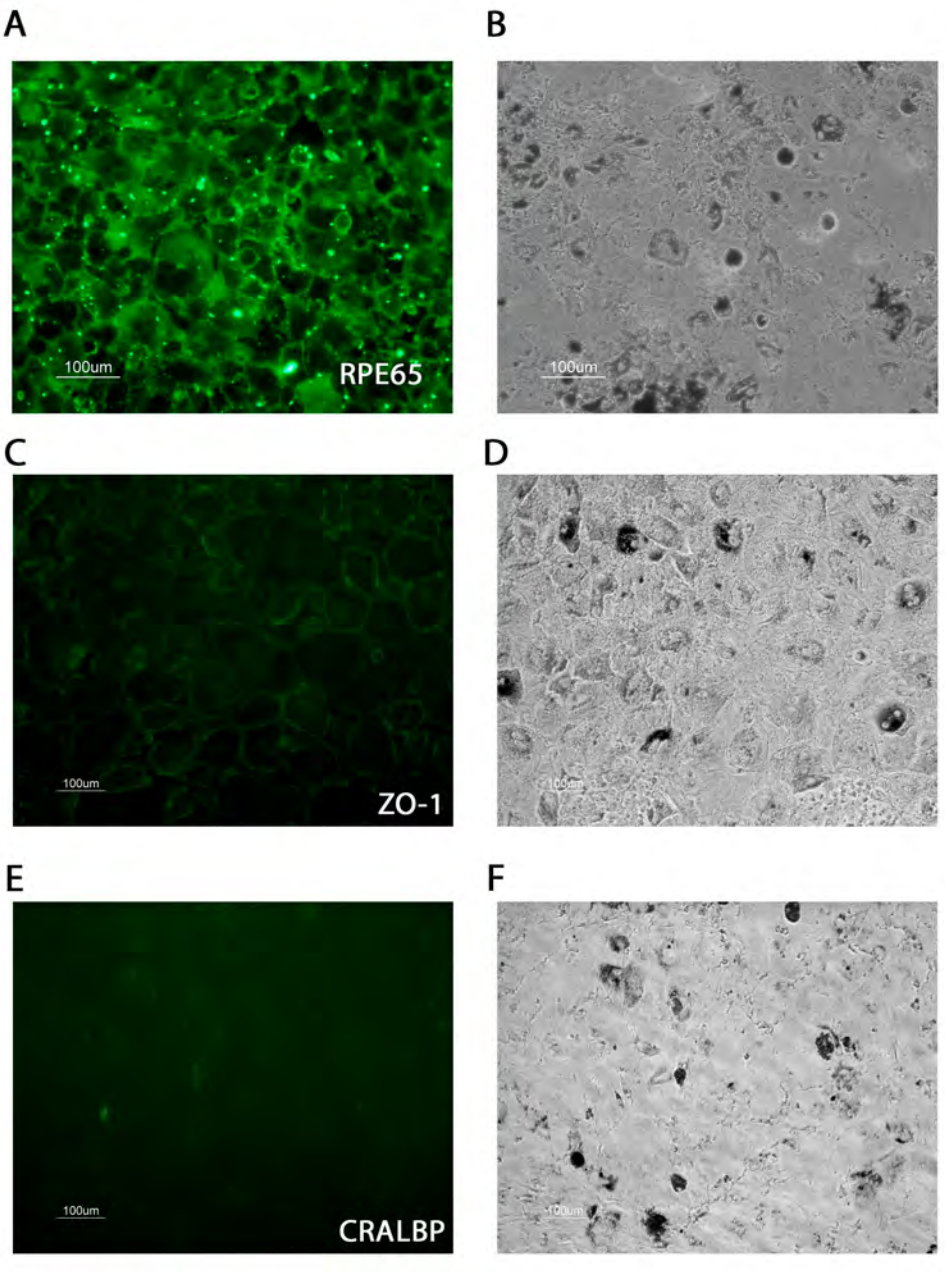

Figure 1. RPE cell morphology and identity. RPE cultures without any treatment were stained with antibodies against RPE65 (**A**), zonula occludens 1 (ZO-1) (**C**), and cellular retinaldehyde-binding protein (CRALBP) (**E**), as described in the experimental procedure section. The corresponding bright-field images are shown in the right column (**B**, **D**, **F**).

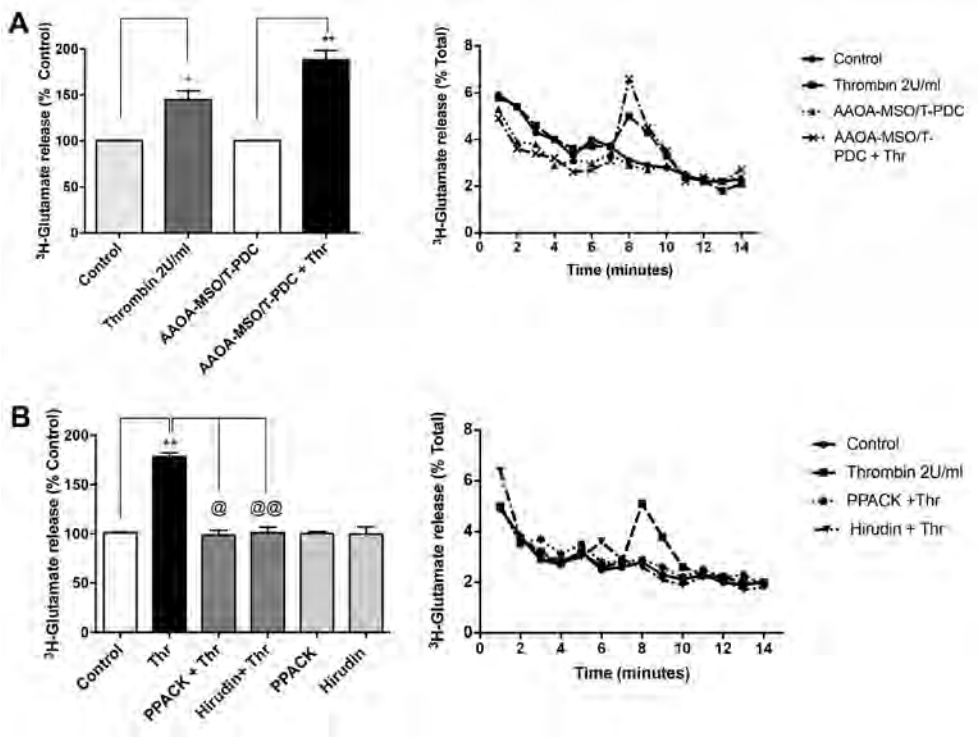

Figure 2. Thrombin induces glutamate release from rat RPE cells. Primary cultures of rat RPE cells were incubated for 30 min with 1 mM amino-oxyacetic acid and 0.5 mM methionine sulfoximine (AAOA-MSO) before loading with ^{3}H-glutamate in Krebs ringer bicarbonate (KRB; 1 µCi/ml 30 min). Cultures were superfused with KRB containing 50 µM 1-trans-pyrrolidine-2,4-dicarboxylic acid (trans-PDC) and stimulated with 2 U/ml thrombin. One milliliter samples were collected at 1 min intervals. Results are expressed as % of total ^{3}H-Glu incorporation or as a % of unstimulated control. **A**: Thrombin stimulates glutamate release. Thrombin-induced ^{3}H-Glu release was increased by the inhibition of glutamate (Glu) metabolism and reuptake. Values are the mean ± standard error of the mean (SEM) of three independent experiments. The Student *t* test with respect to negative control was statistically significant (*p<0.05; ** p<0.005). **B**: Specificity of the thrombin effect. Thrombin-induced Glu release was prevented by the inclusion of thrombin inhibitors hirudin (4 U/ml) and D-Phenylalanyl-Prolyl-Arginyl Chloromethyl Ketone (PPACK; 10 µM) during superfusion. Values are the mean ± SEM of three independent experiments. The Student *t* test with respect to negative control was statistically significant (**p<0.005); the Student *t* test with respect to thrombin stimulation was statistically significant (@p<0.05; @@p<0.005).

about 40% in this condition. Furthermore, the removal of extracellular calcium by the inclusion of 1 mM EGTA inhibited PAR-1 stimulation of Glu release to the same extent as calcium-free medium (about 40%). In contrast, preloading of the cells with the permeable calcium chelator BAPTA-AM completely prevented SFLLRN-induced ^{3}H-glutamate release; this effect was not modified by the joint inclusion of BAPTA-AM plus EGTA. These results indicated that thrombin induction of Glu release from RPE cells depends primarily on intracellular calcium increase, although extracellular calcium is required to attain the maximum effect. To further confirm the requirement of calcium from intracellular stores for glutamate release, RPE cells were treated with 5 µM ionomycin, known to promote the release of calcium from the endoplasmic reticulum (ER) to the cytosol, and showed a highly significant increase in thrombin-stimulated glutamate release in this condition (Figure 4B).

Additional mechanisms promoting Ca^{2+} entry into RPE cells, such as the reverse activity of the Na^{+}/Ca^{2+} exchanger (NCX) [41] and the L-type calcium channels, have been identified [42]. We tested the effect of the NCX inhibitors KB-R7943 (75 µM) and SEA0400 (50 µM), and that of the L-type channel blocker nifedipine, on thrombin-induced Glu release. Figure 4C shows that the inhibition of NCX by both tested inhibitors completely prevented the release of Glu, whereas nifedipine had no effect on thrombin-induced glutamate release Figure 4D, supporting the requirement of extracellular Ca^{2+} entry through NCX activity for a thrombin-induced effect.

Signaling pathways involved in thrombin-induced glutamate release: Thrombin promotion of phospholipase C-β (PLC-β) activity and the consequent release of calcium from the ER through IP3 receptors, has been reported [43]. To analyze this pathway, cells were stimulated with 10 µM SFLLRN in the presence of the PLC-β inhibitor U73122 (2.5 µM). Figure 5A shows that the inhibition of PLC-β decreases PAR-1-mediated Glu release by about 50%, suggesting the participation of ER-IP3 calcium channels in SFLLRN-induced Glu release. Moreover, the inhibition of ryanodine receptor by 10 µM ryanodine or 30 µM dantrolene did not modify thrombin-induced Glu release (data not shown).

PLC-β activity generates diacyl-glycerol (DAG), a known activator of c/n PKC. Figure 5B shows that preincubation of

Molecular Vision 2019; 25:546-558 <http://www.molvis.org/molvis/v25/546> © 2019 Molecular Vision

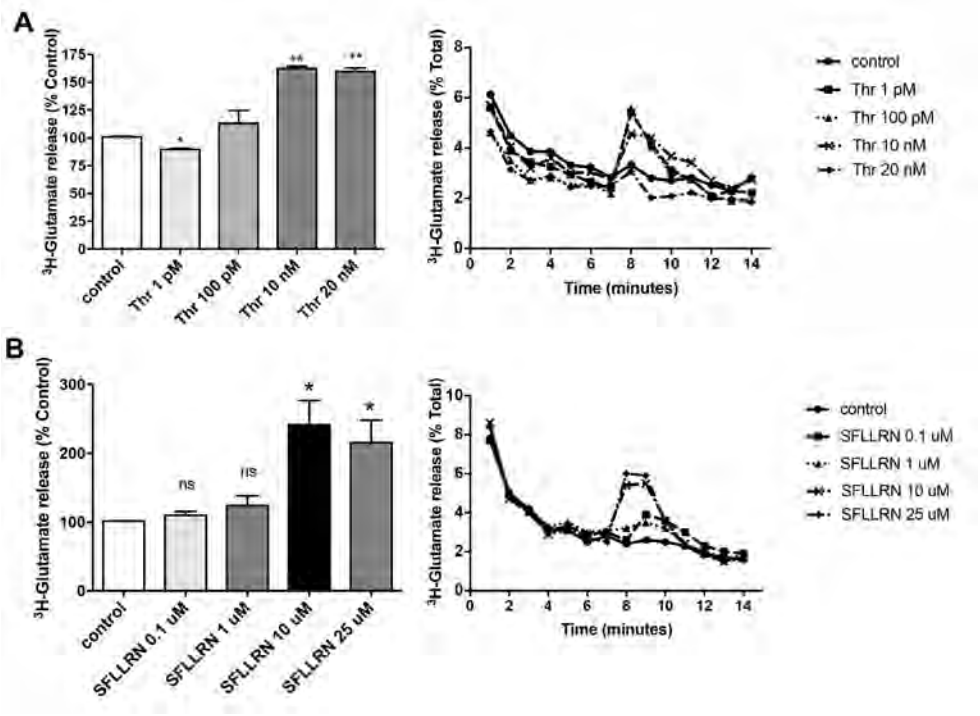

Figure 3. Thrombin-induced glutamate release is mediated by PAR-1. Primary cultures of rat RPE cells were loaded with 1 µCi/ml ^{3}H-glutamate and superfused with Krebs ringer bicarbonate (KRB; negative control) as described in Methods. Stimulation was carried in KRB containing increasing concentrations of thrombin (**A**) or of the specific protease-activated receptor 1 (PAR-1) agonist peptide Ser-Phe-Leu-Leu-Arg-Asn-amide trifluoroacetate salt (SFLLRN) (**B**), as described for Figure 2. Values are the mean ± standard error of the mean (SEM) of three independent experiments. The Student *t* test with respect to negative control was statistically significant (*p<0.05).

RPE cells with 20 µM of the c/n PKC-specific inhibitor Ro 32–0432 inhibits PAR-1 stimulation of glutamate release by about 80%. This result further confirmed the participation of the PLC-β/DAG/c/n PKC signaling pathway in thrombin-induced Glu release.

We previously demonstrated that thrombin activates $G_{12/13}$, known to activate phosphoinositide-3 kinase (PI3K) via the dissociated G-protein βγ subunit in a Ca^{2+}-independent manner [44,45]. In turn, PI3K may lead to the stimulation of mitogen-activated protein kinases pathway (MEK/ERK) [44,46]. We tested the effect of the PI3K inhibitor wortmannin (2.5 µM) and of the MEK inhibitor U0126 (20 µM) on PAR-1-stimulated Glu release, and showed that neither the inhibition of PI3K nor that of MEK prevented PAR-1-induced Glu release. This result indicated that activation of the Gβγ signaling pathway is not involved in thrombin-induced glutamate release.

PAR-1-induced glutamate release is not mediated by vesicular transport or the reverse activity of GLAST: Control of the extracellular glutamate concentration is a crucial mechanism in the prevention of excitotoxic cell death. Among the mechanisms involved in this process, Glu released by the reverse activity of the reverse activity of the Glutamate Aspartate Transporter (GLAST) or through Ca^{2+}-dependent vesicular release in a neurotransmitter-like mode could contribute to the thrombin effect. To test this possibility, we used the vesicular release inhibitor bafilomycin (Figure 6A) and the reverse transport inhibitor DL-threo-β-Benzyloxyaspartic acid (TBOA; Figure 6B). Neither had an effect on PAR-1-induced glutamate release.

DISCUSSION

Glutamate is the excitatory transmitter in the main signaling pathway of the retina from photoreceptors to ganglion cells. Because the elevation of the Glu concentration in pathological conditions has been shown to induce the excitotoxic death of retinal neurons, the extracellular Glu concentration must be tightly regulated [47]. Glutamate has also been shown to promote RPE cell proliferation by activating distinct signaling pathways linked to selective glutamate receptor subtypes [46,48,49]; thus, Glu release induced by thrombin may autoactivate Glu receptors on RPE cells, resulting in the alteration of RPE physiology, and the consequent death of retinal neurons.

The RPE is separated from the photoreceptor outer segments by the sub-retinal space. Although the actual volume of this space is minimal, the communication that occurs across this microenvironment is important to the visual process. In pathological conditions that alter the BRB, exposure of RPE cells to blood-contained thrombin promotes the EMT of RPE cells, including the transformation, increased proliferation, and migration to the vitreous which ultimately

Molecular Vision 2019; 25:546-558 <http://www.molvis.org/molvis/v25/546> © 2019 Molecular Vision

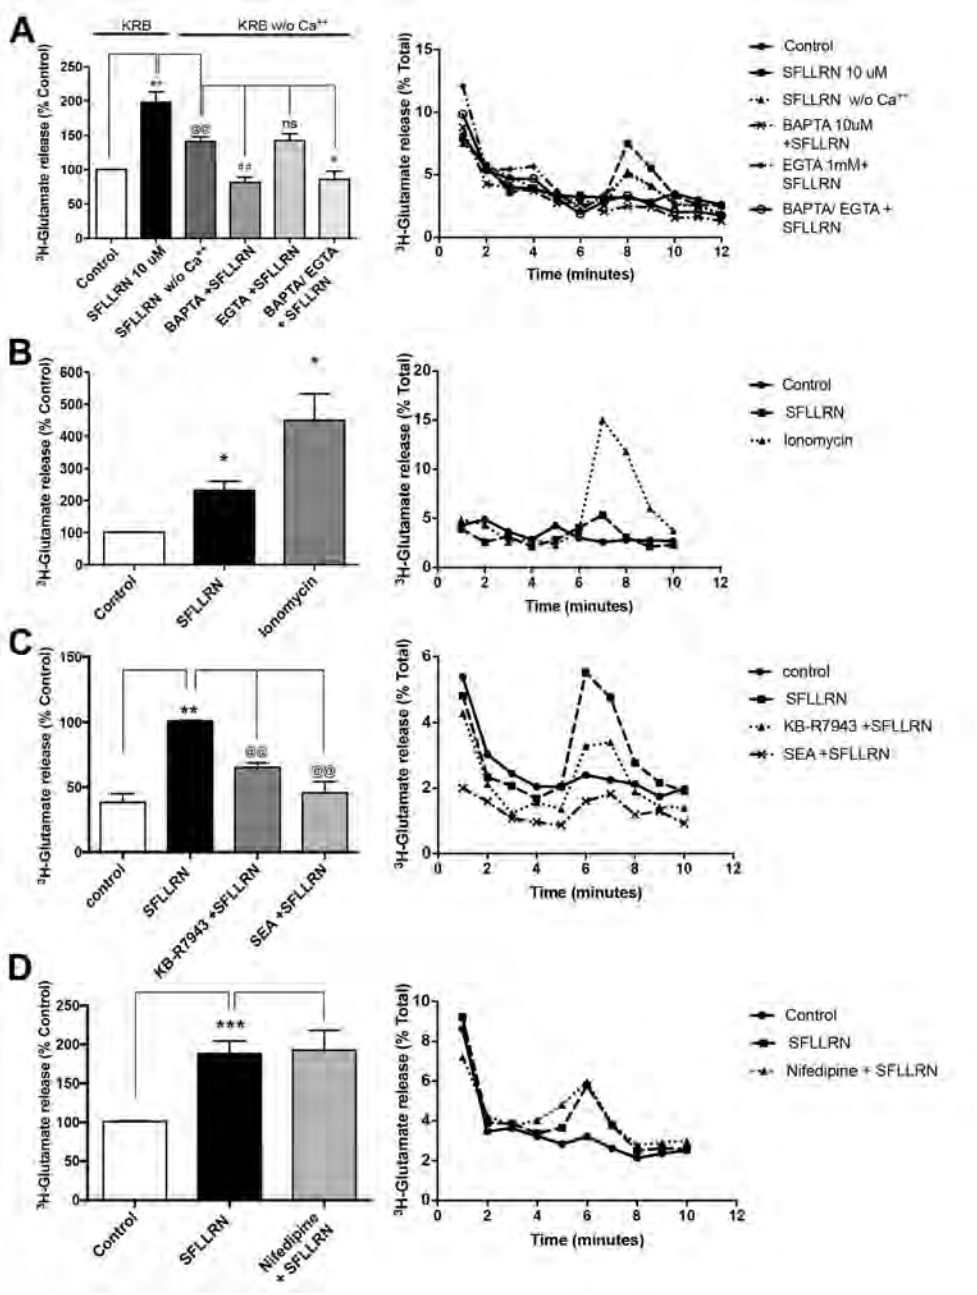

Figure 4. SFLLRN-induced glutamate release is calcium-dependent. Primary cultures of rat RPE cells loaded with 1 µCi/ml ^{3}H-glutamate in Krebs ringer bicarbonate (KRB) for 30 min and stimulated with 10 µM protease-activated receptor 1 (PAR-1) AP (Ser-Phe-Leu-Leu-Arg-Asn-amide trifluoroacetate salt [SFLLRN]). **A**: SFLLRN-induced glutamate release is calcium-dependent. 1,2-Bis(2-aminophenoxy)ethane-N,N,N',N'-tetraacetic acid tetrakis(acetoxymethyl ester) (BAPTA AM) and/or EGTA were included in Ca^{2+}-free KRB for 15 min in the presence or absence of the Ca^{2+} chelators BAPTA-AM (10 µM) and/or EGTA (1 mM) before stimulation. Values are the mean ± standard error of the mean (SEM) of three independent experiments. The Student *t* test with respect to negative control was statistically significant (**p<0.005); the Student *t* test with respect to SFLLRN w/ Ca^{2+} was statistically significant (@@p<0.005); the Student *t* test with respect to SFLLRN w/o Ca^{2+} was statistically significant (#p<0.05, ##p<0.005). **B**: Ca^{2+} release from intracellular stores is the main contributor to PAR-1 induced glutamate release. Cells were stimulated with 5 µM ionomycin to further demonstrate the requirement for intracellular Ca^{2+}. Values are the mean ± SEM of three independent experiments. The Student *t* test with respect to negative control was statistically significant (*p<0.05). **C**: Extracellular Ca^{2+} contributes to PAR-1-induced glutamate release. Cells were incubated with the Na^{+}/Ca^{2+} exchanger (NCX) inhibitor SEA 0400 (50 µM), and of the inhibitor of the exchanger reverse activity KB-R7943 (75 µM) before stimulation with 10 µM of the PAR-1 agonist peptide SFLLRN. Results showed that PAR-1-induced release was statistically significantly decreased by these compounds. Data are the mean of three independent experiments. The Student *t* test with respect to negative control was statistically significant (**p<0.005); the Student *t* test with respect to SFLLRN was statistically significant (@@p<0.005). **D**: PAR-1-induced glutamate release is independent of L-type calcium channel activation. Thrombin stimulation in the presence of the L-type calcium channel blocker nifedipine (5 µM) showed that Glu release is unrelated to L-calcium channel activity. Values are the mean ± SEM of three independent experiments. The Student *t* test with respect to negative control was statistically significant (***p<0.005). The Student *t* test with respect to SFLLRN was not statistically significant.

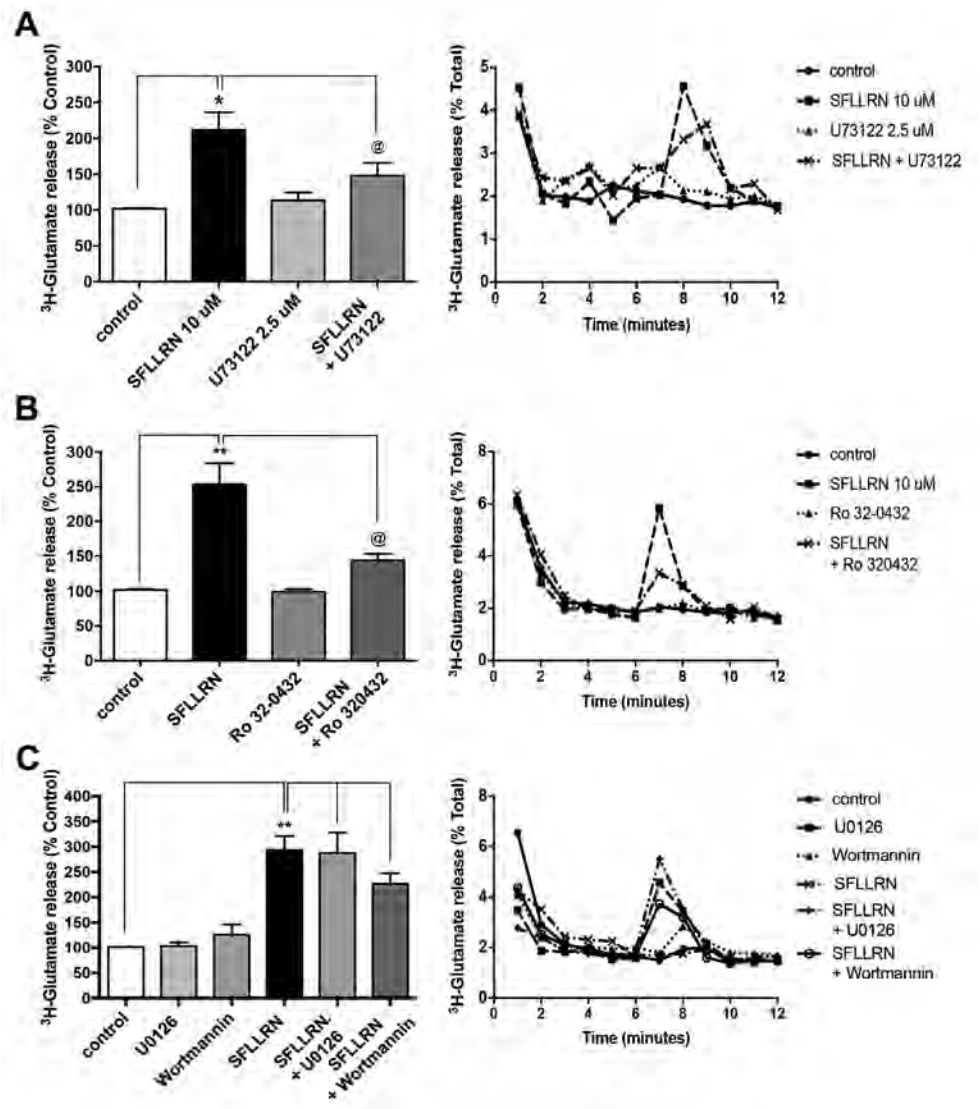

Figure 5. Signaling pathways involved in thrombin-induced glutamate release. **A**: Protease-activated receptor 1 (PAR-1)-induced glutamate (Glu) release requires phospholipase C-β (PLC-β) activity. Cells were incubated in the presence of the PLC-β inhibitor U73122 (2.5 μM) for 30 min. The inhibitor was removed before stimulation with 10 μM PAR-1 AP. Results showed that Ser-Phe-Leu-Leu-Arg-Asn-amide trifluoroacetate salt (SFLLRN) induced Glu release which was prevented by the inhibition of PLC-β. Results are the mean of three independent experiments. The Student *t* test with respect to negative control was statistically significant (*p<0.05). The Student *t* test with respect to SFLLRN was statistically significant (@ p<0.05). **B**: Inhibition of c/n protein kinase C (PKC) isoforms prevents SFLLRN-induced Glu release. Cells were incubated with the c/n PKC inhibitor Ro 32–0432 (20μM) for 30 min, and removed before stimulation with 10 μM PAR-1 AP. Data are the mean ± standard error of the mean (SEM) of three independent experiments. The Student *t* test with respect to negative control was statistically significant (**p<0.005). The Student *t* test with respect to SFLLRN was statistically significant (@ p<0.05). **C**: Thrombin-induced Glu release is independent of phosphoinositide 3-kinase (PI3K) and mitogen-activated protein kinase kinase (MEK) activity. The MEK inhibitor U0126 (20 μM) and the PI3K inhibitor wortmannin (1 μM) were included in KRB for 30 min and removed, before stimulation. Data are the mean ± SEM of three independent experiments. The Student *t* test with respect to negative control was statistically significant (**p<0.005). The Student *t* test with respect to SFLLRN was not statistically significant.

contributes to neuronal death and the development of blindness. Despite the close apposition of the photoreceptors and RPE cells, the possible release and diffusion of glutamate from RPE, and its influence on retinal signaling, have not been examined. The present results showed that thrombin induces the fast, specific, dose-dependent release of Glu from RPE cells, suggesting that under pathological conditions or surgical procedures in which the BRB is compromised, the elevation of extracellular Glu induced by thrombin activation of PAR-1 may contribute to the long-term increase in RPE cell proliferation, a main feature in the development of fibroproliferative eye diseases.

Numerous factors seem to be involved in the proliferation and transformation of RPE cells in PVR [50,51]. Although the glutamate concentration in PVR tissue has not been determined, an increase in glutamate levels in the vitreous cavity of patients is increased by retinal detachment and hypoxia [52], due to a decrease in the expression of glutamate transporters in retinal glia [35,53-55]. Additionally, glutamate from serum or from damaged retinal cells which

Molecular Vision 2019; 25:546-558 <http://www.molvis.org/molvis/v25/546> © 2019 Molecular Vision

contain millimolar concentrations may reach the RPE [56]. Thus, under pathologic conditions in vivo, elevation of glutamate could contribute to the development of PVR through the activation of specific receptors on RPE cells.

Activation of PAR-1 by endogenous agonists, including thrombin and plasmin, or by specific agonist peptides (TFLLR and SFLLRN) has been shown to elevate intracellular Ca^{2+} in RPE cells [57,58] and astrocytes [59]. Consistent with these data, the present results showed that removal of intracellular calcium by BAPTA-AM completely prevents PAR-1-induced Glu release, clearly indicating that downstream pathways associated with Ca^{2+} release from internal stores are involved. This was further confirmed by the robust induction of Glu release by ionomycin (Figure 4B), known to deplete ER Ca^{2+} pools. Because EGTA modestly decreased PAR-1-induced Glu release, a contribution of extracellular calcium is also required, possibly aimed to the refilling of ER intracellular calcium stores. Therefore, it is tempting to speculate that the thrombin-triggered rise in $[Ca^{2+}]i$ primes cells for glutamate release, as it has been shown for the release of ATP [37].

There are several mechanisms that trigger the elevation of intracellular Ca^{2+} levels. One mechanism for Ca^{2+} release from internal stores involves the activation of inositol 1,4, 5-trisphosphate (IP3)-sensitive Ca^{2+} channels on the ER membrane. PAR-1 coupling to the GPCR $G_{q11}\alpha$ subunit activates PLC-β, which catalyzes the formation of inositol 1,4,5-trisphosphate (IP_3) and DAG, leading to an increase in the intracellular Ca^{2+} concentration and DAG activation of c/n PKC isoforms [2]. We examined the contribution of this pathway to thrombin/PAR-1-induced Ca^{2+}-dependent glutamate release from RPE cells, and demonstrated that the pharmacologic inhibition of PLC-β by U73122, or that of its downstream target c/n PKC by Ro-32–0432, statistically significantly decreased PAR-1-induced Glu release, further confirming that the intracellular Ca^{2+} increase required for glutamate release is induced by activation of this pathway. Although PAR-1 is coupled to Gβγ subunits, essential for glutamate efflux from cultured astrocytes [34], inhibition of PI3K by wortmannin and of MEK/Erk by U0126 (Figure 5C) had no effect on PAR-1 evoked glutamate release, indicating that signaling through Gβγ subunits is not involved in this process.

Additionally, we examined the contribution of the caffeine/ryanodine-sensitive ER Ca^{2+} store to thrombin-induced Ca^{2+}-dependent glutamate release. Unexpectedly, the results showed that neither the pharmacological blockage of these pathways nor the inhibition of the thapsigargin-sensitive ER Ca^{2+} ATPase had an effect on thrombin-induced Glu release (data not shown). On this matter, RPE cells and

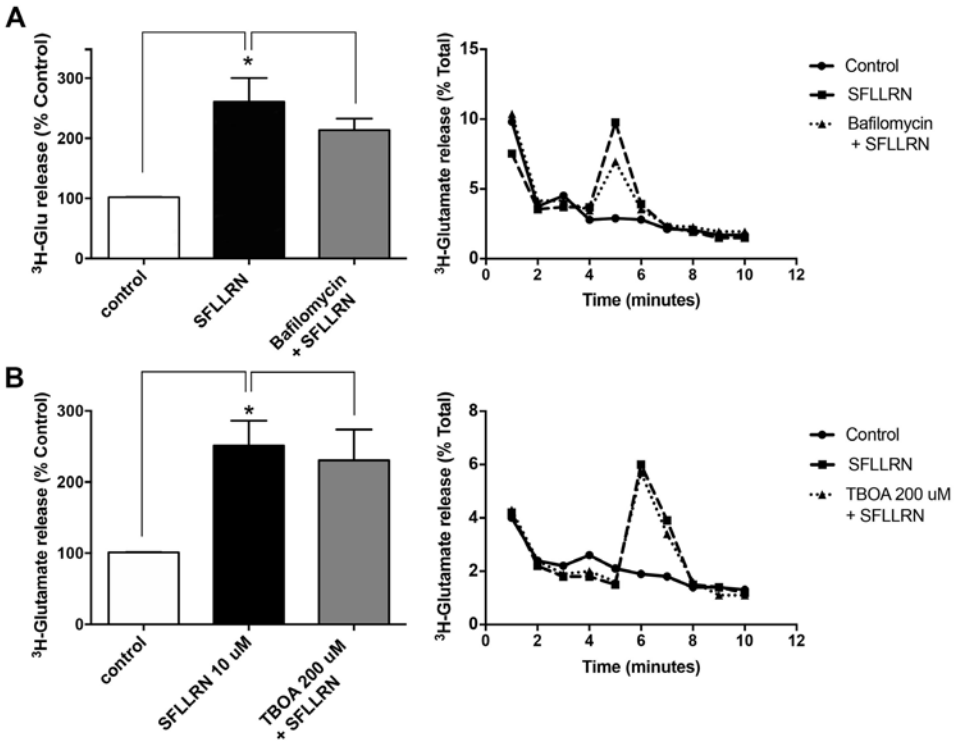

Figure 6. Thrombin induces glutamate release in a non-vesicular mode. The participation of vesicular mechanisms (Figure 6A) or reverse activity of Glutamate Aspartate Transporter (GLAST; Figure 6B) in thrombin induction of glutamate (Glu) release was tested. Results showed that neither GLAST inhibition by DL-threo-β-Benzyloxyaspartic acid (TBOA) nor that of vesicular release by bafilomycin prevented thrombin induction of Glu release. Data are the mean ± standard error of the mean (SEM) of three independent experiments. The Student *t* test with respect to negative control was statistically significant (*p<0.05). The Student *t* test with respect to Ser-Phe-Leu-Leu-Arg-Asn-amide trifluoroacetate salt (SFLLRN) was not statistically significant.

Molecular Vision 2019; 25:546-558 <http://www.molvis.org/molvis/v25/546> © 2019 Molecular Vision

astrocytes express several types of transient receptor potential (TRP) channels [60,61] which contribute to modulate Ca^{2+}-dependent vesicular glutamate release by the promotion of store-operated Ca^{2+} entry (SOCE) [62,63]. However, bafilomycin, a macrolide that specifically targets vacuolar-type H^+-ATPase (V-ATPase), therefore inhibiting vesicular release, had no effect on thrombin-induced Glu release (Figure 6A).

Interestingly, recent evidence suggested that L-type calcium channels present in RPE are linked to intracellular signaling pathways by protein kinase-dependent regulation. RPE L-type Ca^{2+} channels can be activated by protein kinase C, protein tyrosine kinases of the Src-subtype [64,65], and receptor tyrosine kinases [66]. Although we tested this possibility, the lack of effect of nifedipine indicates that these channels are not involved in thrombin-induced release of glutamate.

The deregulation of the thrombin-PAR system in pathological conditions results in the loss of barrier function [67]. Thrombin is capable of modifying endothelial cell permeability [12], and it has been suggested to play a role in retinal disease [67,68]. Recent reports on this matter showed that the ion transporter NCX operating in the Ca^{2+}-influx (reverse) mode promotes endothelial barrier dysfunction in response to thrombin, which is prevented by the reverse-mode NCX inhibitor (KB-R7943) or NCX1 knockdown in vitro [69]. Ca^{2+} entry by this exchanger has been identified as a mechanism for inducing amplification of Ca^{2+} signals that occur during conditions of agonist activation. Thus, we investigated whether Ca^{2+} influx through NCX was involved in Glu release in response to thrombin, and showed that the specific inhibition of this process by KB-R7943 completely blocked thrombin-induced glutamate release.

In conclusion, the present study demonstrated that contact of RPE cells with thrombin, which may be present in pathological conditions, promotes the release of glutamate in a dose-dependent-specific manner. This effect is mediated by an increase in the intracellular Ca^{2+} concentration induced by the activation of the PLC-β/PKC pathways, and by the reverse activity of the Na^+/Ca^{2+} exchanger. Therefore, the deregulation of this system may allow glutamate diffusion to the inner retina, thus promoting the excitotoxic death of neurons.

As current levels of antimicrobial resistance are alarming, the World Health Organization urged the development of new antimicrobials to fight infections produced by multidrug resistant bacteria. Antibiotics impose severe selective pressure for the development of resistance, and currently bacteria resistant to all of them exist. In this review, we discuss the release and development of new antibacterial drugs and their properties as well as the current advances in the development of alternative approaches to combat bacterial infections, including the repurposing of drugs, anti-virulence therapies, the use of photosensitizers, phage therapy, and immunotherapies, with an emphasis on what is currently known about the possible development of bacterial resistance against them.

Introduction

Current levels of antimicrobial resistance are alarming [1] and the projections indicate that if no new effective antimicrobials are introduced, by the year 2050 there will be more deaths caused by multidrug resistant (MDR) bacteria (MDR) than by current leading causes of death including cancer [2]. The most recent World Health Organization's (WHO) review about antibiotic resistance announced a global priority pathogens list, classifying the bacteria depending on priority in critical, high and medium. The majority of infections in hospitals are caused by 'ESKAPE' pathogens (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa* and *Enterobacter* spp.) [3,4]. Antibiotics interfere with essential bacterial processes such as cell wall, protein, and nucleic acid synthesis, interrupting DNA replication, disrupting membrane integrity and important metabolic pathways, either killing or arresting bacterial growth, therefore exerting an intense selection pressure for the development of resistance. Since the introduction of penicillin in the early 1940's, the selection of resistant bacteria is typical and the percentage of resistant strains against multiple antibiotics and even to all is increasing. Antibiotic resistance can be achieved by modifications in the antibiotic targets, expression of alternative ones, expression of efflux pumps that expel several groups of antibiotics, decrease in antibiotic permeability or antibiotic inactivation by enzymes (e.g. β-lactams by β-lactamases [5•]). Other less well characterized mechanisms are the sequestration of antibiotics such as in *P. aeruginosa* biofilms via glucans that sequester aminoglycosides [6], and the protection of the antibiotic's target (protection of the fluoroquinolone target site by a protein designated Qnr or ribosomal protection proteins that confer resistance against tetracycline [7–9]).

In general, resistance against antibiotics that had single protein targets such as β-lactams (penicillin binding proteins), quinolones (topoisomerases) or rRNA targets, like macrolides and aminoglycosides, is readily achieved by mutations. In contrast, antibiotics like polymyxins that

target the non-protein components of the cell membrane such as LPS, often require the accumulation of multiple gene mutations that encode the enzymes used for their biosynthesis, (e.g. *lpx* lipid A biosynthesis genes) or in regulators of their modification, like *pmrAB* that influence the expression of the lipid A modification genes in response to pH and cation levels [10], and hence the appearance of resistance against these kind of antibiotics arises slowly. In the last decades, polymyxins have been reused worldwide as a last therapy resource for Gram negative infections, regardless their complex pharmacokinetic knowledge and potential serious adverse events. Nevertheless, in 2016 plasmid mediated colistin resistance was reported for the first time, in commensal *Escherichia coli* isolated from pigs, the resistance was mediated by the *mcr*-1 gene, encoding a phosphoethanolamine transferase that adds phosphoethanolamine to lipid A [11]. Another old antibiotic used in Gram negative severe infections is fosfomycin that, although it has a unique mechanism of action at earlier bacterial cell biosynthesis, it is not recommended to be used as monotherapy because of its faster and higher resistance appearance [12].

Resistance is the ability to proliferate in the presence of an antimicrobial that previously inhibited growth; however, bacteria survive antibiotics also through tolerance and persistence. Tolerance is the ability to survive a transient exposure to antibiotic, unlike resistance, which is only observed against bactericidal antibiotics and can be acquired through a genetic mutation or conferred by environmental conditions [13]. Tolerance may evolve more rapidly than resistance and it may extend to other classes of antibiotics [13]. Persistence is the survival of a small proportion of antibiotic susceptible cells after the exposure against high antibiotic concentrations [14]. Persisters have strong clinical implications in several infectious diseases, such as tuberculosis, syphilis and typhoid fever and unlike resistance, which is genetically acquired and passed on to subsequent generations, persistence is a transient phenotype, which could spontaneously switch to fast growth and generate a population that is susceptible to the antibiotic with a small proportion of tolerant antibiotic cells [15•]. Factors like the presence of toxin–antitoxin (TA) loci promote persistence, since overproduction of toxin arrests bacterial growth [16]. A better understanding of the mechanisms behind bacterial persistence may lead to the design of drugs to combat chronic and recurrent infections. This review provides an overview of the current state of antimicrobials, then discusses the development of new antibiotics and finally presents a series of promising alternatives for the future combat of bacterial infections.

Current balance of antimicrobial utilization

Around one-half of the antibiotics used today were found between 1950 and 1960, mainly from soil bacteria. After this period, several factors such as the saturation of the screening approaches, the inability to culture most soil bacterial species, and the lack of interest among the pharmaceutical companies [17]; had severely decreased the rate of antibiotic discovery and their introduction into the clinic. Moreover, new antimicrobials under development often fail, among other reasons since their targets readily mutate, therefore, selecting for resistance rapidly [18]. Also many active molecules against bacteria are not selective and damage the host, hence new antibiotics are frequently reserved as a last resort for MDR infections [18]. Nevertheless from 2010 at least a dozen of new antimicrobial agents and combinations have been approved for the treatment of infectious diseases (Table 1). However, these molecules are improved versions of previous antibiotics namely β-lactams, aminoglycosides, glycopeptides, tetracyclines, and so on, that although are less susceptible to current resistance mechanisms, are not impervious to them; in fact, for all of them, except omadacycline, resistant strains have already been found. Therefore, if the same approaches are repeated, the introduction of new antibiotics likely will be almost simultaneous to the appearance of resistance. Hence, the discovery of novel antibiotics with new structures, action mechanisms, and targets, as well as the implementation of alternative strategies less prone to the development of resistance, is highly advisable (Table 2).

Development of new antibiotics

New promising antimicrobials under development include oxadiazoles, heterocyclic aromatic compounds of the azole family, that have anticancer, anti-inflammatory, antiretroviral, analgesic, anticonvulsant, and antibacterial activities. Recently, several new compounds were tested as antimicrobials, being F6 (Figure 1A) the only one with antibacterial activity, and the basis for the synthesis of analogs with improved activity. From all the analogs only F6-5 (Figure 1B) was slightly better than the original compound and in contrast with ciprofloxacin did not select resistance after several culture passes. This molecule is a bacteriostatic agent active only against Gram positive bacteria [19]. Other novel molecules such as 4(3*H*)-quinazolinone derivatives are present in agents with antibacterial application as first generation cephalosporins such as cefatrizine. Moreover, 2,3-triazole linked 4(3*H*)-quinazolinone derivatives (3-chlorophenyl; 4-chlorophenyl; 3-tolluoyl; phenyl; 3-bromophenyl; 4-methoxyphenyl and 4-nitrophenyl) (Figure 1C–I) were non cytotoxic against Vero cells and showed activity against *S. aureus* but not against Gram negatives, probably due to the presence of the external membrane; however, resistance development was not tested for these molecules [20]. Since 2014, new compounds from thiazole and its derivatives have been synthesized. Alkoxyphenylthiazoles, analogs of phenylthiazole, showed activity against Gram positive bacteria. In comparison with vancomycin, these phenylthiazoles showed good activity and shorter

DE LABORES 2019

Table 1

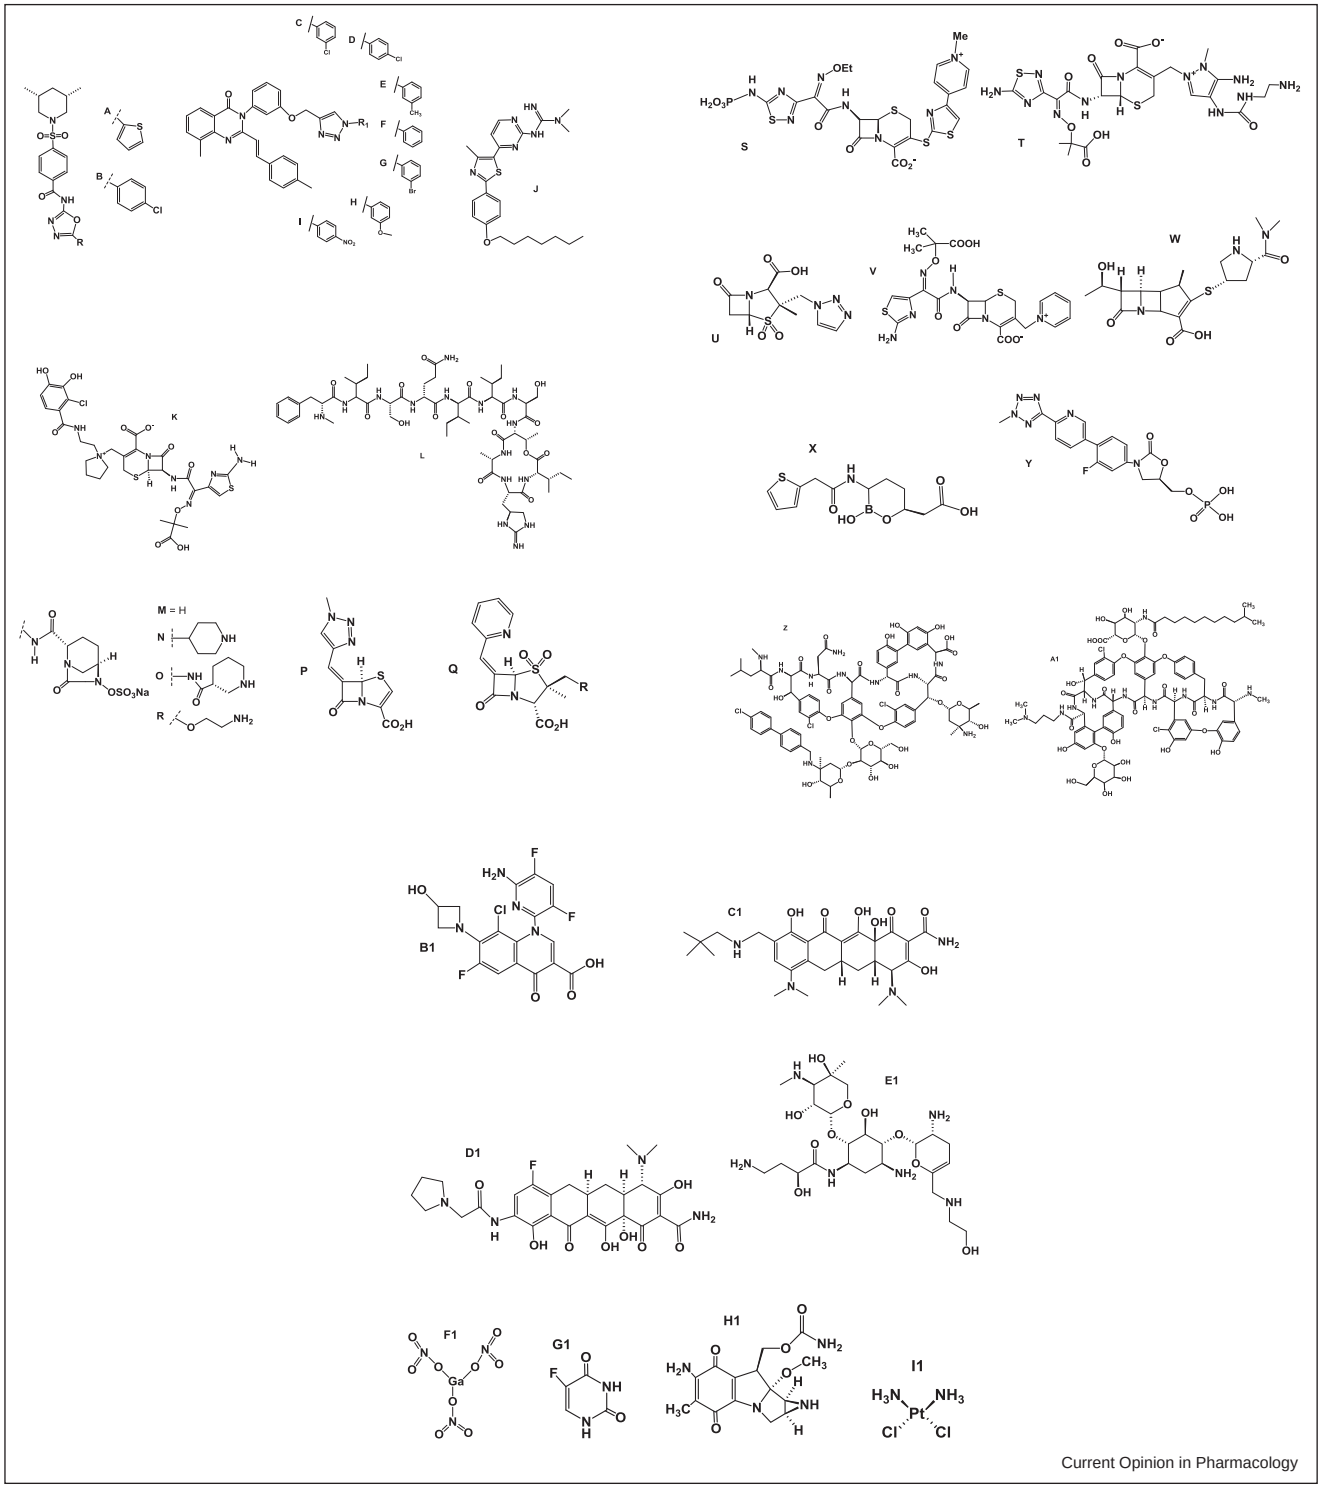
New antimicrobials that have been approved in the last decade to be used in the clinical field against MDR bacterial infections

Antibiotic	Kind	Year approved	Target	Clinical uses	Year of resistance emergence
Ceftaroline (Figure 1S)	Fifth-generation cephalosporin	2010	Penicillin-binding protein (PBPs) β-lactamase inhibitor	Community-acquired bacterial pneumonia (CAP) and acute bacterial skin infections (ABSSSI)	2014 [65]
Ceftolozane/tazobactam (Figure 1T/1U)	Cephalosporin plus β-lactamase inhibitor	2014	Penicillin-binding proteins (PBPs)/inhibits the action of bacterial ß-lactamases	Complicated intra-abdominal infections (cIAIs) complicated urinary tract infections (cUTI)	2014 [66]
Ceftazidime/avibactam (Figure 1V/1M)	Third-generation cephalosporin and the novel, non-β-lactam β-lactamase inhibitor avibactam (bicyclic diazabicyclooctane)	2015	Penicillin binding protein 3 (PBP3)/β-lactamase inhibitor	Complicated urinary tract infections (cUTIs), complicated intra-abdominal infections (cIAIs), hospital-acquired pneumonia (HAP) including ventilator-associated pneumonia (VAP)	2015 [67]
Meropenem/vaborbactam (Figure 1W/1X)	Carbapenem and non-β-lactam, cyclic, boronic acid-based, β-lactamase inhibitor	2017	Penicillin-binding-protein (PBP)/β-lactamase inhibitor	Complicated urinary tract infections	2017 [69]
Tedizolid (Figure 1Y)	2-Oxazolidone	2014	Protein synthesis, inhibits the binding of fMet-tRNA to 70S ribosomes	Acute bacterial skin and skin structure infections (ABSSSI)	2015 [70]
Oritavancin (Figure 1Z)	Lipoglycopeptides antibiotic	2014	Inhibits cell wall biosynthesis by binding noncovalently to the D-alanyl-D-alanine terminal ends of the peptidoglycan chain and pentaglycine bridge, thereby inhibiting transglycosylation and transpeptidation	Acute bacterial skin and skin structure infections (ABSSSI)	2016 [71]
Dalbavancin (Figure 1A1)	Second-generation lipoglycopeptide antibiotic	2014	Inhibition of cell-wall biosynthesis, prevents incorporation of *N*-acetylmuramic acid (NAM)-peptide and *N*-acetylglucosamine (NAG)-peptide subunits from being incorporated into the peptidoglycan matrix	Acute bacterial skin and skin structure infections (ABSSSI)	2018 [72]
Delafloxacin (Figure 1B1)	Fluoroquinolone	2017	Bacterial DNA topoisomerase IV and DNA gyrase (topoisomerase II)	Acute bacterial skin and skin structure infections (ABSSSI)	2012 [73]
Omadacycline (Figure 1C1)	Tetracycline	2018	30S ribosomal subunit	Community acquired bacterial pneumonia (CABP) and acute skin and skin structure infections (ABSSSI)	Not yet [8]
Eravacycline (Figure 1D1)	Tetracycline	2018	30S ribosomal subunit	Complicated intra-abdominal infections (cIAIs) in adults	2018 [74]
Plazomicin (Figure 1E1)	Next-generation aminoglycoside	2018	30S ribosomal subunit	Complicated urinary tract infections	2013 [75]

INFORME DE LABORES 2019

Table 2

Alternative approaches to the use of antibiotics



Approach	Function	Target	Susceptible bacteria
Gallium nitrate (Figure 1F1)	Disrupts iron acquisition and iron-dependent processes	Iron transport by siderophores, iron containing enzymes	*P. aeruginosa, A. baumannii*
QS inhibition	Disruption of bacterial cel–cell communication and virulence	QS receptors, signal disruption, inhibition of signal synthesis	Gram negative including *P. aeruginosa*, Vibrio spp., *A. baumannii* Gram positive including *S. aureus*
Inhibition of T3SS	Disrupts T3SS blocking the secretion of toxins	T3SS	Gram negative bacteria including *E. coli* and *P. aeruginosa*
5-Fluorouracil (Figure 1G1)	Quorum sensing/biofilm inhibitor	QS systems, inhibition of uridine synthesis	Gram negative such as *E. coli* and *P. aeruginosa* Gram positive such as *S. mutants*
Mitomycin C (Figure 1H1)	Crosslinks DNA promoting damage	DNA	*A. baumannii* and *E. coli, P. aeruginosa, S. aureus* (regular and persister cells)
Cisplatin (Figure 1 I1)	Crosslinks DNA promoting damage	DNA	*E. coli, P. aeruginosa, S. aureus* (regular and persister cells)
Photosensitizers	Promoting DNA damage	DNA	Gram negative bacteria *E. coli* and Gram positive *S. aureus*
Far-UVC light	Promoting DNA damage	DNA	*S. aureus*
Adjuvants	Restore antibiotic efficacy	β-Lactamases, efflux pumps, membrane permiability	Gram negative bacteria such as *A. baumannii*, *P. aeruginosa* and Enterobacteria
Antibodies	Bind and neutralize bacterial toxins or cells. Promote destruction of bacterial cells	Toxins, surface proteins, LPS, components of cell wall	Gram negative such as *E. coli* and *P. aeruginosa* Gram positive such as *S. aureus, S. mutants, C. difficile*
Cytokines and other immunomodulatory agents	Adjunctive immunostimulation during sepsis	Host immune cells	Gram negative such as *Pseudomonas* spp., *Enterobacteriacae* spp., Gram positive such as *S. aureus*
Vaccination	Elicit an immune response against an antigen	Host immune cells	*M. tuberculosis*, *S. typhi*, *S. aureus*, *C. difficile*, *E. coli*, *P. aeruginosa*, and so on
Phage therapy	Elicit cell lysis	Bacterial enzymes and cofactors to replicate phages	Gram negative such as *P. aeruginosa,* Gram positive such as *C. difficile*

killing times, and also good antimicrobial activity against antibiotic resistant Gram positive cocci [21]. In 2015, teixobactin, a novel depsipeptide antibiotic that inhibits cell wall synthesis in Gram positive bacteria by binding to conserved motifs of lipid II and lipid III was discovered using a novel culture technique that allowed growth of soil bacteria *in situ* [22]. Interestingly, no resistance to *S. aureus* was found upon 27 daily serial passes in the presence of teixobactin (Figure 1L) [22], suggesting that the presence of multiple simultaneous mutations are needed to achieve resistance, and that if eventually this experimental drug reaches the clinic, resistance against it will be slowly developed. Although several new antibiotics have been developed against Gram positives, MDR Gram negative bacteria represent a higher risk because of lack of treatment possibilities. *A. baumannii*, *P. aeruginosa* and Enterobacteriacea resistant to carbapenems have several resistance mechanisms limiting the use of new antibiotics or antibiotics/adjuvants mixtures such as ceftazidime/avibactam which is active against KPC (*K. pneumoniae* carbapenemase), OXA-48 (oxacillin) and AMPc ß-lactamases producing bacteria, but not against metallo β-lactamases or other OXA like enzymes [23]. Moreover, ceftolozane/tazobactam is active against ESBL (Extended Spectrum ß-Lactamases) but not against carbapenemases, including metallo β-lactamases [24]. Nevertheless a new molecule, cefiderocol (Figure 1K), a combination of a cephalosporin and a catechol group present in siderophores, that allows its internalization, is effective against bacteria expressing metallo β-lactamases, KPC's and OXA members [25••], including non-fermenter bacteria such as *P. aeruginosa*, *A. baumannii* and *Stenotrophomonas maltophilia* [26].

Alternative approaches to the use of antibiotics

An alternative to antibiotics is the use of metals with antimicrobial properties such as silver and copper that are actually used in the clinic [27]. One metal with promising antibacterial activity is gallium, which is a non-redox iron (III) mimetic able to inhibit growth of the majority of MDR isolates of *P. aeruginosa* [28] and *A. baumannii* [29]. Gallium replaces iron in enzymes such as respiratory complexes, anti-oxidant enzymes (catalase), ribonucleotide reductase, and so on, inactivating them. It also disrupts iron transport via the siderophore pyoverdine in *P. aeruginosa* and promotes the generation of oxygen reactive species [28,30,31]. Since it has multiple targets, it was postulated that resistance would be not likely to arise. Indeed, studies in the *P. aeruginosa* reference strains PA14 and PAO1 indicate that either no selection of resistance [32] or only mild selection against it, is achieved by

INFORME DE LABORES 2019

decreasing its uptake via the iron transporter HitAB or by increasing the production of the redox active phenazine pyocyanin [30,33,34]. In addition, gallium is effective in treating murine lung infections and improved the respiratory function of patients with cystic fibrosis infected with *P. aeruginosa* [30]. Moreover, one recent report demonstrated that gallium maltolate is active not only against *P. aeruginosa* and *A. baumannii* but also against some strains of *K. pneumoniae* [35].

A different approach for the treatment of infections is based on the inhibition of virulence, arguing that this would not exert a strong selective pressure for the development of resistance (expression of virulence factors in the presence of the virulence inhibitors [36]). To date, anti-virulence therapies have been focused in the inhibition of quorum sensing (QS) [37]; however, experimental evidence shows that selection of resistance against anti-virulence therapies is possible [38,39]. Recent preclinical studies show that it is possible to attenuate bacterial infections with quorum quenching (QQ) enzymes. In the mouse model of pulmonary infection with *P. aeruginosa*, administration of the acylase PvdQ decreased inflammation and bacterial load, and prolonged mice survival [40•]. Also, flavones reduce bacterial load and damage in a murine model of dermonecrosis with methicillin-resistance *S. aureus* [41]. Nevertheless, it has not been possible to demonstrate that QQ therapies have the capacity to eliminate the damage and clear infections and recent studies indicate that QS inhibition is not sufficient to completely block bacterial virulence in *P. aeruginosa* since this does not block the expression of important virulence factors such as the type three secretion system (T3SS) [42•]. The T3SS is used by many Gram negative pathogenic bacteria including enterohemorrhagic *E. coli*, *Shigella flexneri*, *Salmonella enterica* and *P. aeruginosa*, to inject effector proteins into the cytoplasm of host cells [43]. The importance of the T3SS has been demonstrated in animal models [44]. It has also been shown that cystic fibrosis patients infected with *P. aeruginosa* strains carrying a T3SS were more prompt to develop severe acute infections [45]. In contrast to conventional antibiotics, inhibiting the T3SS would not affect the resident microbiota, avoiding opportunistic infections. Moreover, even though resistance to T3SS inhibition could arise, this would likely not be a resistance mechanism that would be horizontally transferred to non-pathogenic bacteria. Therapeutic strategies against the T3SS include antibodies, small molecules, natural compounds and peptides that inhibit its function [46].

Potential sources of antimicrobial and anti-virulence molecules ready to be used are drugs currently in use in the clinical setting for other purposes, since their implementation will be much faster compared to antimicrobials developed *de novo*, examples are 5-fluorouracil, gallium nitrate, and anticancer drugs such as cisplatin and mitomycin C that are able to kill MDR bacteria and persister cells [47,48]. Nevertheless, more studies aiming to evaluate the development of bacterial resistance against these molecules are necessary.

Another promising strategy to combat MDR bacteria is the administration of photosensitizers, which generate reactive oxygen species upon illumination killing bacteria without promoting the selection of resistance [49], or the utilization far-UVC light, which kills MDR bacteria, without damaging cells in tissues [50]. Nevertheless, the potential for the development of resistance against these treatments is still unexplored.

Recently phage therapy has regained attention to be used as an alternative or complement to antibiotics. The potential effectiveness of phage therapy could be of great use especially in patients with chronic MDR infections. Successful phage therapy in humans was demonstrated in two recent case reports, one concerning a patient with *P. aeruginosa* septicaemia [51] and the other a patient with *P. aeruginosa* aortic graft infection [52], aiming a favorable outcome. Some issues such as bacteriophage choice, isolation, preparation, purification, storage, and pharmacology must be considered, as well as regulations for their production.

A way to circumvent bacterial resistance is the use of adjuvants (that administered simultaneously with antibiotics), rescue the antimicrobial action via the disruption of bacterial resistance pathways. To date three main types of adjuvants exist: β-lactamase inhibitors, efflux pumps and external membrane permeabilizers. The β-lactamase inhibitors are widely used, among them clavulanic acid, sulbactam and tazobactam are in clinical use and act as covalent inhibitors, although they are not effective against class C and D β-lactamases. Compounds such as avibactam (Figure 1M) a diazabicyclooctane (DBO) have high inhibitory activity in the majority of β-lactamases of class A and C, as mentioned above. Other DBO compounds in clinical trials are relebactam (Figure 1N), zidebactam (Figure 1O), BRL 42715 (Figure 1P, LN-1-255 (Figure 1Q) and OP0595 (Figure 1R); however, to date there are no inhibitors for class B β-lactamases [5•].

Although several efflux pump inhibitors such as piperidines, quinolines, pyridopyrimidines and arylpiperazines, have been discovered they are still not in use in the clinic [5•,53]. Alternatively, the external membrane permeabilizers could be useful for the treatment of Gram negative bacteria by facilitating the entry of antibiotics as they destabilize the outer layer of the membrane interacting with polyanionic lipopolysaccharides or trapping cations of the outer layer, among them some cationic peptides and polyamines, had shown promising results [5•].

Other clever strategies recently developed to combat bacterial infections include cytotoxic pore-forming toxins secreted by Gram positive bacteria sequestered by

artificial liposomes [54]. The use of an extracorporeal device that cleanses circulating blood using magnetic nanobeads coated with an engineered human mannose binding lectin that reduce the load of circulating bacterial cells and toxins [55], and immunotherapies with antibodies, cytokines or vaccines [56,57,58•]. Antibodies bind and neutralize bacterial toxins or cells promoting their phagocytosis and destruction by macrophages and neutrophils; additionally, opsonization promotes bacterial lysis via complement [57]. Currently, 78 therapeutic antibodies are FDA-approved and hundreds more are in clinical trials [IMGTDB]. Although only 2 targeting bacterial epitopes are in the market (bezlotoxumab and raxibacumab), about 20 more are currently in clinical trials [IMGTDB]. Antibodies targeting MDR bacteria could be used therapeutically or for prophylaxis, if the epitope is highly conserved or is involved in pathogenesis, the probability of resistance is low [57]. Although one of the concerns is their narrow spectrum [58•], specificity is one of their strengths [59]. Moreover, antibodies that target host antigens can correct exacerbated inflammation or reverse immunosuppression [56].

The use of cytokines as immunostimulators has been proved useful during sepsis (IFNg, IL-7, GM-CSF, thymosin-a1, IL-15, FLT3L) and tuberculosis (IFNg, TNF, IL-1) [56,60], and some are in clinical trials [56]. However, in-depth knowledge of host–pathogen interactions is necessary to design effective immunotherapies as overdoses of cytokines may lead to hyper inflammation and death of immune cells [56].

Vaccination has the potential to prevent infections by MDR bacteria [58•]. Among the recent technologies in vaccine development are reverse vaccinology, new adjuvants, structural vaccinology, glycoconjugate vaccines, live vaccines, and engineered outer membrane vesicles [58•].

An additional important aspect to consider related to immunotherapies is that MDR acquisition is closely related to modifications in bacterial structures that modulate the host immune system [61–64], so the host–pathogen interactions might not be equivalent in susceptible versus resistant bacterial strains. Hence, to develop effective immunotherapies to control and eradicate this health problem, it will be critical to use MDR clinical isolates to assure its efficacy *in vivo*.

Concluding remarks

Although the current situation regarding MDR resistance is alarming, there are several approaches to fight drug-resistant bacteria. The interest in the development of new antimicrobials, open several research avenues and bring hope for the development of effective and robust therapies against bacterial infections that eventually could give us an advantage in the race between antimicrobial

Front. Microbiol. 10:2657. doi: 10.3389/fmicb.2019.02657

Pseudomonas aeruginosa is an opportunistic bacterium associated with healthcare infections in intensive care units (ICUs), ventilator-associated pneumonia (VAP), surgical site infections, and burns. This bacterium causes 75% of death in burned patients, since it can develop a persistent biofilm associated with infections, express several virulence factors, and antibiotic-resistance mechanisms. Some of these virulence factors are proteases such as elastase and alkaline protease, or toxic metabolites such as pyocyanin and is one of the few microorganisms able to produce cyanide, which inhibits the cytochrome oxidase of host cells. These virulence factors are controlled by quorum sensing (QS). In this work, 30 *P. aeruginosa* clinical strains isolated from burned patients from a tertiary hospital in Mexico City were studied. Antibiotic susceptibility tests were done, and virulence factors (elastase, alkaline protease, HCN, and pyocyanin) were determined in presence of an N-acylhomoserine lactonase, AiiM able to hydrolyze a wide range of acyl homoserine lactones. The treatment reduced significantly the activities of elastase and alkaline protease, and the production of pyocyanin and HCN in all producer strains but not the secretion of toxins through the type III secretion system. Our work suggests that AiiM treatment may be an effective therapy to combat *P. aeruginosa* infection in burn patients.

Keywords: AiiM lactonase, virulence factors, *Pseudomonas aeruginosa*, quorum quenching, burned patients, anti-virulence therapy

INTRODUCTION

Pseudomonas aeruginosa is an opportunistic bacteria associated with healthcare infections in intensive care units (ICUs), ventilator-associated pneumonia (VAP), central line-associated blood stream infections, surgical site infections (Cohen et al., 2017), burnt wounds (Fournier et al., 2016), and urinary tract infections, otitis media, and keratitis (Chatterjee et al., 2016; Olivares et al., 2016). In the United States, according to the Centers for Disease Control and Prevention, in 2013 it was estimated that every year around 51,000 health-care infections are associated to *P. aeruginosa,* of which 6,700 are multidrug resistant, causing 440 deaths per year (Centers for Disease Control and Prevention, 2018)[1]. Both *P. aeruginosa* and *Acinetobacter baumannii* complex are the most important, resistant and dangerous microorganisms infecting burnt patients (Tredget et al., 1992; Estahbanati et al., 2002; Turner et al., 2014; Centers for Disease Control and Prevention, 2019). Despite medicine advances, these sorts of complications are still a huge problem to solve, and as a consequence, around 75% of burned infected patients die. Burn infections related to *P. aeruginosa* often promote a faster deterioration allowing the spread of bacteria causing death in weeks and even in days (Mcmanus et al., 1985; Turner et al., 2014). *P. aeruginosa* has a wide arsenal of virulence factors that enable it to colonize and cause infections in the host, the relevance of these virulence factors has been demonstrated using *P. aeruginosa* strains with deficiencies in their production, leading to a reduced ability of colonizing and a lower dissemination in the host (Pavlovskis and Wretlind, 1979; Rumbaugh et al., 2009; Jimenez et al., 2012; Castillo-Juarez et al., 2015). Elastase is a metalloprotease that disrupts several proteins such as: collagen, elastin, immunoglobulins (IgA and IgG), complement components, and cytokines like interferon gamma and tumor necrosis factor alpha (Pavlovskis and Wretlind, 1979; Lyczak et al., 2000; Ben Haj Khalifa et al., 2011). Alkaline protease is also a zinc metalloprotease that inhibits phagocytosis, killing through neutrophils, opsonization, the action of the complement cascade by degrading C3b and is as well related to corneal damage (Howe and Iglewski, 1984; Ben Haj Khalifa et al., 2011; Laarman et al., 2012; Lee and Zhang, 2015). *P. aeruginosa* is one of the few microorganisms that can synthesize cyanide through the oxidative decarboxylation of glycine by hydrogen cyanide synthase enzyme, under micro-aerobic conditions (O_2 < 5%). HCN is a poison that inhibits respiration by inactivating cytochrome oxidase C (Huber et al., 2016). Another important virulence factor is pyocyanin, a blue phenazine, that promotes oxidative stress, which inhibits ciliary movement and delays inflammatory response due to the damage of neutrophils and apoptosis induction (Ben Haj Khalifa et al., 2011; Lee and Zhang, 2015). In burn injuries, pyocyanin plays an important role because it stimulates colonization, damage of surrounding tissue and promotes dissemination. Furthermore, *P. aeruginosa* strains are often multi-drug resistant, limiting treatment options in healthcare settings around the globe, owing this the World Health Organization classified *P. aeruginosa* as the second more threatening bacterium. Moreover, although new antibiotics are available, each time, resistance against those new drugs quickly appears (Fournier et al., 2016; Shortridge et al., 2017; Karampatakis et al., 2018; Shields et al., 2018). In many pathogenic bacteria, virulence factors are controlled by cell to cell communication known as quorum sensing (QS). *P. aeruginosa* has two QS systems mediated by N-acyl homoserine lactones, Las and Rhl, each one is constituted by three elements, a synthase, a signal receptor and an autoinducer signal. The Las system is formed by LasI which is the synthase, the receptor is LasR and the autoinducer is N-3-oxo-dodecanoyl-L-homoserine lactone, meanwhile the Rhl system is formed by the synthase RhlI, RhlR as receptor and the auto-inducer is N-butyryl-homoserine lactone. These two systems are hierarchically organized and each one of them controls several virulence factors. The Las system regulates the Rhl system and virulence factors such as elastase, protease, exotoxin A, alkaline protease and type II secretion system; while the Rhl system enhances the production of rhamnolipids, hydrogen cyanide, and pyocyanin (Van Delden and Iglewski, 1998; Douzi et al., 2011; Lee and Zhang, 2015). Due to the fast increase in bacterial resistance, alternative strategies such as quorum quenching (QQ) have been proposed. QQ consists of blocking or inhibiting cell to cell communication by obstructing the autoinducer synthases, the signal receptors or by degrading the autoinducers via two enzymatic strategies: disrupting the lactone ring through a lactonase or through the cleavage of the acylic tail by acylases (Defoirdt et al., 2013; Defoirdt, 2018). The aim of this work is to evaluate the activity of AiiM, a lactonase enzyme, in *P. aeruginosa* clinical bacterial strains isolated from burnt patients in a third level center of Mexico City, in order to find out if its utilization could eventually be proposed to treat infected burnt patients.

MATERIALS AND METHODS

Clinical Strains

Randomly 200 strains were selected[2] from the collection belonging to Infectious Diseases Laboratory at Centro Nacional de Investigación y Atención de Quemados at Instituto Nacional de Rehabilitación Luis Guillermo Ibarra, to avoid genomic redundancy pulsed field, gel electrophoresis was performed and only one strain per clonal group was selected for further experiments. Clinical strains were identified with Vitek 2 Compact® (Biomerieux, France) with Gram negative card identification, some biochemical tests included were oxidase, indole production, growth at 42°C, arginine dihydrolase and glucose oxidation/fermentation. The origin of each clinical isolate is shown in **Supplementary Table S1**.

Minimal Inhibitory Concentrations

Minimal inhibitory concentrations were determined according to Clinical and Laboratory Standards Institute® (CLSI) M07-A10 (CLSI, 2015) in 96-well plates. Breakpoints interpretation were made according to the M100 Performance Standards for

[1]https://www.cdc.gov/hai/organisms/pseudomonas.html

[2]www.randomization.com

Antimicrobial susceptibility testing 28th edition (CLSI, 2019). Antibiotics included were amikacin (Sigma Aldrich A1774), gentamicin (Sigma Aldrich G3632), aztreonam (Sigma Aldrich PZ0038), ceftazidime (Sigma Aldrich C3809), cefepime (Sigma Aldrich PHR1763), ciprofloxacin (Sigma Aldrich 17850), levofloxacin (Sigma Aldrich 28266), doripenem (Sigma Aldrich 32138), imipenem (Sigma Aldrich I0160), meropenem (Sigma Aldrich M2574), colistin (Sigma Aldrich C4461), and piperacillin/tazobactam (Sigma Aldrich P8396/T2820). *P. aeruginosa* ATCC® 27853 was used as control as according to CLSI (**Supplementary Table S1**).

las/rhl Genes Detection

DNA Extraction

Pseudomonas aeruginosa strains were cultured in 5% sheep blood agar during 18 h at 37°C, and then one single colony was taken and lysed in an Eppendorf tube with 500 μL of TE buffer (10 mM Tris–HCl, 1 mM EDTA, pH 7.5) and were set into a heat block at 95°C for 5 min. Tubes were centrifuged, and the supernatant was added into a new tube.

Genes related to Las and Rhl systems were amplified (**Table 1**) in a final volume of 25 μL of buffer 1X, 3 mM $MgCl_2$, 200 μM dNTP′s, 0.2 μM primer forward and reverse, 0.026 U/μL Taq polymerase (Amplitaq Gold® DNA Polymerase, Applied Biosystems N808-0241, United States). The amplification conditions used were: 95°C 10 min, 95°C 30 s, 58°C 45 s and 72°C 50 s during 35 cycles, 72°C 5 min and finally 4°C (Veriti 96 Well thermal cycler, Applied Biosystems, United States). Amplification products were loaded into a 1% agarose gel stained with SYBR® green I (S7567, Life Technologies, United States) and visualized with Gel DOC™ XR + with Image Lab™ software (Bio-Rad, United States). *P. aeruginosa* PAO1 was used as positive control in each one of the systems and Δ *lasR/rhlR* PAO1 as negative control of transcriptional regulators.

AiiM Purification

AiiM construction was provided by Dr. Toshinari Maeda (Nguyen et al., 2019). Briefly 50 mL *Escherichia coli* M15/pQE30 AiiM was grown overnight (ON) in Luria Bertani broth with 100 μg/mL of carbenicillin (Sigma Aldrich C1389) and 50 μg/mL of kanamycin (Sigma Aldrich K1876), afterward, 10 mL of the ON cultures were taken and inoculated into 1 L of terrific broth with carbenicillin and kanamycin as above described, cultures were incubated at 37°C 220 rpm, optical density (OD) at 600 nm was measured until the culture reached an OD of 0.5 and immediately after, it was induced with 500 μM IPTG. The cultures were incubated at 37°C 220 rpm for 6 h and centrifuged at 10,000 rpm for 40 min. Pellets were resuspended in 40 mL of purification buffer (50 mM NaH_2PO_4, 300 mM NaCl and 10% glycerol, pH adjusted to 8.0) and 500 μM PMSF (Sigma Aldrich P7626), sonicated (45% amplitude for 45 s and 2 min of rest, all this 10 times; Ultrasonic processor, Cole Parmer) and centrifuged at 10,000 rpm during 40 min. The supernatants were passed through a 0.2 nm filter and loaded onto Protino® Ni-TED resin (Macherey-Nagel, 745200.600) for purification of His-tagged proteins previously equilibrated with 3 column volumes (CV) of 20 mL of purification buffer, then filtered protein extracts were passed through the column, after that, 2 additional CV of purification buffer were passed. Protein was eluted with 150 mM imidazole (Sigma Aldrich I5513) in 2 CV of purification buffer. AiiM fractions with higher purity were selected, concentrated with polyethylene glycol 35 KDa (Sigma Aldrich 946-46) into dialysis tubing cellulose membrane (Sigma Aldrich D9777). Afterward, dialysis was done to remove imidazole using dialysis buffer (50 mM Tris, 300 mM NaCl adjusted at pH 7.5). SDS-PAGE was done to estimate the amount and purity of AiiM. Protein was quantified by its absorbance at 280 nm with NanoDrop 2000 (Thermo Fisher Scientific, United States), using an extinction coefficient (Abs 0.1%) of 1.08. Aliquots of protein were made and stored at −20°C until they were used.

AiiM Activity Against N-acyl Homoserine Lactones

To evaluate the HSL lytic activity of the purified AiiM, an analytical assay was developed in an Alliance HPLC system (Waters, United States) with a Symmetry (Waters, United States) C18 Column (75 mm, 3.5 mm). Both short and long acylated chains were included, 1 mM *N*-butyryl-DL-homoserine lactone (C4-HSL; Sigma Aldrich 09945), 1 mM *N*-(3-oxooctanoyl)-L-homoserine lactone (3OC8-HSL;Sigma Aldrich O1764), 1 mM *N*-decanoyl-DL-homoserine lactone (C10-HSL; Sigma Aldrich 17248), 1 mM *N*-(3-oxodecanoyl)-L-homoserine lactone (3OC10-HSL; Sigma Aldrich O9014), and *N*-(3-oxododecanoyl) homoserine lactone (3OC12-HSL; Sigma Aldrich O9139). 60 mM NaOH was used as positive control since it can hydrolyze HSL molecules and the reaction was stopped with the addition of 2N HCl. Several concentrations, from 250, 100, 50, 25, 10, and 5 μg/mL of purified AiiM were tested. Time exposition was also varied; 24 h, 2 h, 1 h, 30 min, 20 min, 10 min, and 5 min. All experiments were performed in triplicate. Chromatographic conditions were: column temperature 25°C, sample temperature 25°C, injection volume 10 μL, flow rate 1 mL/min, detection 205 nm. Elution mixture was made with 50 mM phosphates buffer pH 2.9:acetonitrile. For C4-HSL the relation was 90:10, 3OC8-HSL 60:40, C10-HSL 60:40, 3OC10-HSL 60:40, and 3OC12-HSL 50:50.

Bacterial Growth With and Without AiiM

Grow curves were analyzed to test the effect of AiiM on *P. aeruginosa* PAO1 and Δ *lasR/rhlR* PAO1 growth kinetics.

A 50 mL flask with 5 mL of LB was inoculated with each one of the strains at an initial OD_{600nm} of 0.05 with and without 5 μg/mL of AiiM, samples were taken each hour for 12 h.

Virulence Factors Determination

Elastase was determined for clinical strains and *P. aeruginosa* PAO1 Δ*lasR/rhlR* and Δ*lasI/rhlI* PAO1 mutants according to methods previously described (Ohman et al., 1980), with some modifications. ON of each clinical strain and control strains were cultured in LB at 37°C 220 rpm and were inoculated at an initial OD_{600nm} of 0.05 in 5 mL of LB with and without AiiM (5 μg/mL), samples were incubated for 18 h at 37°C and 220 rpm, and centrifuged at 14,000 rpm for 2 min. 50 μL of the supernatant were taken and set into 950 μL of elastase buffer (100 mM Tris–HCl, 1 mM $CaCl_2$, pH 7.5) with 2.5 mg of elastin-congo red (Sigma Aldrich reference E0502) as substrate. Tubes were incubated at 37°C, 220 rpm for 2 h, centrifuged at 14,000 rpm for 5 min and the released die in the supernatant was measured at 495 nm with a spectrophotometer SmartSpec Plus (Bio-Rad, United States). All determinations were performed by triplicate.

Alkaline Protease

Alkaline protease was determined according to methods previously described (Howe and Iglewski, 1984), with some modifications. ON of each strains were cultured into LB at 37°C 220 rpm and were inoculated in 5 mL of LB at an initial OD_{600nm} of 0.05 with and without AiiM (5 μg/mL). AiiM protein was added at the beginning of the cultures, samples were incubated for 18 h at 37°C and 220 rpm, and centrifuged at 14,000 rpm for 2 min. 50 μL of supernatant were taken and added into 950 μL of protease buffer with 2.5 mg of Hide-Remazol brilliant blue R (Sigma Aldrich reference H6268) as substrate. Tubes were incubated at 37°C, 220 rpm for 20 min centrifuged at 14,000 rpm 5 min and the supernatant was measured at 595 nm with a spectrophotometer SmartSpec Plus (Bio-Rad, United States).

Pyocyanin

For pyocyanin production ON of each clinical and control strains were cultured in LB at 37°C at 220 rpm and inoculated into 5 mL of LB at an initial OD_{600nm} 0.05 with and without AiiM (5 μg/mL). AiiM protein was added at the beginning, samples were incubated 18 h at 37°C and 220 rpm. One milliliter of supernatant was taken, centrifuged at 14,000 rpm for 5 min, and then 800 μL of supernatant were set into new 1.5 mL conic tube and 400 μL of chloroform was added, each tube was mixed in vortex for 2 min. Tubes were centrifuged for 5 min at 14,000 rpm, 300 μL of the organic phase were taken and deposited into a new tube, 800 μL of 0.2 N HCl were added and mixed for 2 min in vortex then samples were read at 520 nm (Maeda et al., 2012). *P. aeruginosa* PAO1, Δ*lasR/rhlR* PAO1 and Δ*lasI/rhlI* PAO1 were used as positive and negative controls, respectively.

HCN Determination

For HCN determination, bacteria were cultured in 3 mL of LB medium in flasks with rubber stoppers at 37°C and 200 rpm for 18 h, after the incubation two needles were inserted in the rubber stopper, one of them was used for pumping air for 1 h and the other to collect the outflow in 5 mL of 4 M NaOH. HCN concentrations were determined as described by Gallagher and Manoil (2001), briefly, samples were mixed with a 1:1 fresh mixture of 0.1 M *o*-dinitrobenzene and 0.2 M *p*-nitrobenzaldehyde both dissolved in 2-methoxyethanol, and following 20 min of incubation at room temperature, the absorbance at 578 nm was determined and compared with a calibration curve made with KCN standards.

AiiM Dose Response Curve and Suppression of Its Activity by Exogenous Addition of 3OC12-HSL

For these control experiments, the PAO1 reference strain and the clinical isolate P809 were used. Three independent cultures per strain were inoculated in LB medium at an initial OD_{600nm} of 0.05 without and with AiiM at 0.5, 1, 2.5, and 5 μg/mL, and incubated 37°C at 220 rpm, supernatants were then obtained and used for the determination of pyocyanin concentration and elastase activity (as described before). In addition another 3 cultures per strain with AiiM 0.5 μg/mL were grown to an OD_{600nm} of ∼ 1.0, supplemented with a final concentration of 30 μM of 3OC12-HSL, and incubated until 18 h of incubation were completed, supernatants were collected and pyocyanin concentration and elastase activity determined.

Long Chain HSL Autoinducer Detection and Its Inactivation by AiiM

To identify autoinducer production and its inactivation by AiiM, each one of the 30 clinical strains were grew up onto MacConkey agar plates, then one colony was taken and inoculated into 5 mL of LB for ON growth. After that, new cultures were inoculated at an initial OD_{600nm} 0.05 in 5 mL of LB and grown at 37°C, with 220 rpm shaking during 18 h, with AiiM 5 μg/mL and without AiiM enzyme. LB cultures then were centrifuged 14,000 rpm for 5 min. Supernatants were separated in new tubes. For long chain HSL detection *Agrobacterium tumefaciens* NT1 pZLR4 (Shaw et al., 1997) was used as a biosensor strain. Previously the biosensor strain was grown in one liter of M9 medium and incubated at 37°C and 220 rpm for 18 h. Bacteria were concentrated by centrifugation at 12,000 rpm during 5 min to a final volume of 15 mL, then aliquots of 1 mL of concentrated bacteria were separated. M9 agar plates were prepared and before solidification 1 mL of the concentrated biosensor plus Xgal at a final concentration of 40 μg/mL (5-bromo-4-chloro-3-indolyl- ß-D-galactopyranoside, USB corporation, Cleveland, OH, United States) were added for 100 mL of M9 agar. 15 μL of each supernatant (with and without AiiM) were then added onto 6 mm filter paper sterile disk on the M9 agar. All experiments were done by triplicate. 1 mM *N*-decanoyl-DL-homoserine lactone (C10-HSL; Sigma Aldrich 17248), 1 mM *N*-(3-oxodecanoyl)-L-homoserine lactone (3OC10-HSL; Sigma Aldrich O9014) and *N*-(3-oxododecanoyl) homoserine lactone (3OC12-HSL; Sigma Aldrich O9139) were used as positive controls and the molecules treated with AiiM 5 μg/mL as negative controls. Plates were incubated at 28°C and results were observed, a positive reaction associated to the production of long chain HSL was observed as a green halo and inactivation of the signals when the halo was absent.

Type III Protein Secretion Profiles

For type III secretion assays *P. aeruginosa* strains (PAO1, PA14, and the clinical isolates H015 and P729) were grown overnight in LB medium. Bacteria were diluted 1:200 into 4 mL of a modified LB medium supplemented with 10 mM $MgCl_2$, 0.5 mM $CaCl_2$ and 5 mM EGTA (pH 7.4) in the presence or absence of 5 μg/mL of AiiM, and grown at 37°C to an OD_{600nm} of 0.8 to 1.0. 1 mL of each culture was collected into a microcentrifuge tube and bacteria were pelleted by centrifugation. The resulting pellet was resuspended in 200 μl of 1× Laemmli SDS sample buffer normalized for OD_{600nm}. The supernatant was centrifuged once again and the resulting supernatant was transferred into a clean tube. Supernatant proteins were precipitated overnight at 4°C by adding trichloroacetic acid to a final concentration of 10%, pelleted by centrifugation and resuspended in 20 μL of 1x Laemmli SDS sample buffer containing 10% saturated Tris base normalized for OD_{600nm}. Samples were separated by 15% SDS-PAGE, transferred onto a nitrocellulose membrane and probed for the presence of the effectors ExoS and ExoU by immunoblotting. Detection was performed using the Immobilon Western chemiluminescent HRP substrate (Millipore), and bands were visualized on X-ray films (Carestream MXB Film).

ß-Lactams Inactivation

As ß-lactams have a lactone ring, we performed the inactivation disk method to determine whether AiiM would be able to inactivate this kind of antibiotics. Briefly, 2 mL of 0.8% isotonic saline solution (ISS) was added into sterile 12 mm × 75 mm tube, disks of 30 μg ceftazidime (Becton Dickinson, United States), 30 μg cefepime (Becton Dickinson, United States), 10 μg imipenem (Becton Dickinson, United States), and 10 μg meropenem (Becton Dickinson, United States). One set of disks containing ISS was used as negative control, another set of all antibiotics above mentioned with 5 μg/mL of AiiM, and finally, since NaOH can break the lactone ring another set of all antibiotics was used as positive control with 60 mM NaOH. *Escherichia coli* ATCC® 25922 was used as a pansusceptible strain. Disks were incubated for 1 and 10 min, 2 and 24 h. A suspension of 0.5 McFarland was made with *E. coli* ATCC® 25922 and was plated onto Müller Hinton agar (Becton Dickinson, United States), tubes were incubated at 37°C until their use. All experiments were made by triplicate; the inhibition diameter was measured using a Vernier device.

RESULTS

All clinical isolates were obtained from burned patients infected with *P. aeruginosa*. The most common burn etiology was fire (66.7%) followed by scalds (23.3%) and electrical burns (10%). Medians of hospital length of stay were 53 days (8-303), the mean total body surface area was 40% (10-85%) with a mortality rate of 26.6% ($n = 8$). *P. aeruginosa* strains were isolated from urine ($n = 8$), quantitative biopsies ($n = 8$), blood ($n = 6$), endotracheal aspirates ($n = 3$), bronchoalveolar lavage fluid ($n = 2$), catheter tips ($n = 2$), and qualitative biopsy ($n = 1$).

Pseudomonas aeruginosa Antibiotic Susceptibility Patterns

Susceptibility tests were carried out for all clinical isolates with different antibiotic families including aminoglycosides, monobactams, cephalosporins, fluoroquinolones, carbapenems, lipopeptides, and ß-lactam combination agents. The strains were resistant to almost all antibiotics except colistin (**Figure 1**), resistance rates against all antibiotics families were over 50%. The highest resistance rates were for carbapenems which, until recent decades, were the most potent antibiotics against *P. aeruginosa* and other non-fermentative Gram negative rods; therefore colistin represents the last treatment option for these types of infections (**Supplementary Table S1**).

Gene Amplification

In order to determine if Las/Rhl systems were present in *P. aeruginosa* isolated from burned patients, PCR was performed using the primers described in **Table 1**. Results showed that the genes encoding the Las system (*lasI* and *lasR*) and Rhl system (*rhlI* and *rhlR*) were found in all the clinical strains. *P. aeruginosa* PAO1 was used as positive control and Δ*lasR/rhlR* PAO1 was used as negative control (data not shown).

AiiM Purification

AiiM protein was obtained at a purity of >90% as judged by SDS-PAGE. After elution with 150 mM imidazole, fractions were collected, and those in which AiiM was present were concentrated into dialysis tubing cellulose membrane with polyethylene glycol, then protein concentration was determined and kept at −20°C until used. The purified protein consists of a single band of ≈ 27 kDa, compared with a theoretical molecular mass of 27.2 kDa (**Supplementary Figure S1**).

AiiM Activity Against Homoserine Lactones

In order to prove AiiM activity against acylated chains of diverse HSL, cleavage was determined by HPLC. Five HSL autoinducers with both short and long chains were tested (C4-HSL, 3OC8-HSL, C10-HSL, 3OC10-HSL, and 3OC12-HSL). First HSL alone was run to identify retention times (**Supplementary Table S2**), later the same HSL were treated with 60 mM NaOH to disrupt the lactone ring and finally HSL molecules were treated with AiiM and HPLC experiments were performed under the same conditions. Several AiiM concentrations (250 μg/mL, 100 μg/mL, 50 μg/mL, 25 μg/mL, 10 μg/mL, and 5 μg/mL) were used, in order to identify the lowest one suitable for inhibiting the expression of virulence factors. Each HSL was used at 1 mM. The lowest concentration of AiiM tested (5 μg/mL) was enough to cleave all the HSLs in 5 min (**Figure 2** and **Supplementary Figure S2**) and therefore, this concentration was used for all subsequent experiments.

AiiM Does Not Affect *Pseudomonas aeruginosa* Growth

Growth curves of *P. aeruginosa* with and without AiiM were done to determine if its addition had any effect in the growth rates.

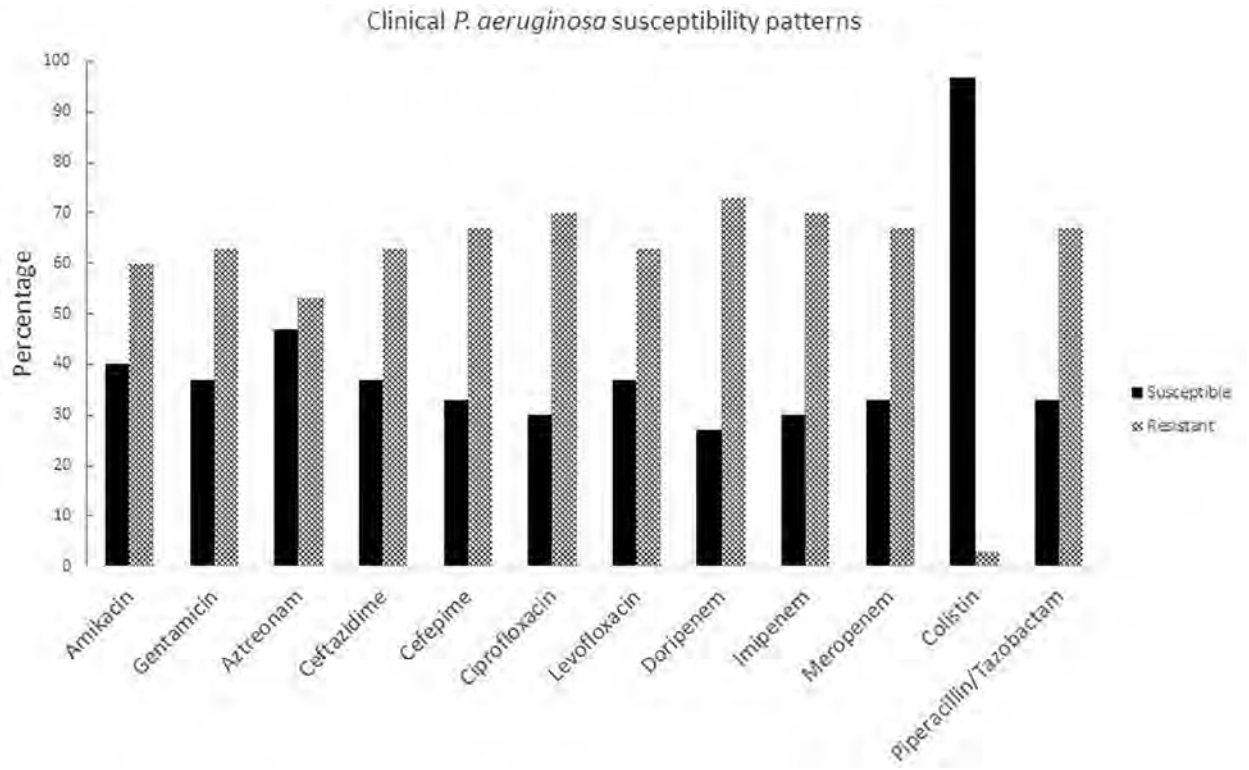

FIGURE 1 | Susceptibility patterns of clinical *P. aeruginosa* strains isolated from burned patients.

As expected, there was no difference in the growing dynamics between these cultures (**Supplementary Figure S3**). PAO1 and Δ *lasR/rhlR* strains were used as controls.

QS-Controlled Virulence Factors Inhibition

Once it was confirmed that AiiM did not affect *P. aeruginosa* growth, its effect over the expression of the QS-controlled virulence factors was determined. Experiments were classified in two groups, one without AiiM addition, and the other with 5 μg/mL addition of AiiM. For elastolytic activity (**Figure 3A**), activity was found in 29 clinical samples, while for alkaline protease activity (**Figure 3B**) there were 27 producing strains; only 12 strains produced pyocyanin (**Figure 3C**), and seven strains were HCN producers (**Figure 3D**). At the same time, experiments with AiiM addition were carried out and the same virulence factors were measured. A significant decrease in the production of each virulence factor was found (elastase $p = 0.000002$, protease $p = 0.000004$, pyocyanin $p = 0.001$ and $p = 0.008$ for HCN).

In addition, AiiM dose response experiments using it at 0.5, 1, 2.5 and 5 μg/mL were performed with the reference strain PAO1 and the clinical isolate P809 measuring pyocyanin production and elastase activity, as expected the degree of inhibition of both phenotypes was dependent in the concentration of AiiM for both virulence factors (**Supplementary Figure S4**). Moreover the effect of 0.5 μg/mL was partially reversed by the addition of 30 μM of 3OC12-HSL (**Supplementary Figure S4**). In order to verify that the clinical strains had active QS systems and that the inhibitory effect in the expression of QS-dependent virulence factors exerted by AiiM was mediated by the degradation of QS signals. Identification of long chain HSL for each strain was done using the biosensor strain *Agrobacterium tumefaciens* NT1 pZLR4 (Shaw et al., 1997), as expected all strains were long chain HSL producers, moreover also for all strains AiiM at 5 μg/mL was enough to degrade the long chain HSL of all strains as determined with the biosensor strain (**Supplementary Figure S5**).

AiiM Does Not Inhibit the Type III Secretion System

Despite its strong inhibitory activity against QS-controlled virulence factors, AiiM had no effect on the secretion of T3SS effectors in both PA14 and PAO1 type strains as well as in the clinical strains P729 and H015 at 5 μg/mL (**Supplementary Figure S6**) and even using 20 μg/mL (data not shown). These two clinical strains were selected as representative examples of a secretion profile similar to strains PAO1 or PA14, respectively.

AiiM Does Not Inactivate ß-Lactam Antibiotics

Wang et al. (2010) defined AiiM as a member of the superfamily of alpha/beta hydrolases, this may represent a problem if it has the ability to inactivate the broad spectrum of ß-lactam antibiotics

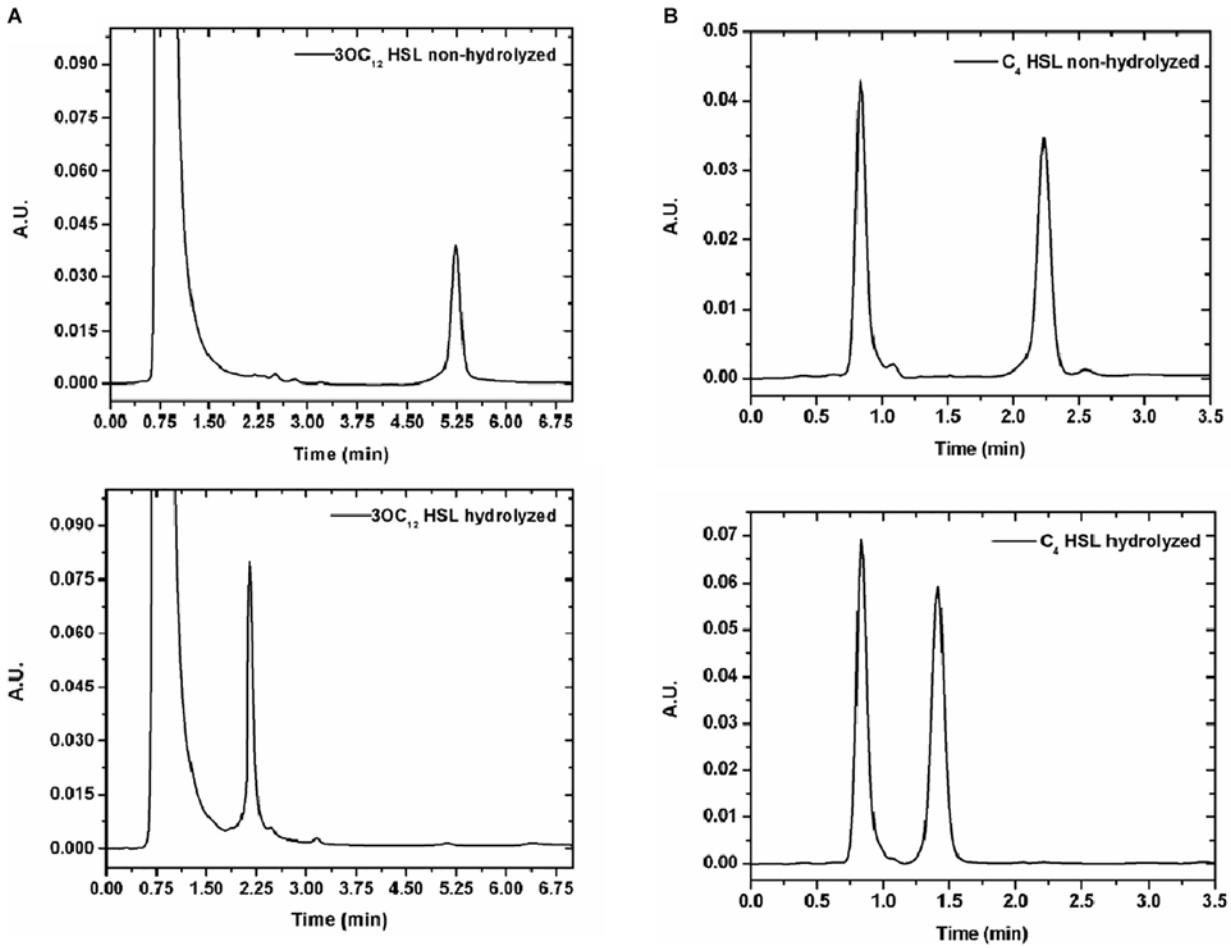

FIGURE 2 | (A) HPLC of HSL without (above) and with 5 μg/mL of AiiM (below) after 5 min of exposition. 2A *N*-(3-oxododecanoyl) homoserine lactone. Retention time for non-hydrolyzed HSL is 5.3 min whereas for hydrolyzed is 2.24 min. **(B)** 2B *N*-butyryl-DL-homoserine lactone. Retention time for non-hydrolyzed is 2.29 min whereas for hydrolyzed is 1.42 min.

as other carbapenem enzymes do, such as NDM, IMP or VIM. In order to test this, we exposed anti *Pseudomonas* ß-lactam antibiotics to 5 μg/mL of AiiM (**Supplementary Figures S7, S8**). Nevertheless, AiiM did not degrade any anti *Pseudomonas* ß-lactam antibiotics.

DISCUSSION

Pseudomonas aeruginosa is one of the main bacteria that causes hospital acquired infections in immunocompromised patients and vulnerable ones (Azam and Khan, 2018). *P. aeruginosa* is one of the 12 priority multi-drug resistant bacteria according to the WHO list published in 2017 (WHO, 2017) and belongs to the ESKAPE group, together with *Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, A. baumannii,* and *Enterobacter* species (Chen et al., 2018). In addition to acquired resistance mechanisms such as carbapenemases (Carmeli et al., 2016), *P. aeruginosa* has many intrinsic antibiotic tolerance mechanisms, for instance low permeability in its external membrane, and expression of several efflux pumps (Malhotra et al., 2018; Ferrer-Espada et al., 2019).

Burn injuries are one of the most common and devastating forms of trauma and patients with serious thermal injury require immediate specialized care in order to minimize morbidity and mortality (Church et al., 2006). *P. aeruginosa* is one of the most frequent bacteria associated to infection in burn patients together with *A. baumannii* (Li et al., 2018). In a recent Mexican study (Garza-Gonzalez et al., 2019), *P. aeruginosa* had around 27% of resistance to carbapenems, in a global context it was one of the main bacteria in 47 Mexican health centers in 20 states, 175/1995 strains were multi-drug-resistant, 165/1995 were possible extreme drug resistant and 87/1995 possible pandrug resistant. In our 30 isolates we had more than 60% of resistance to cephalosporins (ceftazidime and cefepime), carbapenems (dorypenem, imipenem, and meropenem), aminoglycosides (amikacin and gentamicin), fluoroquinolones (ciprofloxacin and levofloxacin), and piperacillin/tazobactam. Moreover, one strain was resistant to colistin, which is the last antibiotic resource.

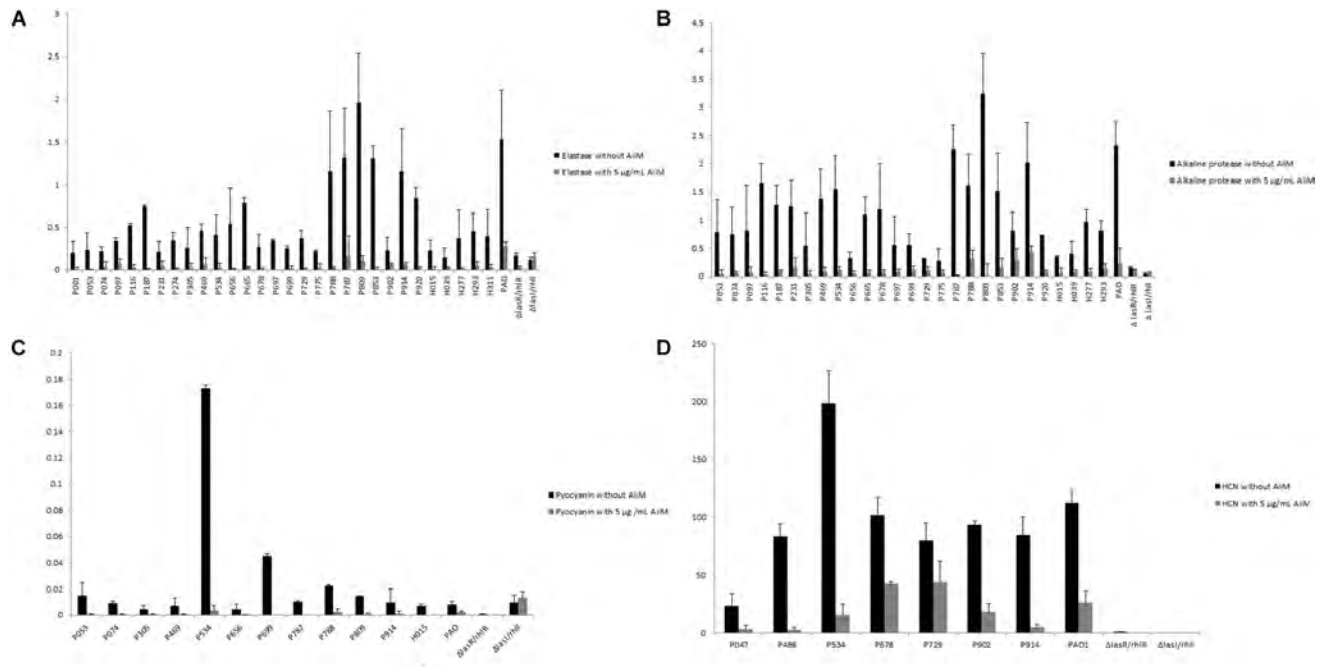

FIGURE 3 | (A) Elastase activity, black bars correspond to clinical strains determination without addition of AiiM, gray bars correspond to clinical strains with 5 μg/mL of AiiM with $p = 0.000002$. **(B)** Alkaline protease activity, black bars correspond to clinical strains without AiiM addition while gray bars correspond to strains with the addition of 5 μg/mL of AiiM with $p = 0.000004$. **(C)** Pyocyanin production, black bars correspond to clinical strains without AiiM addition, whereas gray bars correspond to clinical strains with AiiM 5 μg/mL with $p = 0.001$. **(D)** HCN production, black bars correspond to clinical strains without AiiM addition while gray bars correspond to clinical strains with AiiM 5 μg/mL having a $p = 0.008$.

AiiM showed a wide activity and was able to cut all HSL molecules tested, consistent with a previous report by Wang et al. (2010). Even though we did not analyze it in a quantitative form, we infer a strong activity of AiiM due to its ability to degrade all HSL tested within 5 min of exposition, moreover in our study 5 μg/mL were enough to break down these molecules. One of the main characteristics that a quorum quencher must fulfill is that it should not inhibit bacterial growth (Defoirdt et al., 2013; Defoirdt, 2018) and as expected, AiiM treatment did not affect *P. aeruginosa* growth kinetic.

In contrast, AiiM significantly reduced the four QS-dependent virulence factors tested in our study following a dose response pattern; moreover, others have demonstrated that AiiM had very good activity in a mouse model of acute pneumonia (Migiyama et al., 2013) and reduces methane production in waste sewage sludge (Nguyen et al., 2018). Although to date, the majority of studies with QQ enzymes have been performed only in type strains like PAO1, PA14 (Fetzner, 2015), recently, Guendouze et al. (2017) did the first investigation with *P. aeruginosa* clinical strains isolated from diabetic foot using the lactonase *Sso*Pox with a substitution in the amino acid 263 changing a tryptophan to isoleucine, in order to increase the enzymatic activity, using 0.5 mg/mL of protein, they found some strains with certain tolerance to the *Sso*Pox addition. In our study, AiiM reduced elastase and alkaline protease activities, pyocyanin and HCN concentrations, and we did not find any strain with tolerance against AiiM treatment, in spite that AiiM was used at a 100 times lower concentration than SsoPox. Moreover, AiiM effectivity is much higher than the effectivity of small molecule QS inhibitors such as brominated furanones and 5-fluorouracil, that cannot inhibit QS-virulence factor production of several of the clinical strains tested, and that are very toxic to some of them (García-Contreras et al., 2013, 2015; García-Contreras, 2016; García-Contreras et al., 2016; Guendouze et al., 2017).

Nevertheless, for type III secretion, no inhibition by AiiM was found, which is consistent with recent findings showing that in a Δ*lasR/rhlR* mutant of *P. aeruginosa* PAO1, T3SS effector toxins are secreted at the same levels than in the wild-type strain, demonstrating that this virulence factor is not positively regulated by QS (Soto-Aceves et al., 2019), instead it may be used at low cell densities to establish infections in the host (Hauser, 2009). These highlights the importance of targeting both QS and T3SS to develop robust anti-virulence therapies (García-Contreras, 2016). Moreover, other results indicate that the inhibition of QS systems and T3SS by molecules such as coumarin (Zhang et al., 2018) must be due to independent effects over the QS systems and T3SS.

One possible limitation of the utilization of AiiM and other QQ enzymes for treating *P. aeruginosa* infections is the fact that *lasR* defective mutants are often found in infections and although in principle these mutants will produce low levels of QS-dependent virulence factors, this is not always the case due to a rewiring of the virulence factor regulation

(Morales et al., 2017). And these strains could be tolerant against the effect of QQ enzymes.

Since AiiM is a member of the alpha/beta hydrolases superfamily and several antibiotics are inactivated by metallo ß-lactamases, reducing clinical options to treat infections (Hong et al., 2015), we tested if AiiM could cleave these ß-lactamase antibiotics, however, AiiM did not inactivate those tested, and hence it could be safely used in combination with them.

Although *in vivo* tests in burn infection models are lacking, our work suggests that AiiM treatment may be an effective addition for the treatment of *P. aeruginosa* infections, and since research by other groups had shown also the utility of the lactonase *Sso*Pox against clinical isolates from diabetic foot patients *in vitro* (Guendouze et al., 2017) and *in vivo* using an amoeba model (Mion et al., 2019), and in rat pneumonia against the PAO1 strain (Hraiech et al., 2014) lactonase utilization became an strong candidate for its eventual application in the clinical practice, moreover although *in vivo* studies using acylases are scarce, recently it was shown the PvdQ in addition to their inhibitory properties *in vitro* (Sio et al., 2006) and in *Caenorhabditis elegans* model was also able to increase survival, reduce damage and decrease bacterial loads in a pulmonary infection mice model (Papaioannou et al., 2009; Utari et al., 2018). Hence QQ enzymes may be beneficial for the treatment of burn and lung infections as well.

CONCLUSION

AiiM showed a strong activity against C4-HSL, 3OC8-HSL, C10-HSL, 3OC10-HSL, and 3OC12-HSL. It reduced elastase and alkaline protease activities as well as pyocyanin and HCN concentrations in all tested clinical strains of *P. aeruginosa* isolated from burned patients and no AiiM tolerant strain was found. However, it had no inhibitory effect against the T3SS.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/**Supplementary Material**.

ETHICS STATEMENT

Pseudomonas aeruginosa clinical strains used in this study were isolated as part of routine clinical hospital procedures to diagnose infection and hence ethical approval was not required, according to the National Institute of Rehabilitation ethical committee. All bacterial isolates were stored as part of laboratory and epidemiology necessities.

AUTHOR CONTRIBUTIONS

LL-J, GG-R, MH-D, DR-M, PN, MD-G, DL, JS-R, and DD-R performed the experiments. RF-C, TM, BG-P, GG-R, LL-J, and RG-C designed the study, supervised the project and discussed the results. LL-J wrote the manuscript with input from all authors.

FUNDING

This work was supported by Grants from the Programa de Apoyo a Proyectos de Investigación e Innovación Tecnológica (PAPIIT), the Universidad Nacional Autónoma de México number IN214218, the Consejo Nacional de Ciencia y Tecnología number SEP-CONACYT CB-A1-S-8530, and the CONACYT INFR-2015-252140 grant.

ACKNOWLEDGMENTS

RG-C is grateful to Beatriz Meráz Rios for her assistance with some experiments. We acknowledge Dr. Norma Espinosa Sánchez and Eugenia Flores Robles for technical assistance. LL-J is a doctoral student from the Programa de Doctorado en Ciencias Biomédicas, Universidad Nacional Autónoma de México.

ABSTRACT

Ion channels display conformational changes in response to binding of their agonists and antagonists. The study of the relationships between the structure and the function of these proteins has witnessed considerable advances in the last two decades using a combination of techniques, which include electrophysiology, optical approaches (i.e. patch clamp fluorometry, incorporation of non-canonic amino acids, etc.), molecular biology (mutations in different regions of ion channels to determine their role in function) and those that have permitted the resolution of their structures in detail (X-ray crystallography and cryo-electron microscopy). The possibility of making correlations among structural components and functional traits in ion channels has allowed for more refined conclusions on how these proteins work at the molecular level. With the cloning and description of the family of Transient Receptor Potential (TRP) channels, our understanding of several sensory-related processes has also greatly moved forward. The response of these proteins to several agonists, their regulation by signaling pathways as well as by protein-protein and lipid-protein interactions and, in some cases, their biophysical characteristics have been studied thoroughly and, recently, with the resolution of their structures, the field has experienced a new boom. This review article focuses on the conformational changes in the pores, concentrating on some members of the TRP family of ion channels (TRPV and TRPA subfamilies) that result in changes in their single-channel conductances, a phenomenon that may lead to fine-tuning the electrical response to a given agonist in a cell.

Introduction

The appearance of the plasma membranes of cells constituted a key event for life during evolution. These structures represent boundaries of the units of life, achieving pivotal functions for the cell, including transport of molecules, communication with the environment, and metabolic functions. The intrinsic hydrophobic nature of these structures renders them impermeable to the flux of charged molecules, a process necessary for cell-cell communication, activation of signaling pathways, as well as for the ability to respond to endogenous and exogenous signals. This issue is resolved by the presence of certain types of proteins in plasma membranes, called ion channels that allow for the passage of ions from one side to the other. The specific structure of one ion channel may differ substantially from another; however, all these proteins contain a pore that opens and closes to permit the flow of ions, mediating ionic currents that, in turn, result in the generation of signals with distinct physiological consequences.

There is an intimate relationship between the structures and the functions of ion channels, with their different component regions serving a specific role in the activity of these proteins. In the 1980s, when the patch-clamp recording technique was developed, it became possible to study the behavior of single ion channels in real time[1]. Furthermore, with the advances seen in the areas of molecular biology, cloning and generation of knockout animal models, we have been provided with valuable methods[1] to carefully determine the roles of ion channels in normal and under pathophysiological conditions. A large variety of ion channels have been cloned and biophysically characterized and, in the past three decades,

INFORME DE LABORES 2019

research-oriented towards determining the structure of ion channels has witnessed remarkable progress.

The Nobel Prize in Chemistry was awarded to Roderick MacKinnon and Peter Agre in 2003, for advancing the field by resolving the molecular structures K^+ channels [2–5] and aquaporins [6,7], allowing us to further understand their functional features.

The present review focuses on a family of proteins named Transient Receptor Potential (TRP) ion channels, which has fundamentally reshaped our knowledge of sensory physiology and their importance is illustrated by their pivotal roles in smell, taste, vision, touch and our ability to detect changes in temperature. Originally, the first *trp* gene was identified in a *Drosophila* mutant with altered vision [8]; however, it was not until it was cloned that the deduced amino acid sequence led to the suggestion that *trp* encoded for a cation channel [9]. Electrophysiological studies later showed that *trp* indeed was an ion channel and that its selectivity could be modified by inserting mutations in the amino acid region that formed the pore loop [10].

The field of study of TRP channels witnessed a boom when mammalian homologs of the *Drosophila trp* channel were cloned and when some of these were identified as temperature sensors [11,12]. A feature of these proteins is that several of these channels are polymodal, that is, being activated by several distinct physical stimuli and more than one ligand. In some cases, different biophysical properties as well as distinct conformational changes in their pores, associated with interactions with different ligands, have been demonstrated.

We will discuss a few examples of ion channels where conformational changes are associated with different ion conductance states. However, we will mainly focus on TRPV1 and other TRP ion channels for which structures have been solved, making emphasis on the conformational changes produced by various ligands and on their effects in the functional properties of these proteins.

Rearrangements in the outer pore of kv2.1 lead to changes in ion conductance

For voltage-gated ion channels, modulation of macroscopic current magnitude archetypically is thought to occur through an effect on the gating (opening and closing properties) of these proteins. In this sense, most studies of gating have concentrated on the voltage-dependent gate at the cytoplasmic entrance to the pore. Moreover, there is a large body of evidence that also supports an important role for the selectivity filter in gating activation [13,14]. It has been suggested that some form of voltage-dependent gating can exist at the selectivity filter (the region that discriminates among types of ions passing through the pore) [15–17], although the main closed-open transition is controlled by the S6 bundle-crossing intracellular gate [18].

These aspects have been explored in Kv2.1 potassium channels, which are slowly inactivating delayed rectifiers present in non-neuronal excitable cells and several neurons. In these channels, the current magnitude is modulated by the external K^+ concentration, making outward currents through Kv2.1 channels become larger when the extracellular K^+ concentration is increased [19]. Kv2.1 channels exhibit two distinct pharmacological profiles as a function of the K^+ concentration since they can either be sensitive to external tetraethylammonium (TEA; $IC_{50} \sim 3–5$ mM), or completely insensitive to this blocker [20]. The underlying mechanism of these effects encompasses the opening of Kv2.1 channels into one of two different outer vestibule conformations with different sensitivities to TEA. It has been shown that the channels that open into a TEA-sensitive conformation produce larger macroscopic currents [19]. In contrast, channels that open into a TEA-insensitive conformation, a phenomenon that occurs in the presence of higher potassium concentrations, yield smaller macroscopic currents [19].

Trapani and collaborators examined the mechanism by which conformational changes in Kv2.1 channels produced changes in current magnitude. By using a combination of single-channel, macroscopic recordings, and hidden Markov modeling they proposed a model in which an outer vestibule lysine residue in position 356 (pore turret region) interferes with the flux of K^+ through the channel [19]. This led to the suggestion that the K^+ concentration-dependent change in orientation of that specific K356 can modify single channel conductance through a change in the level of such an interference [19].

In summary, in the conformation where currents are smaller in magnitude, K356 would be oriented towards the center of the ion conduction pathway, not easily allowing the flux of K^+ ions and resulting in a change in the single-channel conductance. In contrast, when K356 is oriented away from the conduction pathway, it readily allows the passage of ions. Thus, these results obtained by Trapani et al., not only provided evidence where Kv2.1 single-channel conductance is modulated by the outer end of the conduction pathway through the occupancy of open states with different outer vestibule conformations, but they also showed that these occur under physiologically-relevant K^+ concentrations [19].

Hence, in a physiological scenario, it is important to consider that with rising extracellular K^+ concentrations, the current magnitude of K^+ channels in most neuronal cells is reduced as a result of a decrease in electrochemical driving force. However, Kv2.1 counteracts this reduction in net outward current in the presence of higher K^+ concentrations and, as suggested by the authors, this would provide the cells where these channels are expressed with a mechanism that maintains action potential integrity when high-frequency firing conditions are present [19].

The validity of the pore dilation phenomenon to explain changes in ion channel conductance

Ion channels exhibit different permeability and selectivity to various ions. Potassium, sodium, and calcium channels contain ion binding sites in their selectivity filters that enable them to finely discriminate among the ions that will flow through their pores[5][21],. Nonetheless, some ion channels have been shown to exhibit dynamic changes in their ion selectivity in response to agonist activation that could, in theory, allow for changes in their conductance. Examples of these ion channels are P2X receptor channels [22,23], acid-sensing ion channels (ASIC) [24,25] and TRPV1 channels [26,27]. This phenomenon has been called pore dilation and it will be next discussed for P2X receptors, a well-studied example of this process, and for TRPV1 in a later section.

P2X receptors are ion channels gated by extracellular ATP [28] and it was originally thought that the pore first opened rapidly to a conducting state selective for small cations such as Na^+, K^+ and Ca [2]+ (I_1 current) and gradually increased in size or dilated over time, rendering the channel permeable to large organic cations such as N-methyl-D-glucamine ($NMDG^+$) or I_2 current, as well as to large fluorophores and dyes (i.e. YO-PRO1) [22,23]. However, based on the original assumption that P2X receptors experience a slow, time- and agonist-dependent pore dilation, three mechanisms have been suggested to explain this phenomenon: (1) it represents an intrinsic gating property of the functional P2XR channel, where ATP exposure results in the widening of the pore and a change from a state that conducts Na^+, K^+, Ca^{2+} (I_1) to one that conducts $NMDG^+$ and YO-PRO 1, a large propidium dye. Such a switch has been proposed to be modulated by phosphorylation or dephosphorylation events [22,23]; (2) macropores are formed as a result of an agonist-dependent redistribution and oligomerization of P2XRs. The fusion of two or more trimeric P2XRs, as well as an enlargement of the channel pore, or the formation of a separate but larger pore among aggregating trimeric assemblies, could underly macropore formation. This hypothesis has been ruled out by some research groups since no clustering or redistribution of channels expected during oligomerization has been found to occur [23,29], but some others still support it [30]; (3) the permeability to large cations is facilitated by a structurally separate transport pathway downstream of P2XR activation [22].

Although the phenomenon of pore dilation has been extensively explored, accumulating evidence suggests that it may be an artifact of the experimental conditions used, as will be detailed in the Discussion section.

Next, we will discuss some structural characteristics of TRP ion channels that shed light into why these proteins represent an example of conformational flexibility in response to agonists that may result in changes in cellular excitability.

The structures of thermotrp channels reveal conformational flexibility

The TRPV1 channel was the first mammalian TRP channel to be cloned. In 1997, it was shown that

TRPV1 is the receptor for capsaicin [11,12]. In this groundbreaking study, the laboratory of David Julius isolated a cDNA clone that reconstituted the response to capsaicin in non-neuronal cells. By examining the amino acid sequence of this clone, they demonstrated TRPV1 is an integral membrane protein, homologous to a family of putative store-operated calcium channels and that it is expressed by small-diameter neurons within sensory ganglia such as the dorsal root (DRG) and trigeminal (TG). Moreover, these authors showed that TRPV1 is also a thermal sensor, activated in response to temperatures in a range known to elicit pain-associated behaviors in animals and pain in humans [11]. It was later shown, in 1998, that TRPV1 is also activated by low extracellular pH (pH ≤ 5.9) [12].

Continued work on the study of the function of TRPV1, one of the best studied TRP channels, has led to the identification of several other agonists and modulators including resiniferatoxin (RTx) [12], diacylglycerol [31], hydroperoxyeicosatetraenoic acid (HPETE) [32], anandamide [33], *N*-acyl ethanolamines (NAEs) [34], n-acyl-dopamines [35], nitric oxide [36], cations [37,38], hydrogen sulphide (H_2S) [39], the double-knot toxin (DkTx) from the Earth Tiger tarantula [40] and lysophosphatidic acid (LPA) [41].

TRP channels are all tetrameric structures. The structure of TRPV1 had been initially solved in the year of 2008 by the group of Vera Moiseenkova-Bell. These authors obtained a 19 Å resolution cryo-EM structure that showed that TRPV1 exhibits a four-fold symmetry with a large open basket-like domain, formed by the N- and C-termini of the channel as well as a compact transmembrane region [42]. In this first solved structure of TRPV1, the authors described a 150 Å tall ion channel which is divided into a "small" compact region (30% of the total volume) and into a "large" region or the "basket-like" domain (70% of the total mass).

This seminal study was followed by the higher resolution structures for TRPV1 obtained by the research groups of Yifan Cheng and David Julius. Two, back-to-back reports, described structures of 3.4–4.2 Å resolution obtained by cryo-EM [43,44]. They confirmed that TRPV1 has a four-fold symmetry with a central ion pathway that is formed by transmembrane segments S5 and S6 and a pore-loop, all of which are surrounded by the S1-S4 domains with a domain-swapped geometry [43,44]. The pore region was described as one containing a wide extracellular mouth and a short selectivity filter. The important TRP domain, which is a region conserved in these family of ion channels and that is thought to play an important role in their allosteric modulation, was shown to interact with the S4-S5 intracellular linker. Each of four subunits in TRPV1 contains six ankyrin repeats that form the ankyrin repeat domain (ARD) localized to their N-termini [43,44] (Figure 1).

These research groups also described the structures of TRPV1 obtained in the presence of different agonists, providing insight into the mechanisms that allow the polymodal activation of this channel. One of these structures was obtained in the presence of RTx (which also binds to the vanilloid pocket where capsaicin binds through residues Y511 and S512 in S3 and M547 and T550 in S4) and DkTx together. The authors showed that DkTx was bound to the extracellular loops of the outer pore region and defined contacts of the toxin with residues at the top of the pore helix of one subunit and the outer pore loop in the proximal S6 region of another nearby subunit [43,45] (Figure 2).

The structures of TRPV1 obtained in the presence of both agonists display evident rearrangements in the ion conduction pathway and the outer pore region. With RTx and DkTx bound to the channel, the ion conduction pathway appears completely eased of constrictions. This is in contrast to the structure obtained only in the presence of capsaicin, where the lower gate I679 is extended, but the selectivity filter G643 remains unaltered [45] (Figure 2).

When TRPV1 has RTx and DkTx bound, a shift or tilt of the S6 helix 1.9 Å away from the central axis of the channel is produced, as compared to the apo or unliganded state. Moreover, an increase in the distance between the carbonyl oxygens of G643, which constitutes the narrowest point of the selectivity filter, is also observed when both ligands are present: it goes from 4.6 Å in apo (PDB 3J5P) to 7.6 Å in RTx/DkTx (PDB 3J5Q) [45].

As mentioned above, G643 (at the upper gate) remains unaltered between the apo structure (PDB 3J5P) and in the structure in complex with

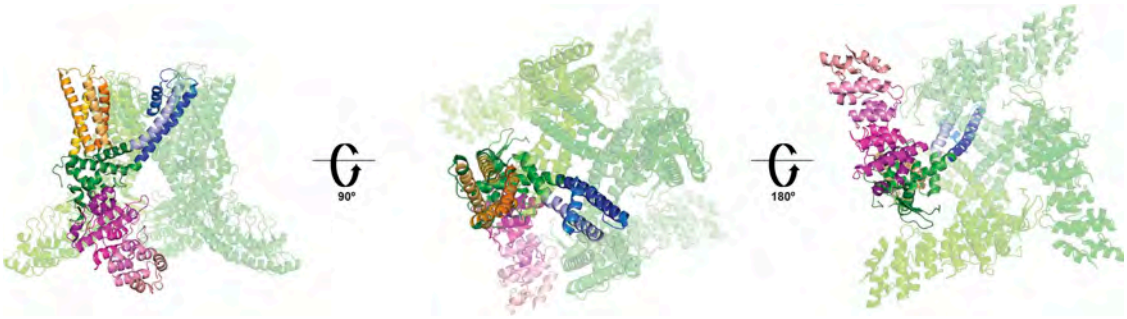

Figure 1. Structure of the TRPV1 channel. Only one of the subunits is highlighted for clarity.
The ankyrin repeat domain is shown in purple, the S1- S4 domain in orange, the pore forming S5-P-S6 is shown in blue. The pre-S1, S4-S5 linker, and TRP domain, which participate in the allosteric modulation of the channel, are shown in green. The left panel is a lateral view, the central and right panels are extracellular and intracellular views, respectively. (PDB 3J5P).

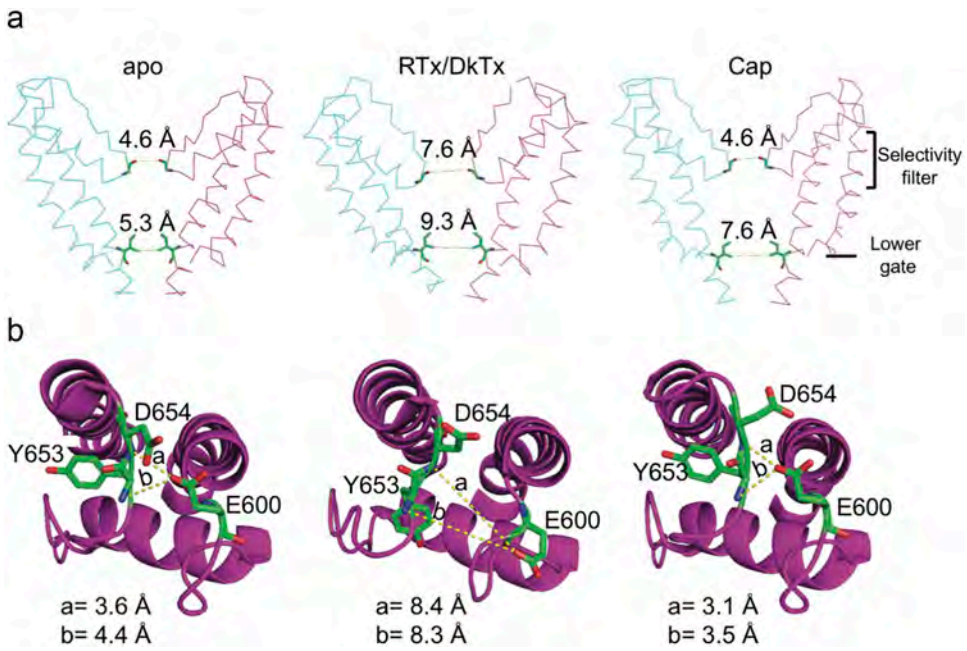

Figure 2. Relative movements of the selectivity filter and lower gate of TRPV1 in the presence of different agonists.
A. Distances between G643 (at the selectivity filter) and I679 (lower gate) in the apo (left, PDB 3J5P), RTx/DkTx (middle, PDB 3J5Q) and capsaicin (right, PDB 3J5R) structures. Compared to the apo structure, in the presence of both RTk and DkTx the selectivity filter and the lower gate expanded. In the structure with capsaicin only (Cap), the outer pore region remains unaltered in comparison with the apo structure, while the lower gate widens. **B**. Interactions among residues in the outer pore that stabilize the closed conformation of TRPV1. The hydrogen-bonds between E600 side chain with the main-chain nitrogen atoms of Y653 and D654 are broken in the structure with RTk/DkTx but maintained with capsaicin only.

capsaicin, and this could be explained because, in the absence of DkTx, the channel could be undergoing transitions to closed states. However, the distance between the I679 residues (lower gate) in the apo state is 5.3 Å (PDB 3J5P) and, when in complex with RTx/DkTx (PDB 3J5Q), it shifts to 9.3 Å, while it is at 7.6 Å with capsaicin only (PDB 3J5R). Therefore, the authors concluded that the structure obtained with capsaicin is likely only a partially activated state of TRPV1 [45].

When TRPV1 is in the presence of capsaicin only, the structure can be superimposed to that of the apo state in the outer pore region. Hydrogen bond interactions among side chains of the E600 residues and main-chain nitrogen atoms of the Y653 and D654 amino acids in the outer pore loops thought to stabilize the ion channel in the closed state, are broken when the distances among them are increased in response to the binding of DkTx and RTx. The distances between residues

that stabilize the closed state change when the channel is in the apo state or in the presence of RTx/DkTx: D654-E600 goes from 3.6 Å to 8.4 Å, while for Y653-E600 it goes from 4.4Å to 8.3Å, respectively [45] (Figure 2).

In summary, this ion channel displays extraordinary flexibility of movement in response to the presence of different agonists.

Another example of conformational changes that may allow for "superactivated" states is that of TRPV2. This channel is activated by temperatures near 52°C [46] and by membrane stretch [47]. Although structurally similar to TRPV1, TRPV2 is not activated by vanilloid compounds. However, the laboratory of Kenton Swartz produced a TRPV2 channel with four-point mutations to form a vanilloid-binding site located in the S4-S5 linker and the base of S5 [48], rendering this channel sensitive to RTx. These results were also confirmed by Yang et al., who used a TRPV2-Quad channel (with the same point mutations in mouse), where capsaicin competed for the same site as RTx [49]. This TRPV2_Quad channel was found to bind RTx, and that leads the channel to an unstable open state through a mechanism that bridges the S4-S5 linker to the S1-domain [49].

A couple of years later, Zubcevic and collaborators obtained the crystal structure of a minimal construct of the rabbit TRPV2 channel (miTRPV2) in the absence of agonist and compared it with that of the vanilloid-sensitive miTRPV2 (F470S, L505M, L508T, and Q528E, in the rabbit TRPV2) in complex with RTx [50].

Interestingly, in the structure in complex with RTx, they found that two subunits adopt distinct orientations between the S4-S5 linker and the S5, as compared to the other two subunits. In other words, while two subunits (A and C) are found to spread away from each other, the other two (B and D) get closer. This rearrangement results in an asymmetric pore that adopts a wider conformation at the selectivity filter when compared to the structure without RTx (Figure 3).

The authors determined that with RTx the distance between the G604 carbonyl oxygens in contracted subunits was ~7.1 Å, and in the widened subunits the distance between the I603 carbonyls was ~12.3 Å, while in the structure with only Ca^{2+} the distances between G604 carbonyl oxygens are 6.1–6.4 Å [50,51]. The conclusion was that, when RTx binds to the channel, it pushes the base of S5 downwards and produces a bend in the S4-S5 linker producing a different conformation that leads to rotation and widening of the entire involved subunit (Figure 3).

The authors also suggested that this wider conformation of the pore could allow for the permeation of larger cations since they performed experiments where it is observed that, upon activation of the vanilloid-sensitive TRPV2 with RTx (250 nM), uptake of the large fluorescent molecule YO-PRO-1 (376 Da) could be attained. With this experiment, they confirmed the functionality of this conformation, and suggested that it was either a fully open state or an intermediate state that occurred before a symmetric open state capable of permeating large organic cations [50].

Just as in TRPV2, a vanilloid-binding site can be introduced into the TRPV3 channel upon the insertion of six residues in the putative vanilloid-pocket: W521Y, H523E, F522S, L557M, A560T, and Q580E, as shown for the mouse TRPV3 channel by Zhang and collaborators [52]. Nonetheless, the insertion of this vanilloid-binding site is not enough to achieve activation of TRPV3 by RTx and the presence of other agonists, such as 2-APB (aminoethoxydiphenyl borate) or heat, is required [52]. These results demonstrate that gating pathways are conserved among the TRPV channels, but they also show that the energetics for activation can dictate their sensitivity to certain stimuli since adding a binding site for an agonist does not necessarily result in the activation of the ion channel [52].

Structurally, the sensitized state of the human TRPV3 undergoes an α-helix to π-helix transition in the S6 which, in turn, disrupts the S4-S5 linker and S6 and the latter bends ~9° away from the pore [53]. In a previous report, the open conformation of the mouse TRPV3 obtained with 2-APB only shows a π-helix in the S6 [54], leading the authors to suggest that the secondary structure transition could be a hallmark for a sensitized channel, in other words, a state that requires less energy to activate [53].

Additionally, Zubcevic and collaborators also observed that during the activation of TRPV3

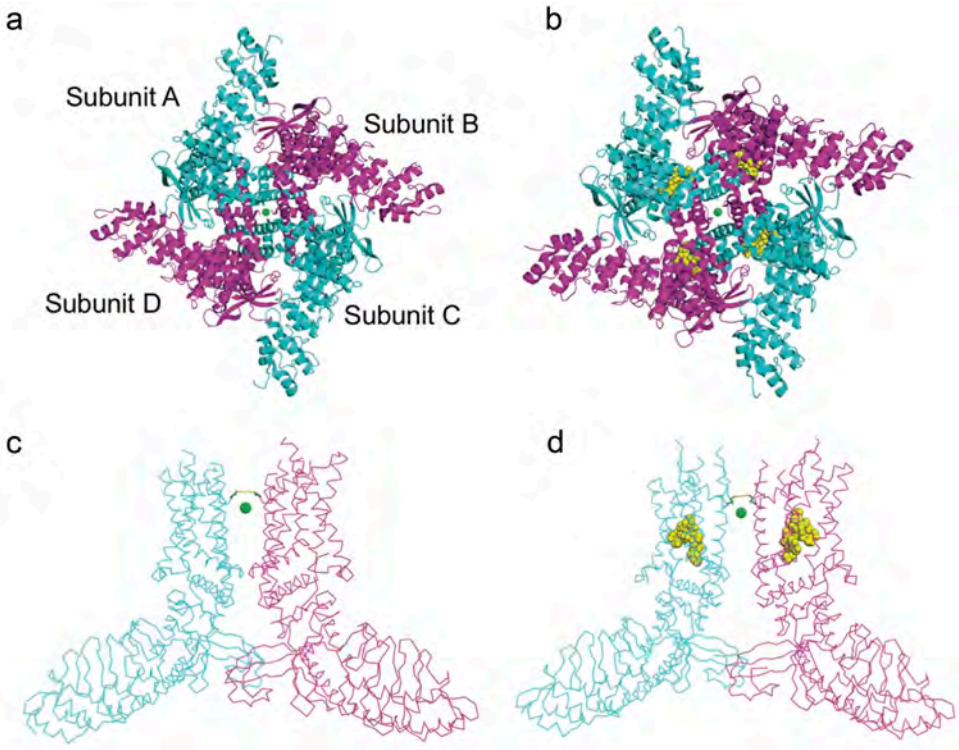

Figure 3. Comparison of open and closed states of TRPV2.
Extracellular views of A) a closed miTRPV2 channel (PDB 6BWM) and B) vanilloid-sensitive miTRPV2 (PDB 6BWJ) in complex with RTx shown as yellow spheres, representing the open state. On the lower panel are side views of the closed (C) and open (D) channel. Only two subunits are shown for simplicity. The green sphere is Ca^{2+} trapped in the pore which is notably wider in the open configuration, its also visible the rearrangement of the intracellular domain. The side chains of G604 are also depicted.

with 2-APB, the intermediate states display asymmetrical rearrangements that are not present in the apo or sensitized states. The differently observed deviations for the subunits are caused because theπ-helices in the S4-S5 linkers begin at different residues. This is interesting because it accounts for a similar phenomenon as the one described above for the activation of TRPV2 with RTx, which also originates at the S4-S5 linker [50]. Together, these results further support the hypothesis that the gating mechanisms of TRPV channels are conserved and a break in symmetry may be characteristic to these channel's gating.

The TRPV4 channel was first described as an osmosensor, capable of activating after exposure to extracellular hypotonic conditions [55,56]. Subsequent reports demonstrated that, like other members of the TRPV subfamily, TRPV4 is a heat-sensitive channel activated by temperatures above 27°C [57] and chemical agonists such as phorbol derivates [58] and 5,6-epoxyeicosatrienoic acid, a metabolite of arachidonic acid [59,60].

Deng and collaborators obtained the first high-resolution cryo-EM structure (3.8 Å) of the TRPV4 channel [61]. These authors determined that the channel was in a closed conformation, that the narrowest diameter in the pore (5.3 Å) was located at residue M714, which impeded the permeation of ions. Even in the closed state, TRPV4 displayed a particularly wide selectivity filter: the diameter at G675 in TRPV4 was 10.6 Å, while the diameter at G643 in TRPV1 in complex with RTx/DkTx was 7.6 Å[45]. This evidence suggested that unlike TRPV1, the TRPV4 channel lacks an upper gate [61].

The single-channel conductance of TRPV4, when stimulated with hypotonic solutions, has been reported to be around 310 pS, at positive voltages [55]. However, reports for its single-channel conductance during spontaneous activity is near 88 pS [56], which is near the value (around 98 pS) obtained with other agonists such as 4α-Phorbol 12,13-didecanoate (4αPDD) and with heat (around 105 pS) [58]. Altogether these results

suggest that the channel can adopt a different functional state when it is stimulated under hypotonic conditions vs. heat or phorbol, and that differences in the conductance of TRPV4 may be observed with other agonists, but further studies must be performed.

TRPA1 is a channel mainly expressed in nociceptive neurons which responds to multiple noxious stimuli, including pungent chemicals present in garlic, mustard oil, cinnamon or wasabi [62,63]. Moreover, TRPA1 was initially described as a channel activated by noxious cold temperatures [64,65], but there has been controversy around this topic since this channel functions as a temperature receptor in a species-specific fashion [66–68]. Chemical agonists of TRPA1 have been divided based on their mechanism of action into electrophilic and non-electrophilic agonists. Examples of the first are allyl isothiocyanate (AITC) [69] or allicin [62] that activate the channel through covalent modification of cysteines at the N-terminal domain. In fact, allicin can also activate TRPV1 through the same mechanism [70–72]. The non-electrophilic agonists include carvacrol, oleocanthal, Δ9-tetrahydrocannabinol (THC) and acidic pH, which activate TRPA1 by mechanisms not associated with cysteine modifications and which remain mostly unclarified [73–75].

Cavanaugh et al., determined, in excised TRPA1-expressing membrane patches, that the channel needs to be exposed to polyphosphates (PPPi) [76] in order to be activated by AITC, but in this AITC-insensitive conformation (in the absence of PPPi) it can be activated by THC [77]. This result indicates that the channel shifts to a different functional conformation unresponsive to cysteine modification but responsive to activation by a different mechanism [77], each with a distinguishable function and agonist dependence.

The different functional states described by Cavanaugh et al., have not been structurally compared. Unlike TRPV1, the cryo-EM structure for TRPA1 was not obtained in the presence of different agonists, but only with AITC (PDB 3J9P). Nonetheless, it was possible to determine that the pre-S1 helix, linker S4-S5, and TRP-like domain are bound by hydrophobic interactions and represent an important site for allosteric modulation, similar to what happens with TRPV1 [45,78].

Nevertheless, recent studies have compared the structural rearrangements of TRPA1 in the presence of different agonists using techniques such as limited proteolysis combined with mass spectrometry [75]or circular dichroism spectroscopy only for the N- and C- terminal domains [79]. These robust methodologies show important interactions between cytoplasmatic domains involved in the gating of the channel [79], as well as differences between the activation with electrophilic and non-electrophilic agonists [75].

TRPV5 and TRPV6 display limited structural rearrengements in their pores

Both TRPV5 and TRPV6 ion channels are expressed mainly in the epithelial tissue of the digestive tract and kidney, where they play roles in the reabsorption and transcellular transport of Ca^{2+} [80]. Unlike other members of the TRPV family, TRPV6 and TRPV5 show inward rectification and these highly Ca^{2+}-selective proteins are constitutively active under physiological conditions [81]. Despite the high ion selectivity, in the absence of extracellular divalent cations, they can permeate monovalent cations [80].

TRPV5 and TRPV6 channels share structural traits that differentiate them from the other known TRPV channels. Three phenylalanine residues in S6 give rigidity to the pore, and a ring of aspartates in the selectivity filter confers its high Ca^{2+} selectivity [82]. Neutralization mutation of the negative aspartate charge not only affects Ca^{2+} selectivity but reduces inward rectification [80].

Functionally, both channels can be inhibited by endogenous calmodulin (CaM) [83] or by econazole, an antifungal [84], while PIP_2 helps stabilize their open state [85]. The conformational changes between open and closed states of these channels have been explored by comparing the cryo-EM structures of econazole-bound TRPV5 and of both channels in the presence of either PIP_2 or CaM [86,87].

One of the main findings of this comparison is that the selectivity filter remains mostly the same regardless of the molecule that binds the channel. The lower gate identified in TRPV5 is formed by F574, M578, and H582 that constrict the pore to a diameter between 4.5 and 5.9 Å in the same bundle crossing configuration observed in other TRP channels. The closing seems to involve a change in the position of the S4-S5 linker and the loop connecting S6 with the TRP domain [86,87].

The binding of PIP_2, induce a change in the orientation of the lateral chain of the aspartate in the selectivity filter. This change may be explained by an interaction of the head group of PIP_2 with R584 in the S6 helix, analogous to what has been observed in TRPV1, which rotates and pulls away from the center of the pore accompanied by movement of the S4-S5 linker [87]. The main difference in the response of TRPV5 and TRPV6 was observed in the CaM-bound structures. Both channels bind to a single CaM-molecule which is capable of physically blocking the pore from the intracellular side, but while TRPV5 shows no conformational changes, TRPV6 shows an α- to a π-helical transition of S6 which tilts the helix toward the center, so I575 becomes an inactivation gate [87], which has also been observed in TRPV3 [53].

Analysis of the pores of TRPV5 and TRPV6 points to rigid structures that contrast with the more flexible pores of TRPV1-4. To date, there is no physiological evidence of changes in their single-channel conductances in response to different stimuli, but it has been suggested that their activity might be regulated by the formation of TRPV5/V6 heterotetramers, as they are co-expressed in several tissues. Hoenderop et al. used *Xenopus laevis* oocytes to express such heterotetramers and found that they have Ca [2]+ -dependent inactivation and block by ruthenium red with features intermediate to those of TRPV5 and TRPV6 [88]. Although this is an interesting possibility, they have not been identified *in vivo*, and their biophysical properties at the level of single-channels have not been investigated.

Lysophosphatidic acid: A pain-producing phospholipid

Another activator of TRPV1 shown by our group to directly interact with this ion channel is lysophosphatidic acid (LPA) [41]. This is the only example for which a change in single channel conductance in a TRP channel has been shown to depend upon the presence of different agonists; thus, we will discuss this phenomenon in detail.

LPA has been extensively linked to the generation of chronic neuropathic pain through its interactions with G protein-coupled receptors (GPCRs) [89–92] and to modulate the activity of several ion channels [93–97]. Regulation of the activity of TRPV1 by molecules of a lipidic nature has been explored, and it has been described that PIP_2 [98–106], polyunsaturated fatty acids (PUFAs) [107], monounsaturated fatty acids [108] and cholesterol [109–111] can modulate the activity of TRPV1, either directly or indirectly. However, reports of direct interactions of LPA with ion channels, in general, are scarce [95,112,113].

LPA is a phospholipid constituted by an acyl chain of saturated or unsaturated fatty acids associated with a glycerol backbone by ester links, and that contains a phosphate head group [114]. LPA can be naturally found as different species that vary in their acyl-chain length as well as in their saturation (16:0; 18:0; 16:1, 18:1; 18:2 and 20:4).

Our group studied whether LPA could produce acute pain in mice and showed that it is considerably dependent upon TRPV1. These results led us to determine that LPA could, in fact, produce currents and action potentials in DRG neurons from wild-type mice but not in DRG neurons from $Trpv1^{-/-}$animals. Using a heterologous expression system of HEK293 cells transfected with TRPV1, we found that currents could be induced when LPA was applied to the intracellular or extracellular faces of the ion channels and that the responses were dose-dependent [41].

In our studies, we ruled out the participation of GPCR-related signaling pathways on TRPV1 activation by LPA and identified a site of interaction for this phospholipid, residue K710 in the C-terminus of TRPV1 [41]. Confirmation of these results was obtained later by another group in a study where TRPV1 was expressed in lipid bilayers and activated by LPA [115].

Hence, we extended the aforementioned study and determined that, for fatty acids to activate TRPV1, the following features had to be met by these molecules: the presence of a charged phosphate group, a length of, at least 18 carbons of the acyl chain and a mono unsaturation [116].

LPA produces a different open conformational state to that of capsaicin

Our first study on the effects of LPA on TRPV1 was published in 2011 [41], and since then, we have been studying the specifics of how this molecule regulates the activity of TRPV1. Our most recent study on this subject provides functional

evidence that LPA produces a different open conformational state of TRPV1 that has a larger conductance.

In preliminary experiments, we had found that addition of LPA (5 μM) to excised membrane patches of TRPV1-expressing HEK293 cells resulted in larger magnitude macroscopic currents, as compared to those obtained in the presence of saturating capsaicin concentrations (4 μM). We had also observed that LPA (5 μM) produced activation of TRPV1 single-channel currents with an open probability (Po is 0.8) similar to that of capsaicin (4 μM).

These data could be explained as 1) LPA either producing an increase in the number of ion channels in the excised membrane patches (which was highly improbable); 2) An increase in the membrane negative surface charge near the channel leading to an accumulation of positively-charged ions near the pore mouth of TRPV1, 3) Producing a phenomenon termed "pore-dilation" in which the permeability to large ions occurs in the presence of prolonged exposures to agonists and that had only been described for activation with capsaicin [26] and/or 4) a change in the single-channel conductance.

In this last study, we performed a set of experiments in order to discern among all of these possibilities. We started by studying how LPA affected the unitary TRPV1 currents by first applying capsaicin (4 μM), washing off the agonist and then applying LPA (5 μM) to the same membrane patch. The results showed that LPA produced a 41% increase in the magnitude of single-channel currents at a single voltage (60 mV), which was also observed at other voltages (Figure 4).

Furthermore, our experiments ruled out all of the other possibilities enlisted above and showed that coapplication of subsaturating concentrations of both agonists together resulted in two different types of openings in a single channel, with conductances corresponding to those achieved either by adding capsaicin or LPA alone [117]. This was the strongest indication of these two agonists producing distinct open conformations that varied in their conductance. Finally, we defined that the presence of K710, the residue that is pivotal for the activation of TRPV1 by LPA, was also necessary for the generation of the higher-conductance open state [117].

TRPC and TRPM channels

Until just recently, finely defined structural characteristics of TRPC channels have remained elusive, mainly because of the lack of high-resolution structures. The cryo-EM structures obtained to date are those for the TRPC3, TRPC4, TRPC5 and TRPC6 channels [118–123]. However, no functional studies reporting changes in the conductance of these channels in response to different agonists are available.

These channels exhibit four ankyrin repeats and linker helices at their N-terminal domains and at the C-terminal domains they possess a TRP domain that connects a helix and a coiled-coil domain. Inside the pore, all TRPC members have a conserved "LFW" motif that maintains the structure of the pore [124].

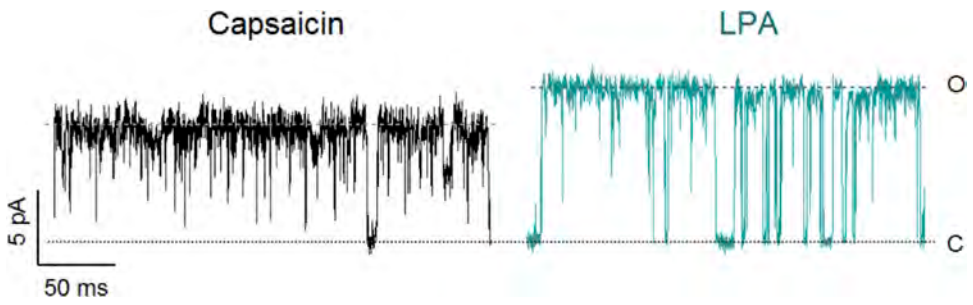

Figure 4. LPA increases single channel currents.
Current amplitude for a TRPV1-expressing membrane patch in the presence of capsaicin (4 μM; left) and in the presence of LPA (5 μM; right). Traces were obtained at +60 mV.

The TRPC subfamily can be divided into two groups that share some distinctive characteristics. The first group is constituted by the TRPC3/C6/C7 channels are activated by DAG. Structurally, both TRPC3 and TRPC6 display a pre-S1 elbow, a TRP re-entrant helix embedded in the membrane bilayer after the TRP domain, and an unusually long S3 that forms a "pseudo" extra cellular domain (ECD) [121,122,124]. Furthermore, unlike most TRP channels, TRPC3 channels possess a linker that connects the TRP domain to the S6. This results in a more flexible TRP domain that exhibits a higher coupling with the S4-S5 linker and a lipid binding site near the pre-S1. All of these peculiar interplays of domains may provide a molecular basis for TRPC3 lipid gating [121].

The second group includes the TRPC4/C5 channels that are modulated by G_q, $G_{i/o}$ GPCRs, membrane lipids, and intracellular Ca^{2+} [119,125]. These channels share the common feature of a disulfide bond between two cysteines at the loop linking S5 and the pore domain that maintains the residue E555 in proper position and thus stabilize the upper region of their selectivity filters [119,120,123,124]. As in other TRP channels, the TRP domain of TRPC4 is an important molecular effector for gating in this protein since it interacts with the S4-S5 linker and other proteins [123].

The structures of TRPC3/C6 and TRPC4 (both human and mouse) show a closed pore conformation. For TRPC3 the lower gate is located at residues I658 and L654 where they present a radius of less than 1 Å [121]. As for the human TRPC4, the residues I617 and N621 were identified as the lower gate where the constriction of the diameter was around 1.6 and 0.7 Å (defined by opposing van der Waals surfaces) [123], and for the mouse TRPC4 the narrowest point is located at N621 (3.6 Å) and constitutes the lower gate along with I617 and Q625 [119].

However, the TRPC5 is considered at least partially open since the constriction at the lower gate formed by the residues I621, N625 and Q629 was around 4.9 Å [120]. Comparing this structure with the closed TRPC4, Duan and collaborators suggest that the extracellular disulfide bond is a transducer of conformational changes. Nonetheless, more structures of TRPC channels at their open conformation will help to elucidate if there are differences in the pore during their gating [120].

The TRPM subfamily is composed of eight members with diverse features and functions [126]. The TRPM members for which cryo-EM structures have been solved in the closed or partially open conformations are TRPM2, TRPM4, TRPM7 and TRPM8 [127–135]. Their subunits are composed of six transmembranal segments, but at their N-terminal domains, they present four TRPM homology regions (MHR) and a C-terminal coiled-coil domain [127–135].

The C-termini of TRPM2, TRPM6, and TRPM7 channels possess enzymatic domains and have been named "chanzymes" [136–139]. Similar to TRPC4/C5 channels, TRPM channels possess disulfide bonds at their extracellular pore that stabilize the pore domain, but these disulfide-bonds form between cysteines at the pore loop and the pore helix S6 [119].

TRPM2 is a non-selective cation channel sensitive to temperature [140] that is activated when ADP-Ribose (ADPR) and Ca^{2+} are co-applied [141]. Wang and collaborators obtained the structures of human apo-, ADPR-bound, and ADPR-Ca^{2+}-bound TRPM2 channels. They observed that the binding of ADPR alone produced a closed conformation, considering it a "primed state" [128].

The lower gate was identified at residues I1045 and Q1053 in the pore and shown to be enlarged in the ADPR/Ca^{2+} structure. Although a change distance of the residues that form the gate was observed, it was not considered large enough to allow passage of Ca^{2+} (~4 Å radius) [128].

For zebrafish TRPM2 channels it was shown that, once ADPR binds to the MHR1/2 domain, a displacement of MHR4 is transmitted to the TRP helix, pushing it towards the S4-S5 linker. Consequently, the S4-S5 relocates the S5 and S6 and finally produces the opening of the channel. Again, as for other TRP channels, the TRP helix is shown to act as a transducer between the intracellular and transmembranal domains during gating [129]. Moreover, the authors propose putative binding sites for Ca^{2+} in the S3, leading them to speculate that Ca^{2+} facilitates the opening due to the movement of the S3 upon the binding of this ion which allows for the relocation of the S4-S5 linker [129].

TRPM4 and TRPM5 channels are among the only TRP members that are not permeable to

divalent cations [132,142,143]. Despite their ion selectivity, TRPM4/5 channels are activated upon intracellular Ca^{2+} increases [144] and can be modulated by $PI(4,5)P_2$ [145,146]. However, TRPM4 is inhibited by intracellular ATP and nucleotides, while TRPM5 is insensitive to these molecules [147,148].

The pore of TRPM4 has two gates: one located at the selectivity filter and another formed by the intracellular portion of the S6. In the human channel, the selectivity filter gate is formed by residues 975-FGQ-977 [130–132]. Likewise, the intracellular gate is formed by the I1040 residue [131,132].

Strikingly, both gates remain unchanged in all reported Ca^{2+}-bound structures, and it has been suggested that Ca^{2+}- binding is required for the opening of the channel in response to voltage [131].

In the structure obtained in complex with ATP, Guo and collaborators located a nucleotide binding domain along with twelve helices and two ankyrin repeats in the N-terminal [149]. The ATP-bound structure is an inhibited state of TRPM4, and there were no overall changes in the pore compared to the apo structure. The TRP domain forms hydrophobic interactions with the S4-S5 linker and forms a cavity between the S1-S4 domain, which harbors a potential Ca^{2+} -binding site [149].

The protein kinase domain in TRPM7 induces phosphorylation of receptor tyrosine kinase (RTK)-signaling intermediates and chromatin modifications [150,151]. TRPM7 is permeable to Mg^{2+}, Zn^{2+} and Ca^{2+} [152], and the cryo-EM structure of TRPM7 was obtained in the presence and absence of Mg^{2+} [133].

There were no notable changes on the pore domain of TRPM7 under different ionic conditions. Interestingly, the selectivity filter identified in TRPM7 (1045-FGE-1047), varies only on one residue to the selectivity filter described in TRPM4 (971-FGQ-973 in mouse TRPM4 channel), which is crucial to confer the monovalent selectivity of the latter. The lower gate was determined to be formed by I1093 and N1097 residues [133].

The TRP domain of TRPM7 interacts with different regions of the channel, highlighting the importance of this region for gating in this protein. For example, the TRP domain interacts with the N-terminal residues S744 and Q740, with the S4-S5 linker by forming hydrogen bonds between W1111 and R1115 (both located to the TRP domain) and with A981 and V982 (in the S4-S5 linker) [133]. Additionally, it establishes π-π stacking (Phe1118/Tyr1122) and cation- π interactions (Arg1115/Trp1111) among its α-helical structure [133]. However, unlike what has been observed in other TRP structures, the TRP domain of TRPM7 does not contact the pre-S1 helix [133].

Another region that may produce important conformational rearrangements in TRPM7 is the pore helix. It has been shown that a disulfide-bond established between residues C1056 and C1066, is only formed in the presence of Mg^{2+}. Thus, it has been proposed that this cation could stabilize the bond and impact directly on the structure of the pore [133].

Finally, the TRPM8 is a non-selective cationic channel permeable to Ca^{2+} and activated by cold temperatures (below 25°C) and menthol [153]. The channel is modulated by $PI(4,5)P_2$ [153,154].

In the same report, the cryo-EM structures for TRPM8 have been obtained in complex with PIP_2, $Ca^{2+,}$ and icilin, and with WS-12 (a menthol analog) together with PIP_2 [134]. These structures demonstrate that both, icilin and WS-12, bind to a cavity formed between S1-S4 and the TRP domain [134].

The structures reveal a different binding site of PIP_2, as compared to other TRP channels. This site is formed by the pre-S1 domain, the S4-S5 junction, the TRP domain and the MHR4 of an adjacent subunit. Interestingly, upon the binding of PIP_2, the S4 undergoes a change from a complete α-helical to a 3_{10} helical conformation [134]. This produces the movement of the TRP domain and the S5 toward the cavity. At the same time, it disrupts the interaction among the S1-S4 domain and the S6-pore domain, enabling gating [134]. Additionally, during gating, the S1-S4 domain of TRPM8 suffers a rigid rotation away from the pore [134], unlike what happens to the S1-S4 domain in TRPV1 which remains static [45].

The lower gate of TRPM8 is formed by L973 where the tightest constriction along the pore was found in a previous structure[134135], Yin and collaborators determined that both structures (PIP_2-Ca^{2+}-icilin and WS-12-PIP_2) were non-conducting states. Although, in the icilin-PIP_2-Ca^{2+} structure the S6 is curved, which

suggested that there may be a π helical turn along the S6 as previously described for the sensitized state of TRPV3[53]. Therefore, the structures may represent sensitized or presensitized states of TRPM8 [134].

Although conformational changes in TRPM channels in response to agonists or modulators of their activities have been clarified, changes in their conductance levels in response to these molecules have not been reported.

Discussion

Here we have summarized some phenomena that could potentially lead to changes in the conductance of single ion channels. For example, pore dilation is a phenomenon suggested to occur in TRPV1 [26,155] and other channels such as the P2X receptors, and it is characterized by a change in the permeability of the ion channel to larger ions, induced by long times in the presence of the agonist. However, the results that we have obtained, as well as those of other groups, suggest that permeability changes may result from changes in the cytoskeleton organization or from time-dependent local changes in the concentrations of ions in the vicinity of the channel, a phenomenon known as ion accumulation, that is at play in whole-cell experiments [156] and is further discussed below.

Li and collaborators have examined this carefully and have shown that P2X receptors readily activate and do not display a slow phase of activation under symmetrical ionic conditions [156]. These authors also show that changes in the equilibrium potential are observed with $NMDG^+$ in the external solution during sustained activation and that this prolonged activation in bi-ionic solutions primes the depletion of internal Na^+ and accumulation of $NMDG^+$ in the cell. Li et al., also discuss that P2X receptors are exceptional in that they demonstrate significant permeability to large cations such as $NMDG^+$ and that, even in the absence of pore dilation, would allow the conduction of relatively large molecules to enter or exit cells [156]. Finally, and most importantly, these authors point out that changes in ion concentration, produced by ion accumulation and revealed during experiments with P2X receptors, are an inherent problem in voltage-clamp recordings, where the flow of ionic currents across the membrane may alter the concentrations of intracellular ions [157,158]. In other words, when symmetrical ionic conditions are used, ion concentrations can be maintained by working under conditions in which current amplitudes are moderate and current measurements will always be equal to or greater than the flux of any individual ionic species. This is in contrast to experiments performed with asymmetric ionic conditions, which require a membrane conductance of an order of magnitude smaller than the access conductance to adequately control ion concentrations.

These results are prompting a reexamination of the concepts of pore dilation and dynamic ion selectivity for all ion channels [156], and highlight the importance of further studying the molecular mechanisms underlying different conformational changes induced by ligands in these proteins.

TRPV1 has been shown to contribute to several physiological and pathophysiological processes, importantly. Among these, the participation of TRPV1 in pain-related processes is an aspect that has attracted the attention of several research groups. Understanding cellular mechanisms leading to the generation of pain constitutes the basis for designing tools in order to attack them. Hence, research directedtoward defining the molecular mechanisms that underlie the production of pain is of invaluable importance. This requires a great effort from many researchers and from several points of view, including that of understanding various particularities of the modulation of the effectors involved in pain processes.

As for changes in the conductance of TRPV1 due to the actions of agonists, it is interesting to note that, it has been recently reported that DkTx diminishes the unitary conductance by 32% of TRPV1, as compared to that observed with capsaicin [159]. DkTx is a molecule composed of two moieties joined by a short linker, which bind in the outer pore region of the channel so that each motif sits at a subunit interface [45]. Moreover, the effect was eliminated when the linker of DkTx was either absent or elongated and also when the pore turret of TRPV1 was removed. The lack of pore turret in the construct used for the cryo-EM of TRPV1 explains why the structure with DkTx/RTx is observed to be fully open. In fact, the unitary

conductance of the construct used to obtain the TRPV1 structure with bound DkTx was similar to that obtained with capsaicin [159].

With this, Geron et al. confirmed that DkTx and capsaicin elicit distinct gating mechanisms that are dependent upon the pore turret of TRPV1. They argued that the binding of DkTx directly restricts the movement of the pore helix and consequently the conductance.

In terms of the physiological relevance of LPA's actions on the conductance of the TRPV1 channel, one can only hypothesize that in the presence of this agonist, as compared to capsaicin, depolarization of the neuron where it is expressed will occur more efficiently. Since the change in the conductance of the channel also occurs at subsaturating concentrations of LPA (i.e., 1 μM), this would mean that such an efficient depolarization could also occur even when lower levels of the phospholipid are present.

TRP channels share conserved sequences of amino acids in some regions of their structures. One such region is the TRP box (Figure 5), the region where the K710 residue that interacts with LPA lies. We have tested the effects of LPA on some TRP ion channels and have found that TRPV2, TRPV3, or TRPA1 channels are not activated by this phospholipid [41]. Although TRPV3 and TRPA1 have a lysine in this position, just as TRPV1, LPA is not capable of activating these channels. Thus, this phospholipid seems incapable of providing the energy necessary to drive the transition from the closed to the open state in this particular ion channels and the question of why this occurs remains open. Moreover, since other members of the TRPV subfamily of ion channels exhibit a lysine in the corresponding position to that of K710, it will be interesting to test whether their activities can be modulated by LPA. If so, this would constitute the identification of an agonist for these other ion channels for which there are few endogenous activators known (i.e., TRPV4, TRPV5, and TRPV6).

Since achieving different conductance states can modulate the response of the cell where ion channels are expressed, not only will it be interesting to determine if LPA activates these other TRP channels, but also whether it can produce different conformational changes as what happens with TRPV1.

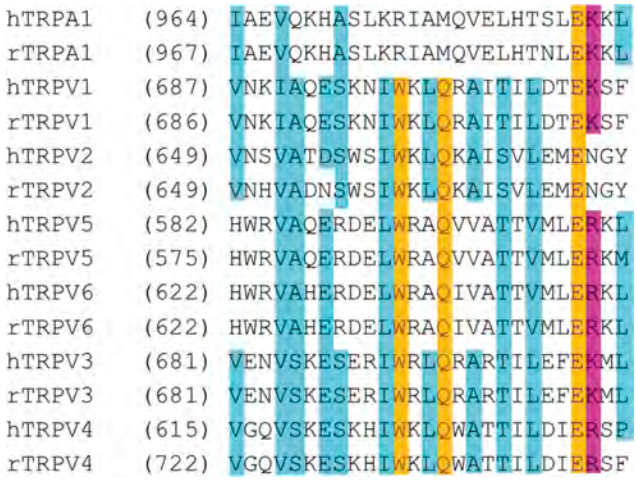

Figure 5. Sequence alignment corresponding to the trp box in rat and human TRPV and TRPA1 channels.

Identical residues are highlighted in yellow and similar residues in blue. Tryptophan and glutamine residues in the middle of the trp box are only present in TRPV channels. The residue K710 in hTRPV1 and the corresponding residue in other TRP channels is highlighted in pink, notice that most channels, including TRPA1 have a positively charged residue in that position.

This would further demonstrate the conformational versatility of this family of ion channels.

Several ion channels have been studied at great detail with respect to their responses to different agonists. In particular, the idea that LPA produces a conformational change that results in a different conductance of TRPV1 at the single-channel level compared to capsaicin challenges the notion in the field of study of ion channels in general.

Here we have discussed that LPA leads the TRPV1 ion channel to open with a single-channel conductance level that is higher than that attained with capsaicin. Both ligands promote nearly maximal open probabilities [117]; hence, this is most probably not a mechanism in which different subconductance levels can be attained in the presence of partial and full agonists.

Thus, it will be interesting to reflect upon and determine what mechanisms or structural rearrangements allow TRPV1, and maybe other TRP channels, to exhibit a higher conductance level in the presence of one agonist or another.

ABSTRACT

S-adenosylmethionine (SAM), biosynthesis from methionine and ATP, is markedly decreased in hepatocellularular carcinoma (HCC) for a diminution in ATP levels, and the down regulation of the liver specific MAT1a enzyme. Its metabolic activity is very important in the transmethylation reactions, the methionine cycle, the biosynthesis of glutathione (GSH) and the polyamine pathway, which are markedly affected in the HCC. The chemo-preventive effect of IFC305 in HCC induced by DEN, and the increase of ATP and SAM in CCl_4-induced cirrhosis have been previously demonstrated. The aim of this work was to test whether this chemo-preventive effect is mediated by the induction of SAM biosynthesis and its metabolic flow. SAM hepatic levels and the methionine cycle were recovered with IFC305 treatment, restoring transmethylation and transsulfuration activities. IFC305 treatment, increased MAT1a levels and decrease MAT2a levels through modulation of their post-transcriptional regulation. This occurred through the binding of the AUF1 (binding factor 1 AU-rich sites) and HuR (human antigen R) ribonucleoproteins to *Mat1a* and *Mat2a* messenger RNAs, which maintained their nuclear localization. Finally, the compound inhibited the polyamine pathway favoring the recuperation of the normal methionine and one carbon cycle recuperating the metabolic flow of methionine, which probably facilitated its HCC chemo-preventive effect.

1. Introduction

Liver cancer, mainly hepatocellular carcinoma (HCC), is the fourth leading cause of cancer-related deaths globally.[1] Risk factors for HCC include chronic infection with hepatitis B and C viruses (HBV and HCV), dietary aflatoxin, excessive alcohol intake, and cigarette smoking, as well as diabetes and obesity, which play a prominent role in HCC development.[2,3] Mortality is high due to difficulties in early detection and a lack of available treatment therapies.[4] HCC is characterized by epigenetic alterations that contribute to preneoplastic and neoplastic lesions. Among them, DNA and protein methylation that induce genomic instability result in a hepatocarcinogenic effect in methyl-deficient conditions with a decrease in S-adenosylmethionine (SAM) in the liver. SAM is an ubiquitous methyl donor that was reported to have chemoprotective activity against liver cancer.[5–8] Several authors have studied the chemopreventive effects of SAM administration in HCC.[5,6]

SAM is synthesized in all mammalian cells but is most abundant in the liver. It is synthesized from L-methionine and adenosine triphosphate (ATP), and this reaction is catalyzed by the enzyme methionine adenosyltransferase (MAT; E.C. 2.5.6.1).[7,8] In mammals, two distinct genes encode MAT enzymes (MAT1A and MAT2A). *Mat1a* is predominantly expressed in the adult liver, while *Mat2a* is ubiquitously expressed in all extrahepatic tissues. MAT2A is found predominantly in the liver during the fetal period and is progressively replaced by MAT1A during development.[7,9]

Chronic liver damage initiates a switch in MAT protein expression due to a decrease in MAT1A activity that occurs concomitantly with MAT2A upregulation.[7,10,11] The kinetics of MAT1A and MAT2A are different since MAT2A is inhibited by its product, which consequently results in lower levels of SAM.[7,12]

SAM is mostly used in the transmethylation pathway to produce S-adenosylhomocysteine (SAH), which is transformed by SAH-hydrolase into homocysteine and adenosine.[7,13] SAH is a potent and competitive inhibitor of transmethylation reactions and must be quickly removed.[7] The SAM/SAH ratio is considered an indicator of methylation activity and liver injury sensitivity.[9,14] Therefore, low SAM levels and high SAH levels are characteristics of the development of liver cancer.[15,16]

Previous studies described the effect of the RNA binding proteins (RBPs) HuR (human antigen R) and AUF1 (binding factor 1 AU-rich sites) on the posttranscriptional regulation of the *Mat2a* and *Mat1a* transcripts, for a review, see ref.[17] Both RBPs are nuclear proteins that are translocated to the cytoplasm to regulate MAT mRNA stability through their association with the 3′ UTR of specific mRNAs. The translocation of the RBPs is related to various processes, including fetal liver dedifferentiation, apoptosis, hepatic proliferation, and HCC progression, and consequently, diminishes the biosynthesis of SAM.[18–21]

Previously, we demonstrated that an increased adenosine level coincided with a rise in SAM levels and a decline in SAH levels, suggesting flux in the methylation pathway and phospholipid methylation.[14,22] In addition, an important circadian change in SAM and adenosine in the rat liver coincides with changes in ATP levels, for a review, see ref.[23] Thus, these findings suggested a correlation between energetic metabolism and SAM formation.

SAM regulates a number of methionine cycle pathways that are perturbed in liver cancer, including the generation of glutathione (GSH) from homocysteine, which can be converted to cysteine via the transsulfuration pathway that utilizes methionine for GSH synthesis.[24–26]

In addition, SAM also donates an aminopropyl group to putrescine to produce spermidine and 5′methylthioadenosine (MTA) through the polyamine pathway. MTA is used to regenerate methionine by the salvation pathway.[9,27] Cancer cells have enhanced polyamine biosynthesis and uptake resulting in high intracellular polyamine concentrations. This increase is coupled with different tumors, such as breast, colon, prostate and liver cancer.[28,29] The high polyamine levels are essential for the rapidly growing cancer cells.[9,30] In fact, a decline in SAM and MTA levels is necessary for the development of liver cancer.[9,28,30] However, many other mechanisms are related to decreases in SAM levels and MAT proteins switching.

It has been shown that adenosine administration induces increased SAM and phospholipid methylation, for a review, see ref.[14]

Recently, we showed HCC chemoprevention by IFC305 in a sequential model of cirrhosis-HCC induced by diethylnitrosamine (DEN) in rats. DEN is a carcinogen used in different experimental models of HCC. To exert its carcinogenic effects, DEN needs to be bio activated by CYP2E1.[31] Once bio activated, DEN can generate DNA adducts through alkylation mechanisms. Moreover, the importance of oxidative stress in the development of hepatocarcinogenesis induced by DEN has been suggested because there is a correlation between the induction of lipid peroxidation and preneoplastic lesions, and it has been further shown that the addition of an antioxidant prevents this effect.[32] IFC305 induces the down-regulation of thymidylate synthase and hepatocyte growth factor (HGF), along with augmented protein levels of the cell cycle inhibitor p27, resulting in the inhibition of cell proliferation, for a review, see ref.[33] In addition, we demonstrated that IFC305 promotes increases in ATP levels and the normalization of mitochondrial function in the cirrhosis-HCC model studied here, for a review, see ref.[34]

As described above, the development of HCC is promoted by a decrease in hepatic SAM. Therefore, the aim of this work was to test whether the chemopreventive effect of IFC305 is mediated by the recovery of the metabolic flow of SAM, the regulation of the SAM/SAH ratio and the inhibition of the polyamine pathway, thereby avoiding cell proliferation.

2. Results

The sequential model of cirrhosis-HCC previously described by Schiffer was histologically corroborated using Masson's trichrome stain. Cirrhosis was detected at week 12, when nodules surrounded by collagen fibers were observed. HCC was established at week 16 when preneoplastic nodules were observed, which were maintained until week 22 (Figure 1 and Supplementary Figure 1). After having ensured the reproducibility of the model, we proceeded to study the effect of IFC305 on SAM synthesis and metabolism.

2.1 IFC305 treatment recovered decreased SAM levels and the SAM/SAH ratio in a sequential model of cirrhosis-hepatocellular carcinoma

A drop in the biosynthesis of SAM affects hepatic function since it regulates cell differentiation and proliferation and thus sensitivity to liver injury. SAM and SAH levels and the SAM/SAH ratio were quantified in this chronic damage model induced by DEN (Figure 2a). Our results showed

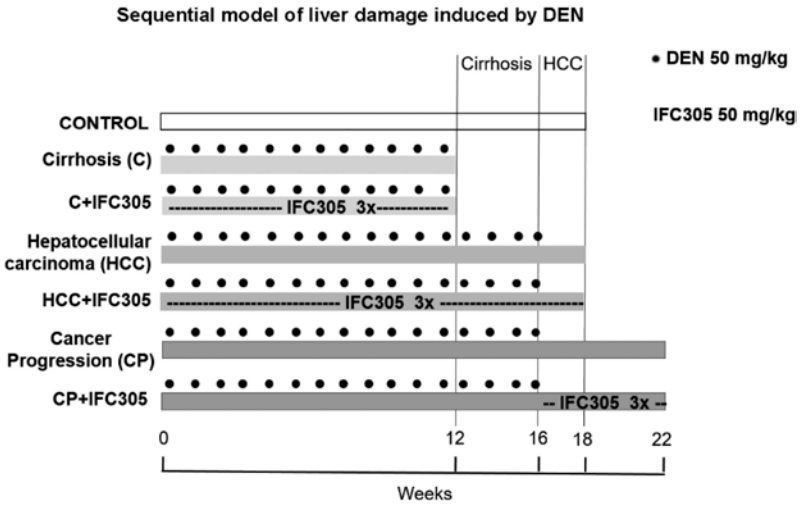

Figure 1. Sequential model of liver damage induced by DEN.

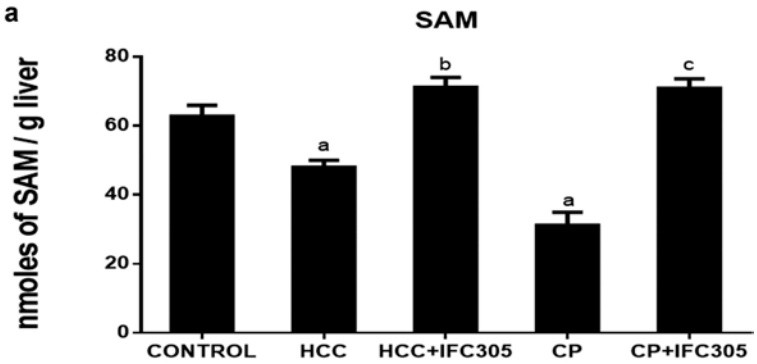
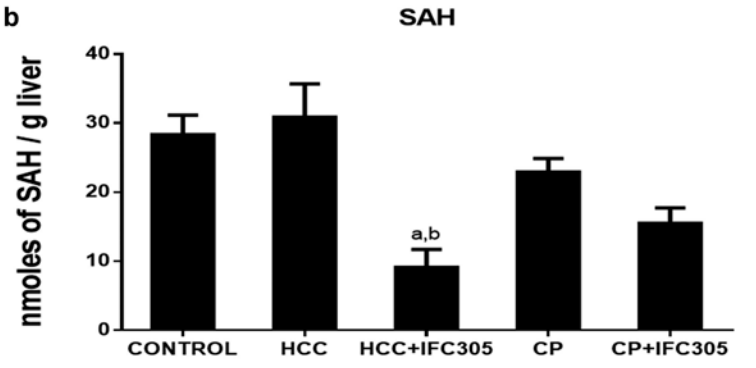


Rats received DEN for 12 weeks to induce cirrhosis (C) and for 16 weeks to induce HCC development. IFC305 was injected in parallel with DEN as a prevention scheme (C+ IFC305 and HCC+IFC305). After suspending DEN treatment, IFC305 was administered from week 16 to week 22 in the cancer progression scheme (CP+IFC305). Rats received DEN dissolved in saline solution once a week, and IFC305 was administered three times per week (IFC305 3X).



a significant diminution in SAM levels in the HCC and CP groups, which were increased with IFC305 treatment in both groups. Once the transmethylation reaction occurs, the product of the reaction is SAH, which is a potent inhibitor of methylation reactions. There were no significant changes in SAH levels in the HCC and CP groups compared to the control group; however, SAH levels diminished significantly in the HCC+IFC305 group and slightly in the CP+IFC305 group (Figure 2b). The SAM/SAH ratio controls the activity of methylation reactions; this calculated ratio indicated a decrease in methylation activity in the HCC and CP groups but a significant increase in the presence of IFC305 (Figure 2c). Similar results in the cirrhosis stage were obtained (Supplementary Figure 2A, 2B, and 2C), in which decreased SAM levels were obtained upon DEN treatment, and IFC305 increased the SAM/SAH ratio.

2.2 IFC305 treatment differentially regulated MAT genes implicated in methionine synthesis in a hepatocellular carcinoma model

We next evaluated the transcriptional changes in the *Mat1α* and *Mat2α* genes in our experimental groups with and without IFC305 treatment. We found that *Mat1a* expression was significantly diminished in DEN-treated samples in both the HCC and CP groups, while treatment with IFC305 increased *Mat1a* expression (Figure 3a). Although *Mat2a* did not show a change in the HCC group, its expression was upregulated in the CP group and downregulated in IFC305-treated rats (Figure 3b).

Next, we analyzed MAT1A protein content. We found that upon DEN treatment, MAT1A protein content was significantly diminished in the HCC group and slightly decreased in the CP group. Our analysis showed a significant increase in

MAT1A protein upon IFC305 treatment (Figure 3c,e). Compared with the control group, the amount of MAT2A protein increased in both the HCC and CP groups, whereas MAT2A protein levels were significantly diminished in the IFC305-treated groups (Figure 3d,e).

We also determined the levels of MAT genes and proteins in the cirrhosis stage. We observed a switch in protein level with a decreased level of MAT1A and an increased level of MAT2A; these changes were prevented by IFC305 treatment (Supplementary Figure 3). Interestingly, the MAT protein switch that was reversed by IFC305 treatment is strongly implicated in liver cancer progression and prognosis.

2.3 IFC305 treatment changed the status of the cellular distribution of RBPs in a hepatocarcinogenesis rat model

The MAT expression pattern in chronic damage can occur through different mechanisms, such as post transcriptionally

through RBPs. For this reason, the levels of the RBPs, HuR and AUF1 were determined in both cellular compartments (nuclei and cytosol). There is a great interest in understanding how the mature *Mat2a* gene transcript is targeted for upregulation by HuR.

Figure 4a shows that the *HuR* expression level was significantly reduced in the HCC group but did not change in the CP group with respect to the control group. The *HuR* expression level was significantly reduced in the HCC+IFC305 group with

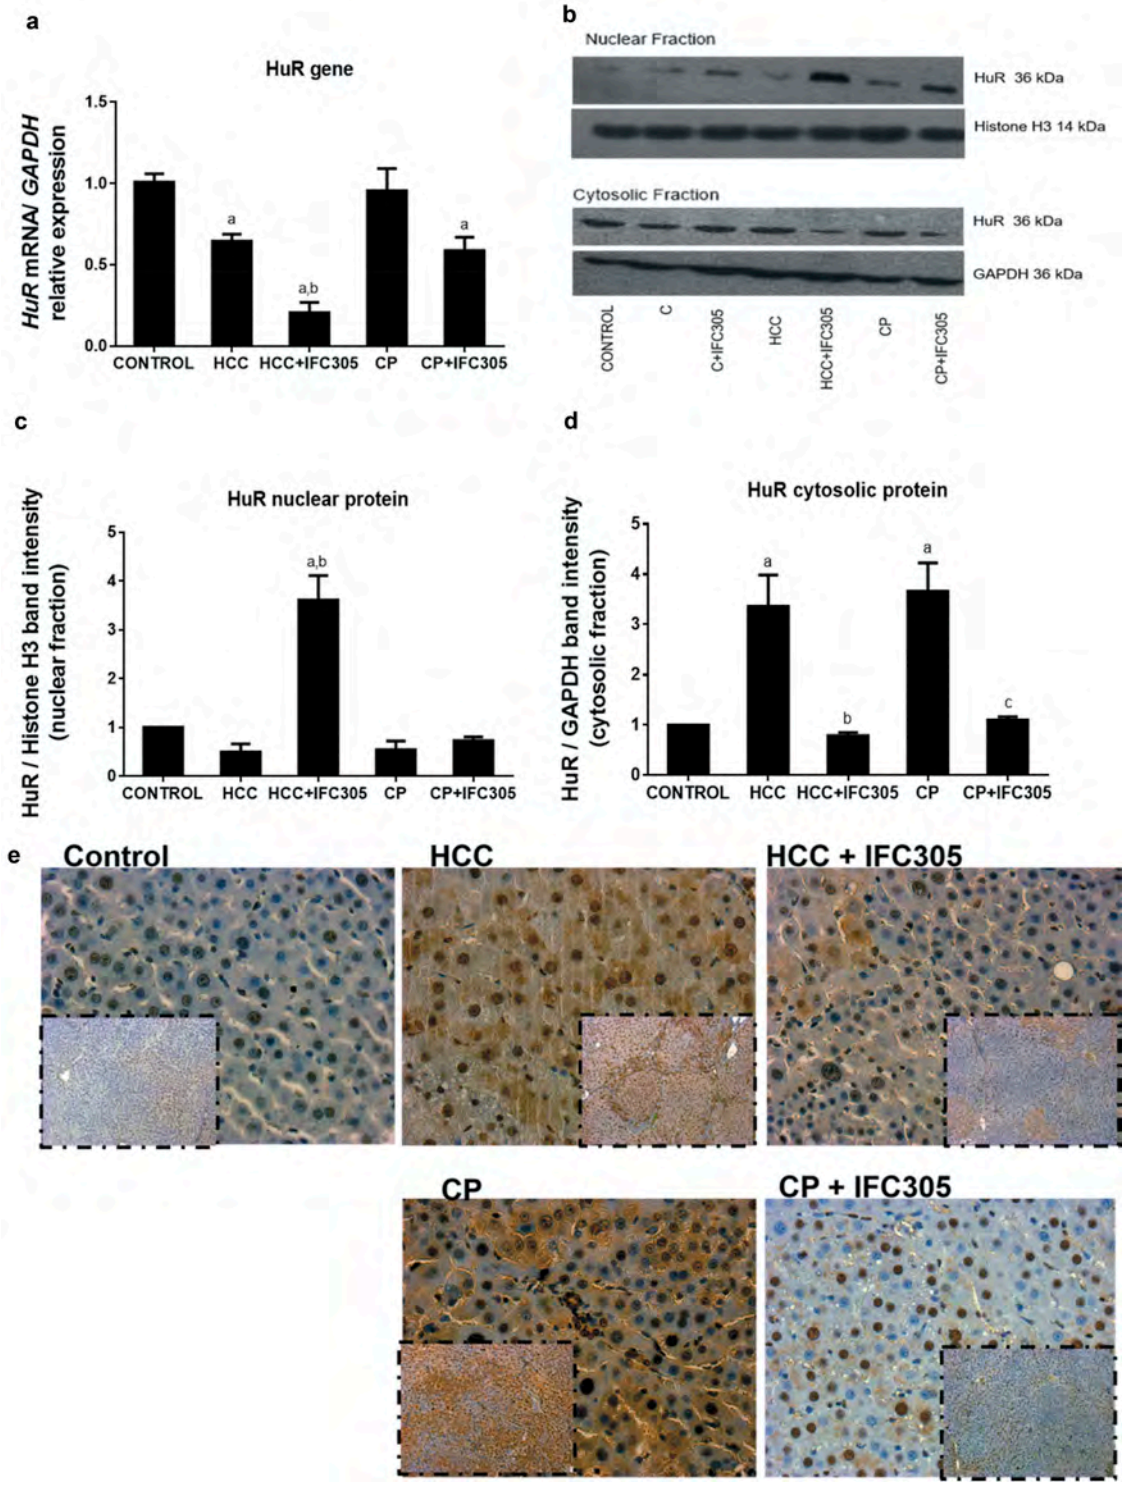

Figure 4. HuR expression, protein level, and immunohistochemical localization.

A) *HuR* mRNA quantification by qRT-PCR; B) Representative blot showing each experimental group of this model including cirrhosis stage; C) Amount of HuR protein in the nuclear compartment; D) Amount of HuR protein in the cytosolic compartment; E) Immunohistochemical localization of HuR at 40X amplification. Values are expressed as the mean ± SE (n = 5 rats/group). [a] indicates a significant difference vs. the control group; [b] indicates a significant difference vs. the HCC group; $P < .05$.

respect to the control and HCC groups, and CP+IFC305 samples was reduced only with respect to the control group.

Next, we analyzed the changes in HuR subcellular localization by Western blot and immunohistochemical analysis. Nuclear HuR levels in the HCC and CP groups decreased slightly compared to the control group, but nuclear levels were increased with IFC305 treatment (HCC+IFC305). By contrast, the CP+IFC305 group did not show a change in the amount of nuclear HuR with respect to the control group (Figure 4b,c). However, we also determined the amount of cytoplasmic HuR protein. This assay showed an important increase in this protein in DEN-treated samples in comparison to the control group, while the IFC305-treated groups maintained and restored cytosolic HuR levels (Figure 4b,d). As shown by the representative images of the control, DEN and IFC305-treated samples in Figure 4e, we observed significantly reduced staining of these proteins in IFC305-treated samples compared to DEN-treated control groups.

The alteration in the subcellular localization of HuR in our sequential hepatic damage model in response to DEN and the IFC305-induced translocation of this protein from the cytosol to the nucleus were also documented at the cirrhosis stage. In addition, the level of the HuR protein in a total liver extract was also measured (Supplementary Figure 4).

There is a great interest in understanding how the mature *Mat1a* gene transcript is targeted for downregulation by AUF1. For this reason, we also evaluated changes in the levels of AUF1 in the nuclear and cytoplasmic compartments.

As shown in Figure 5a, the expression level of the *Auf1* gene was increased in the DEN-treated groups and diminished by IFC305 administration. Furthermore, the amount of AUF1 protein detected in the nuclear fraction was enhanced by IFC305 (Figure 5c). In the cytoplasm, the hepatoprotective IFC305 treatment dramatically reduced AUF1 levels compared with the augmented content in the HCC and CP groups (Figure 5d). The immunohistochemical analysis corroborated these results (Figure 5e).

In cirrhosis, the nuclear AUF1 protein content was reduced in the cirrhosis group, and consequently, the AUF1 cytoplasmic protein content was enriched. This effect was prevented by IFC305 treatment. In addition, the level of the AUF1 protein in a total liver extract was also measured (Supplementary Figure 5).

Additionally, the effect of the IFC305 compound on the level of the MAT proteins and RBPs were evaluated in the HUH7 cell line; we found an increment of MAT2A, HuR and AUF1 after 4 h of IFC305 (5mM) treatment and after this time, a diminution was observed. In the case of MAT1A a diminution was observed at 4 and 6 h after IFC305 (5mM) treatment but a recuperation to the level of the not treated cells was detected. Thus, we observed that IFC305 also modulates the levels of these proteins in the human HuH7 cell line and that supports the data obtained in tissue (data not show).

2.4 The hepatoprotective IFC305 treatment aided in recovering the interactions of RBPs and MAT genes that are altered by DEN

The cytoplasmic stability of eukaryotic mRNA is an important checkpoint in the control of gene expression. In fact, AUF1 and HuR are also involved in liver dedifferentiation and the development and progression of HCC. We next examined the effect of IFC305 on RNP (ribonucleoprotein) complexes.

As shown in Figure 6a, RNP complexes (HuR-*Mat2a* mRNA) were increased markedly in the HCC group, whereas RNP complex formation was reduced in the HCC+IFC305 group. However, in the CP and CP+IFC305 groups, the number of HuR-*Mat2a* mRNA complexes was not modified with respect to the control group.

We found that the AUF1-*Mat1a* mRNA complex was reduced in both the HCC and CP groups, however, only a slight increase in complex formation was observed with IFC305 treatment compared to DEN treatment (Figure 6b).

2.5 IFC305 treatment stimulated GSH biosynthesis and reduced spermidine synthetase expression that is altered by DEN

In hepatocytes, methionine can be generated by the one carbon cycle (Figure 8), and HCyst can be converted to cysteine to generate GSH. We determined the effect of the IFC305 adenosine derivative on the GSH pool and its contribution to protection against hepatic damage. Our results showed that DEN administration for 16 weeks did not induce significant changes in the levels of GSH seen in the HCC group; however, treatment with IFC305 increased GSH levels significantly compared to the control group. No significative diminution was observed in the CP or CP+IFC305 group (Figure 7a). A significant increase in the levels of GSSG were observed in the HCC group (Figure 7b), whereas no changes were observed in the HCC+IFC305 group compared to the control group. A significant decrease in the GSSG content in the CP and CP+IFC305 groups was observed compared to the HCC group. The GSH/GSSG ratio is a useful parameter as an indicator of the redox state. Despite the changes described in GSH and GSSG, no changes in the GSH/GSSG ratio were observed, except in the CP +IFC305 group, where a significant increase was observed compared with the control, HCC and CP groups (Figure 7c). The total glutathione content (GSH+GSSG) is shown in Figure 7d. An increased glutathione content in the HCC and HCC+IFC305 groups compared to the control group was seen. No significant changes in the CP and CP+IFC305 groups compared to the control group were found. Our results from the experimental HCC group treated with IFC305 suggest that this adenosine derivative salt also mediates the GSH biosynthesis in the cirrhosis stage, and the effect of IFC305 on the GSH pool is not significant (Supplementary Figure 6A-D).

It is well known that GSH is the most abundant non-protein thiol in mammalian cells and it protects against oxidative stress. As such, we next assessed the antioxidant potential of IFC305 treatment.

MDA (malondialdehyde) is one of the products of lipid peroxidation and has been related to carcinogenesis induced by DEN; thus, measuring MDA levels is a useful approach to assess lipid peroxidation. A significant increase in lipid peroxidation in the HCC group was observed, which was prevented by IFC305 treatment (HCC+IFC305 group). MDA levels were diminished in the CP group, and there was no change in the CP+IFC305

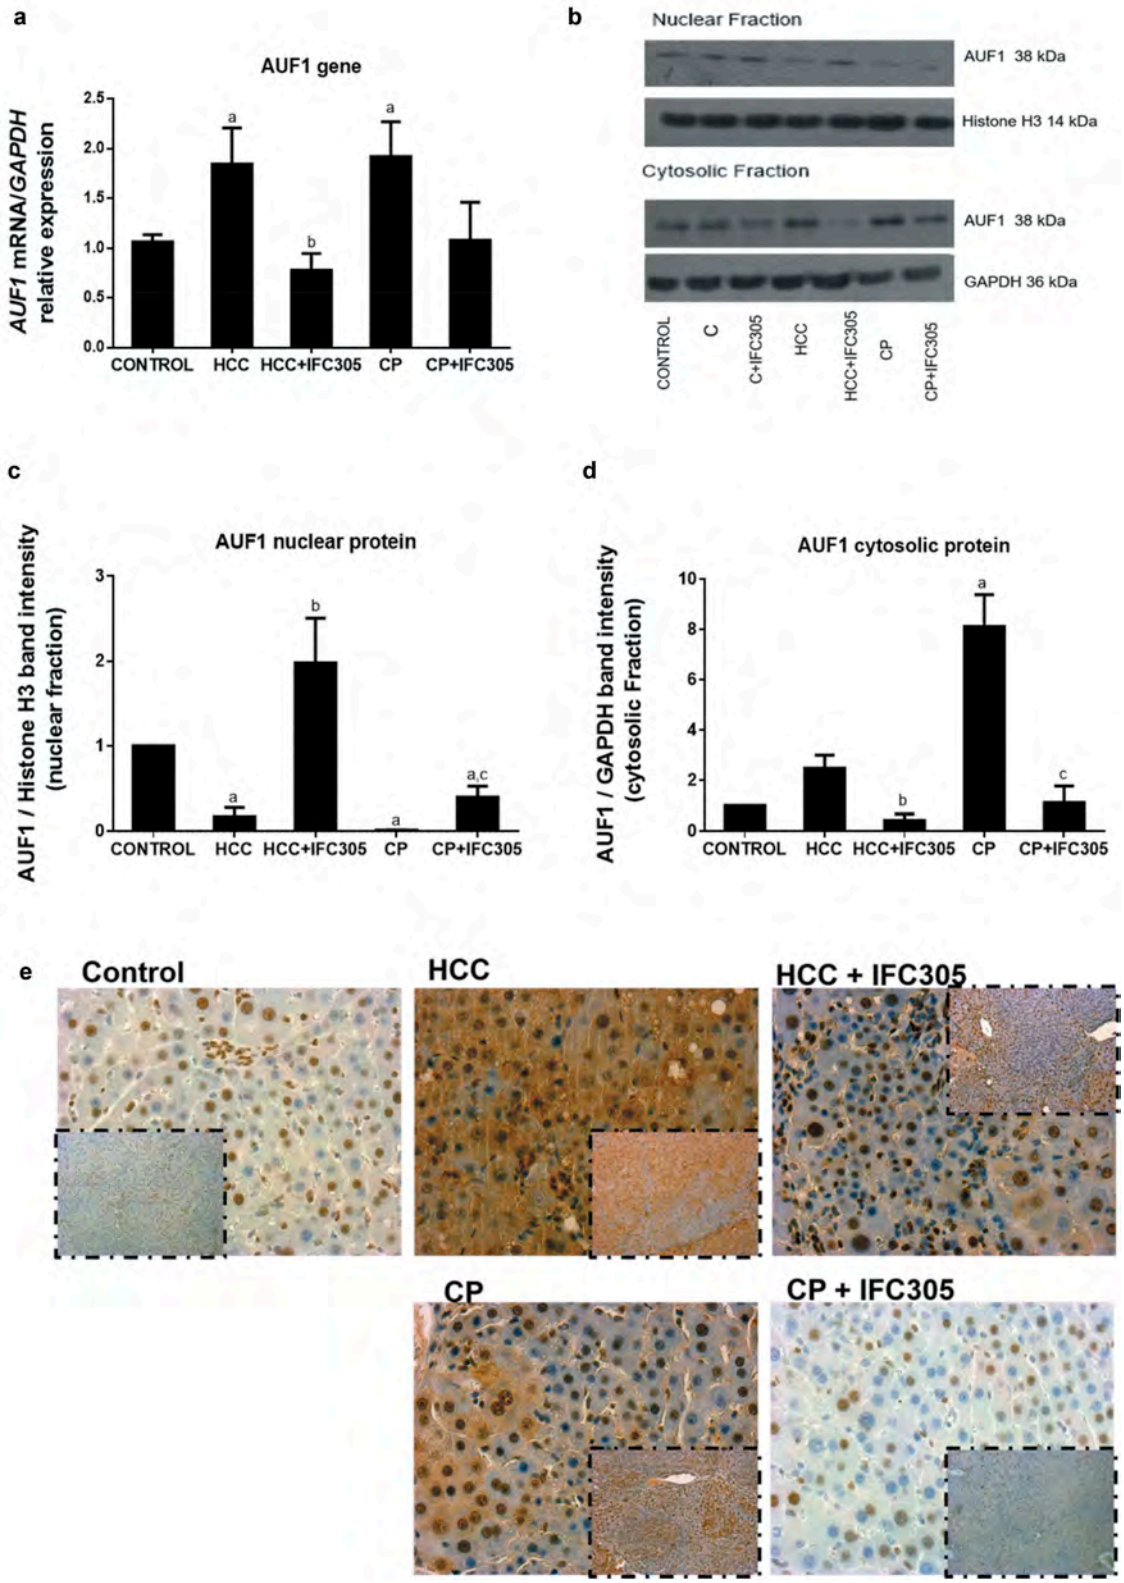

Figure 5. AUF1 expression, protein level, and immunohistochemical localization.

group (Figure 7e). No significant changes in the cirrhotic stage were observed (Supplementary Figure 6E).

As mentioned above, polyamine levels increase in different types of cancer through a pathway derived from SAM. We next measured *Sms* gene expression since it is part of the polyamine pathway. A significant increase in *Sms* expression in the HCC group was observed compared to the control group, and a slight decrease in *Sms* expression was observed in the CP group compared to the HCC group. *Sms* expression was diminished markedly with IFC305 treatment (Figure 7f), which probably decreased the activity of the polyamine pathway. This effect was evaluated in the cirrhosis stage (Supplementary Figure 6F), where diminished *Sms* expression (C group) and a slight effect of IFC305 were observed (C+ IFC305 group).

3. Discussion

S-adenosylmethionine deficiency strongly favors HCC development, which can be inhibited by reconstitution of normal levels by exogenous administration of SAM.[6,35] SAM biosynthesis requires methionine and ATP as substrates for the enzyme MAT1A. Nevertheless, methionine is not synthetized de novo, but it can be recovered from homocysteine remethylation by methionine synthetase or betaine/homocysteine methyltransferase through the one carbon cycle (Figure 8). ATP is an energetic substrate generated through oxidative phosphorylation in mitochondria. Previous studies in hepatotoxicity induced with ethanol or carbon tetrachloride showed that decreased ATP levels generated an energetic unbalance that was recuperated by adenosine treatment.[23,36,37] Similar effects of increasing ATP in hepatocytes[38] and in the blood by adenosine treatment[39] have been reported. At the time of publication, the mechanism of the effect was not clear, but we have recently described an important effect of adenosine

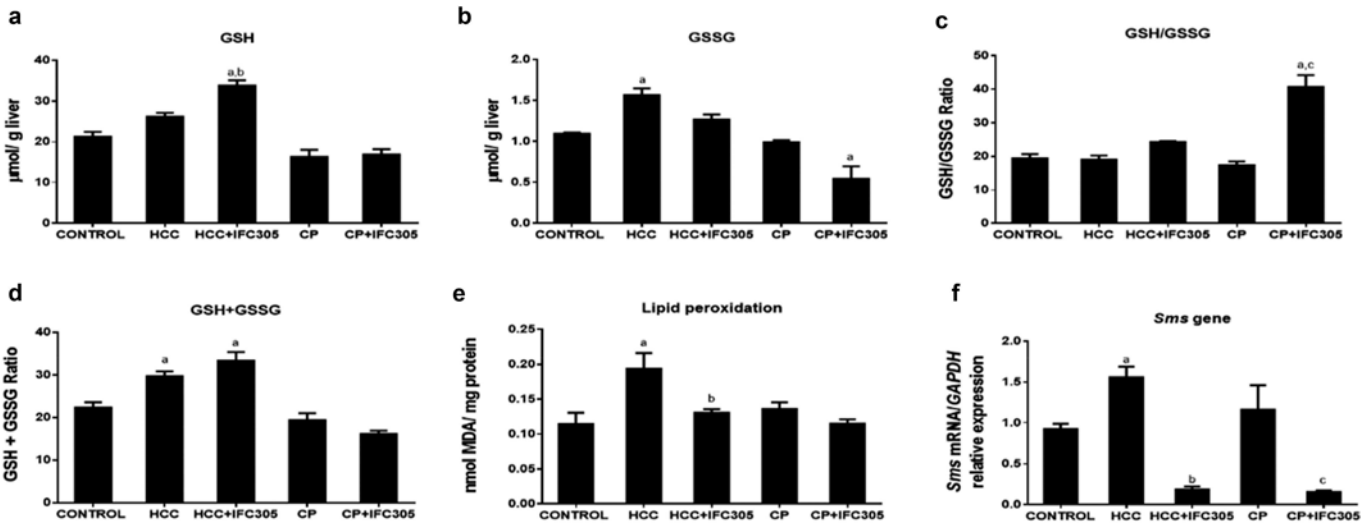

Figure 7. Oxidative stress determined through lipid peroxidation and glutathione content and *Sms* gene expression in the HCC and CP groups and the effect of IFC305.

A) Lipid peroxidation as determined by malondialdehyde (MDA) content; B) Reduced glutathione (GSH) content; C) Oxidized glutathione (GSSG) content; D) GSH/GSSG ratio; E) Total glutathione (GSH+GSSG) content; F) *Sms* gene expression. Values are expressed as the mean ± standard error (SE) (n = 5 rats/group). [a] indicates a significant difference vs. the control group; [b] indicates a significant difference vs. the HCC group; [c] indicates a significant difference vs. the CP group; $P < .05$.

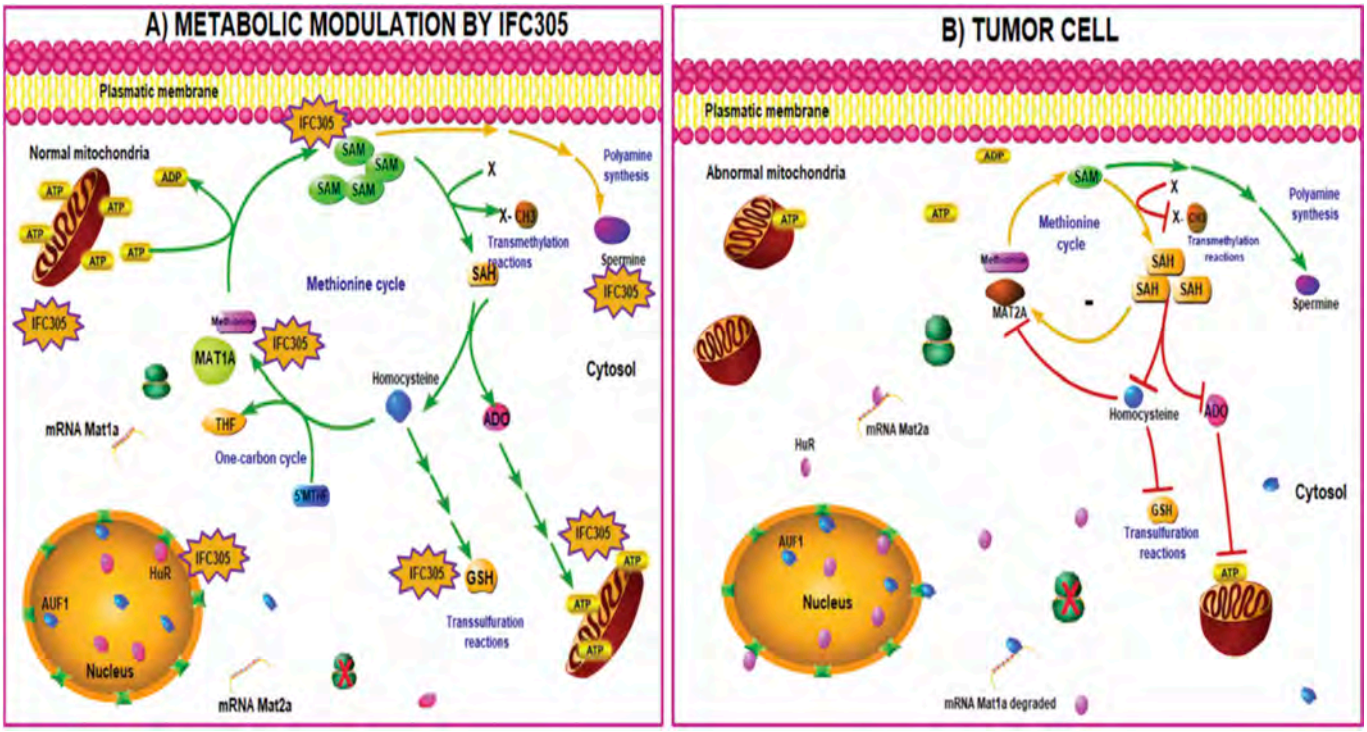

Figure 8. SAM metabolic deficiency in liver cancer and its recovery induced by a hepatoprotective agent derived from adenosine.

A) In tumor cells, SAM synthesis is low due to mitochondrial dysfunction and the consequent decrease in ATP levels. Additionally, biosynthesis catalyzed by MAT2A, which is only expressed in chronic liver damage such as cirrhosis or hepatocellular carcinoma, is limited. This is supported by the RNA-binding proteins HuR and AUF1. HuR positively regulates *Mat2a* mRNA stability, promoting its cytosolic translation and consequently altering the methionine cycle and SAM levels. *Mat1a* mRNA is rapidly destabilized and degraded due to the specific binding of AUF1, which is translocated to the cytosol during the tumor process. B) The hepatoprotective agent IFC305 normalizes mitochondrial function, recuperating ATP levels and SAM biosynthesis, which is also favored by the normalization of MAT1A expression. The IFC305 compound promotes *Mat1a* mRNA translation, avoiding AUF1 translocation to the cytosol, whereas *Mat2a* mRNA is not stabilized by HuR and its translation is not carried out. As a consequence of the recovery of mitochondrial function and SAM levels, the methylation index and the metabolic flow of the methionine cycle are recuperated, which facilitate glutathione biosynthesis, thereby preventing the oxidative imbalance in the tumor.

derivatives in recovering and maintaining ATP synthesis in the HCC and CP groups induced by DEN. We have shown that this occurs through a recuperation of the functional, metabolic and dynamic mitochondrial changes observed in this model.[34] There is much evidence that MAT protein switching and RBPs play an important role in the transcriptional regulation of liver cancer.[20,40,41] The results of this study showed a cytoplasmic increase in HuR and AUF1 in the HCC and CP groups; the presence of IFC305 administration increased the nuclear levels of these RBPs, with a consequent reduction in the cytoplasmic levels favoring the increase in MAT1A and the recuperation of SAM biosynthesis.

Pioneering observations have demonstrated that hepatocyte growth factor (HGF) induces the phosphorylation and activation of LKB1 and, consequently, AMPK.[19,42] AMPK phosphorylation then induces HuR translocation to cytoplasm, promoting an increase in the half-life of MAT2A mRNA, which further contributes to decreasing SAM synthesis. Although a clear mechanism is not described for AUF1, a similar regulation is likely to occur since both RBPs are preferably nuclear and respond to various cell stresses through cytoplasmic translocation. We observed that the hepatoprotective agent IFC305 reduced AMPK protein phosphorylation in our sequential model induced by DEN (data not shown) preventing such translocation.

In chronic liver damage, the nuclear membrane becomes permeable due to the high levels of reactive oxygen species (ROS). Previously, we demonstrated that adenosine and IFC305 have antioxidant properties that repair the mitochondria and prevent the main ROS source from diminishing lipid peroxidation.[34,37] Therefore, the probable mechanism by which IFC305 blocks the cytoplasmic translocation of HuR and AUF1 could be through repairing mitochondrial function and reducing the cellular energy stress and ROS formation. However, other possibilities must be explored, for example, a decrease in proteins that favor subcellular translocation, such as nucleolin 5, or perhaps increased RBP degradation by the proteasome. Once IFC305 is able to maintain the AUF1 protein in the nucleus, MAT1A-mRNA can be translated freely and normally in the cytosol. The MAT1A enzyme is ubiquitously expressed in normal hepatocytes and is downregulated in HCC. In the case of MAT2A mRNA and HuR protein, IFC305 promotes a reduction in the level of these RBPs in the cytosol, and consequently MAT2A protein levels were reduced to control levels. This in vivo study suggests that the IFC305 hepatoprotective compound can reduce the interaction of HuR-MAT2A mRNA in preneoplastic or neoplastic stages of HCC. Furthermore, we found a significant decrease in nuclear AUF1 content, favoring the decrease in Mat1a mRNA expression and consequently SAM content, starting

in the cirrhosis stage and maintained until HCC in this sequential model. Because the exact mechanism of the progression from cirrhosis to HCC is not yet known, this result suggests a potential role for the MAT protein switch in the promotion and evolution of damage.

Once the substrate levels and MAT1A activity recuperated, there was an increase in the SAM level in the HCC and CP groups and in cirrhosis. We calculated the methylation activity through the SAM/SAH ratio, obtaining a high ratio in the HCC and CP groups treated with IFC305. Specific studies are in progress, but previous epigenetic studies in a cirrhotic model induced with CCl_4 showed that IFC305 induced an increase in total DNA methylation, as well as an increase in specific genes, such as the *Col1a1* gene.[43] The low methylation ratio in the HCC and CP groups results from the accumulation of SAH, which is an inhibitor of the methylation reaction and is not degraded by S-adenosylhomocysteine hydrolase, thereby preventing the progression of the methionine cycle. Our results showed that IFC305 helped to maintain the methionine cycle through the activity of SAH-hydrolase, which generates adenosine and homocysteine that can be converted to cysteine, and the transsulfuration pathway, which contributed to maintaining a high GSH pool in the liver in HCC. No changes were observed in glutathione content in the cancer progression groups (CP and CP+IFC305), probably due to the absence of DEN and the fact that IFC305 recovers mitochondrial function and, therefore, decreases ROS generation.

Chemical carcinogenesis is strongly associated with the formation of ROS, and DEN, which was used in this model, generates ROS during its metabolism.[44] In this study, we assessed its participation through lipid peroxidation as evaluated by liver MDA levels. The results showed an important increase in the HCC group that was normalized in the presence of IFC305, possibly by the effect that the compound has on GSH formation and the reduction of damage from free radicals.

Hepatocarcinogenesis is also associated with marked increases in polyamine synthesis, which is also modulated by SAM.[45] This process was evaluated by measuring the expression of the *Sms* gene of the spermine synthase pathway, which was increased in the HCC and CP groups. IFC305 decreased the expression of *Sms* markedly, resulting in the decrease in polyamines and representing another anticarcinogenic effect of the compound. The results of this study reflect the differential effects of IFC305 in a sequential model of hepatocarcinogenesis induced by DEN. These effects include the increase in antioxidant reactions and an inhibition of polyamine synthesis that is related to cell growth, proliferation and the promotion of liver cancer. Furthermore, it was previously demonstrated that this compound induces the downregulation of hepatocyte growth factor and thymidylate synthase, which together with the augmentation of the cell cycle inhibitor p27, resulted in proliferation inhibition,[33] confirming the chemopreventive effect of IFC305.

A schematic representation of the changes observed in the present work and their modulation by the chemopreventive compound IFC305 is shown in Figure 8.

4. Concluding remarks

Cirrhosis-hepatocellular carcinoma induced by chronic DEN intoxication results in SAM diminution, modifies the activity of MAT proteins, induces the posttranscriptional modification of MAT mRNAs, causes abnormalities in the methionine cycle and favors cellular proliferation. Our studies indicated that IFC305 could prevent DEN-induced liver injury by increasing ATP levels, SAM biosynthesis, normalizing MAT protein activities, inducing MAT protein switching and RBP localization to the nucleus, normalizing the methionine cycle that regulates GSH and polyamines in the liver, and reducing proliferation pathways.

The changes in methionine and SAM metabolism induced by DEN strongly contribute to HCC. However, IFC305-induced changes maintain physiological SAM levels, metabolism and function, which could be therapeutic targets in preneoplastic liver lesions and liver tumors.

5. Materials and methods

5.1 Chemicals

IFC305 is the aspartate salt of adenosine, and it was prepared with adenosine free base (MP Biomedicals, (100199)) and L-aspartic acid (MP Biomedicals, (100809)) as described previously (Patent No. MX220780; MX 207422; US 8,507,459 B2).[46–48] N-Diethylnitrosamine (DEN, N0756), SAM (A4377), SAH (A9384), and 1-heptanosulfonic acid sodium salt (PH015877) were purchased from Sigma-Aldrich. $NH_4H_2PO_4$ and $HClO_4$ (109065) solutions (at a 0.4 N concentration) were from Merck (Darmstad, Germany), and methanol (HPLC grade, 822283) was obtained from Merck.

5.2 Study design

Male Wistar rats weighing 200–250 g were obtained from and housed at the Animal Facility of the *Universidad Nacional Autónoma de México (UNAM)*. The animals were fed *ad libitum* and housed under controlled conditions (22 ± 2°C, 50-60% relative humidity, and 12 h light-dark cycles).

The rats received DEN (0.05 g kg^{-1} of body weight, i.p) dissolved in saline solution once a week, and IFC305 was administered (0.05 g kg^{-1} of body weight, i.p) three times per week (IFC305 3X). The sequential model induced by DEN was divided into two main groups: hepatocellular carcinoma (HCC) and cancer progression (CP) (Figure 1).

The HCC group was treated over 16 weeks with DEN, followed by a 2-week wash-out period for multifocal HCC development. The HCC plus IFC305 group (HCC+IFC305) was treated for 16 continuous weeks with both compounds. The cancer progression group (CP) received DEN for 16 weeks, followed by saline solution for 6 weeks. Finally, the cancer progression plus IFC305 group (CP+IFC305) received DEN for 16 weeks and then IFC305 for 6 weeks after DEN was suspended (Figure 1).[49] Age-matched normal rats were used as controls; these animals received only saline solution. Animals were euthanized by sodium pentobarbital (Pisa, Mexico) anesthesia, after which the liver was recovered,

and the cirrhotic area and tumor foci were frozen in liquid nitrogen for the determinations described later. An additional fraction was fixed with paraformaldehyde.

Animals received humane care and were used according to institutional guidelines, and the protocol was approved by the *Comité Institucional para el Cuidado y Uso de Animales de Laboratorio del Instituto de Fisiología Celular (VCHH53-14)* and the Mexican Official Norm (NORM-062-ZOO-1999).

5.3 Total protein extraction

Liver samples were homogenized with RIPA buffer (0.1 g of tissue per milliliter of buffer) supplemented with protease and phosphatase inhibitors (Roche Diagnostics Corp, 116974498001). The homogenate was centrifuged at 15,965 *g* for 10 min at 4°C, and the supernatant was utilized as the total liver homogenate.

5.4 Nuclear protein extraction

The isolation of intact and stable nuclei was accomplished through an isosmotic lysis procedure, as reported previously.[50] The nuclear envelope remained intact even during further manipulations of washing, freezing, and ultracentrifugation. Briefly, 0.8 g of liver tissue was homogenized in 1.6 ml of buffer containing 0.25 M sucrose (S9378, Sigma), 0.05 M Tris-Cl (T1503, Sigma), and 0.005 M KCl (3040–01 JT Baker). The homogenate was filtered and supplemented with 3 ml of a 2.3 M sucrose solution to increase the homogenate's density. Then, a sucrose gradient was created by adding 1.5 ml of a 2.3 M sucrose solution to the bottom of the tube. The nucleus was isolated by centrifugation at 255,000 *g* for 30 min at 4°C. After isolation, nuclear lysis was achieved by incubation and stirring with hypotonic and hypertonic solutions.

5.5 Western blot

Volumes equivalent to 30 µg of protein (determined using a Bradford assay, 500–0114, Biorad) were separated by 12% SDS-PAGE, transferred to a PVDF membrane (IPVH00010, Merck) and blotted using the following antibodies: HuR (sc-20694), MATIA (sc-13142), and MATIIA (H-48) (Santa Cruz Biotechnology); AUF1 (Abcam, ab61193), histone H3 (SC56616, Santa Cruz Biotechnology) and GAPDH (Ab2302, Millipore Corp).[51] Densitometric analyzes of bands were performed with Quantity-One software (Bio-Rad Laboratories, Hercules, CA).

5.6 Assessment of lipid peroxidation

The extent of lipid peroxidation was determined by measuring the formation of malondialdehyde (MDA) using the thiobarbituric acid method as previously described by Okawa et al.[52]

5.7 Determination of GSH and GSSG levels

Liver samples were homogenized on ice in a solution consisting of 3.75 ml of phosphate-EDTA (E5134, Sigma) and 1 ml of 25% H_3PO_4. The total homogenate was centrifuged at 17,700 *g* at 4°C for 30 min, and the supernatant was used in the assay. Determination of the GSH level was performed according to Hissin and Hilf.[53] To dilute the supernatant, 0.01 ml of the supernatant and 4.9 ml of phosphate-EDTA buffer, pH 8.0, were mixed. The assay mixture (2.0 ml) contained 100 µl of the diluted supernatant, 1.8 ml of phosphate-EDTA buffer, and 100 µl of o-phthalaldehyde (1 µg/µl, PO6576 Sigma). After incubation at room temperature for 15 min, the solution was transferred to a quartz cuvette. To determine the GSSG content,[53] 0.5 ml of the supernatant was incubated at room temperature with 200 µl of 0.04 M N-ethylmaleimide (E3876, Sigma) for 30 min to interact with the GSH in the tissue. Then, 4.3 ml of 0.1 N NaOH (S8045, Sigma) was added. This mixture was used to measure GSSG using the assay for GSH, but 0.1 N NaOH was used as the diluent rather than phosphate-EDTA buffer. Fluorescence at 420 nm was determined with excitation at 350 nm.

5.8 RT-PCR

Total RNA was obtained using an RNA isolation kit (Direct-Trizol RNA mini Prep R205S, Zymo Research, The Epigenetics Company). RNA quantity and purity were determined spectrophotometrically at 260/280 nm with a Nanodrop®. RNA quality was verified by agarose-gel electrophoresis. cDNA synthesis was performed with 2 µg of total RNA using the High-Capacity cDNA Archive Kit (Applied Biosystems, Inc., Foster City, CA) following the manufacturer's protocol. The mRNA determinations of *Mat1a* (Rn00563454_m1), *Mat2a* (Rn01643368_g1), *HuR* (Rn01403240_m1), *AUF1* (Rn01450137_g1), *Sms* (Rn01770794_g1), and *Gapdh* (Rn01775763_g1) were carried out with a TaqMan® Gene expression assay using a FAM™ dye-labeled probe for rats (Applied Biosystems, Inc.). *Mat1a, Mat2a, HuR, AUF1* and *Sms* expression was normalized against *Gapdh* expression with the comparative Ct method. All reactions were performed in the Step One Real-Time PCR System (Applied Biosystems).

5.9 HPLC

Liver tissue (0.250 g) was homogenized in ice-cold 0.4 M perchloric acid (500 µl). Then, it was centrifuged at 8380 *g* for 10 min. The supernatant was divided into aliquots and frozen until quantification was done. The method was performed according to She *et al.*[54] Briefly, aliquots of the acid extracts (50 µl) were directly subjected to HPLC analysis.

A Knauer HPLC system (UV detector Model 2500, Isocratic Pump Model 1000 and Manager Model 5000), a UV monitor operating at 254 nm, and a C18 150 × 4.6 mm × 5 µm column (ACE-Generix, Scotland) were used. The mobile phase was chosen according to She et al.,[54] filtered through a 0.45 µm RC membrane filter and degassed under vacuum. The isocratic elution was carried out at a flow-rate of 1 ml/min at 25°C. During HPLC analysis, the SAM and SAH standards and biological samples were identified according to their retention times.

The standards were dissolved in Milli-Q^R grade water at a concentration of 10 mM and then diluted with 0.4 N $HClO_4$ to the final concentration used in the HPLC system (14 µM SAM and 41.5 µM SAH). Aliquots of a standard solution (50 µl) were injected into the column.

5.10 RNA-binding protein immunoprecipitation (RIP)

Liver tissue (200 mg) was finely fragmented, resuspended in 1 ml PBS plus protease and phosphatase inhibitors (freshly prepared) and 37% formaldehyde (F8775, Sigma, 27 µl) and kept at room temperature for 10 min with frequent mixing. Glycine was added (G8898, Sigma, 75 µl), and samples were kept at room temperature for 10 min with frequent mixing, after which they were subsequently centrifuged (1,397.5 *g*, 5 min, 4°C).

The pellet was resuspended in 1 ml PBS plus protease and phosphatase inhibitors (freshly prepared), followed by centrifugation (1,397.5 *g*, 5 min, 4°C).

The pellet was then resuspended in freshly prepared RIP buffer (1.5 ml; 150 mM KCl, 25 mM Tris-HCl pH 7.4, 5 mM EDTA, 0.5 mM DTT (D0632, Sigma), 0.5% IGEPAL I3021, Sigma), 100 U/mL RNase Inhibitor and protease and phosphatase inhibitors).

Samples were homogenized with a Teflon rod with 15–-30 strokes. The nuclear pellet and debris were separated by centrifugation (9,447.1 *g*, 10 min, 4°C).

Next, the supernatant was divided into three fractions of 500 µl (for Input, IgG, and IP). The input fraction was kept at 4°C until use.

Antibody (5 µg for HuR and AUF1) was added to the protein of interest, and IgG (5 µg) was added to the supernatant (500 µg of protein, previously quantified), followed by incubation overnight at 4°C with gentle rotation. A/G beads (40 µl, Chip-Grade Protein A/G Magnetic Beads, Thermo Scientific) were then added, followed by a 2 h incubation at 4°C with gentle rotation. The beads were then pelleted by centrifugation (349.3 *g*, 30 s), the supernatant was removed, and the beads were resuspended in RIP buffer (500 µl). This was repeated for a total three RIP washes, followed by one wash in PBS, and finally centrifugation at 349.3 *g* for 1 min.

For purification of RNA bound to immunoprecipitated RBPs, the coprecipitated RNAs were isolated by resuspending beads in Tripure RNA extraction reagent (1166716S001, Roche; 1 ml, according to the manufacturer´s instructions). An INPUT sample was also included.

The RNA was eluted with nuclease-free water (20 µl). The RNA was reverse transcribed into DNA according to the manufacturer´s instructions (Applied Biosystems High Capacity cDNA Reverse Transcription Kit), and qRT-PCR analyses were performed as described above.

5.11 Tissue preparation, histology and immunohistochemistry

Liver samples were taken from all the animals and fixed with 10% paraformaldehyde in phosphate-buffered saline for 24 h and transferred to 70% ethanol. Fixed tissues were embedded in paraffin, sectioned to a thickness 4 µm and stained for primary antibodies at 1:100, anti-HuR and anti-AUF1; and 1:50 anti-Mat1a and anti-MAT2A with the DakoEnVision®+ System-HRP (DAB) (Dako, Carpinteria, CA) as previously described.[51] Histological slides were analyzed with the MBF ImageJ processing software for microscopy.

5.12 Statistical analysis

Data are expressed as the mean ± standard error of the mean (SE). Statistical significance was evaluated by Tukey's test using Graph Pad Prism 5.0 (Graph Pad Software Inc., La Jolla, CA). Differences were considered statistically significant when $P \leq 0.1$.

Acknowledgments

We are grateful for the Histology unit and the Bioterium technical collaboration of the Instituto de Fisiología Celular. We thank Dr. Julio Isael Pérez-Carreón for the donation of the *SMS* Taqman probe.

Female reproduction

ABSTRACT

Thyroid hormones (THs) regulate several physiological processes in female mammals, many of which are related to reproduction such as steroidogenesis in the ovary, oocyte and granulosa cells maturation, follicular development and differentiation, and ovulation. THs actions require the presence of THs transporters to facilitate their cellular uptake and efflux. MCT8 and OATP1C1 are the principal THs transporters. The aim of the present study was to determine the gene expression and cellular localization of MCT8 and OATP1C1 in the rat ovary during the diestrus-II cycle phase. Ovaries of virgin adult rats were histologically processed. Reverse Transcription-PCR and immunohistochemistry analyses for MCT8 and OATP1C1 were done. MCT8 gene expression level was significantly higher ($P \leq 0.01$) than that of OATP1C1 in the rat ovary. MCT8 and OATP1C1 were found in all types of ovarian cells but with different immunoreactivity. MCT8 showed stronger immunoreactivity in tertiary and Graafian follicles, corpus luteum and blood vessels, whereas OATP1C1's immunoreactivity was stronger in stroma cells, tunica albuginea, and blood vessels. Our results provide evidence that THs and their transporters are both necessary for ovarian function and that any alteration in these transporters could interfere with reproductive processes such as ovulation and steroidogenesis, compromising fertility.

1. Introduction

There is substantial evidence in human and in animals that the hypothalamic-pituitary-thyroid axis plays a key role in female reproduction (Chen et al., 2015; Krassas et al., 2015; Vissenberg et al., 2015; Yoshimura, 2013). In the ovary, thyroid hormones (THs), triiodothyronine (T3) and thyroxine (T4), through their thyroid receptors (TRs), act as modulators of several physiological processes such as steroidogenesis, oocyte and granulosa cells maturation, follicular development and differentiation, and ovulation (Cecconi et al., 1999; Kobayashi et al., 2009; Maruo et al., 1987; Zheng et al., 2015). These receptors have been found in the ovarian surface epithelium, all ovarian follicles, the corpus luteum and corpus albicans indicating a relationship between the THs and the ovary (Aghajanova et al., 2009; Rodríguez-Castelán et al., 2017a; Wakim et al., 1994). Moreover, thyroid dysfunctions have been associated with disturbed folliculogenesis, impaired ovulation and fertilization rate, and in severe cases complete ovarian failure or cancer (Fedail et al., 2014; Hsieh et al., 2017; Meng et al., 2017; Rodríguez-Castelán et al., 2017b; Shinderman-Maman et al., 2016). These effects might be associated with altered levels of THs in the target cell, which depends on various factors. These factors include the concentration of the circulating THs, the activity of the iodothyronine deiodinases D1 and D2 which convert T4 into T3, D3 that converts T4 into T3 reverse (rT3) and T3 into diiodothyronine (T2); the presence of transporters in the plasma membrane is also a related factor (Friesema et al., 2005). In addition, the activity of THs requires the presence of THs transporters to facilitate their cellular uptake and efflux. Therefore, the deficiency of THs transporters can greatly compromise tissue THs homeostasis (Friesema et al., 2005; Müller and Heuer, 2014).

Several proteins are capable to transport THs across cell membranes. These proteins include some members of the monocarboxylate

INFORME DE LABORES 2019

transporters (MCT), organic anion transporter polypeptides (OATP), large neutral amino acid transporters (LAT) and the sodium/taurocholate cotransporting polypeptide (NTCP) families (Friesema et al., 2003, 2001, 1999; Hagenbuch, 2007; Pizzagalli et al., 2002; Visser et al., 2010). Interestingly, the identification of pathogenic mutations of THs transporters or their inactivation in animal models, indicate that only MCT8 and OATP1C1 have a pathophysiological role in thyroid hormone transport (Dumitrescu et al., 2006, 2004; Friesema et al., 2004; Mayerl et al., 2014; Schwartz et al., 2005; Trajkovic et al., 2007; Van Der Deure et al., 2008).

MCT8 (also known as MOT8 or XPCT) is a protein of about 67 kDa with 12 transmembrane domains (both N and C terminus have a cytoplasmic localization) encoded by the *SLC16A2* gene located on the human chromosome Xq13.2. MCT8 is a specific THs transporter that facilitates the uptake of T4, T3, rT3 and T2, but not of sulfated and sulfamated iodothyronines or aromatic amino acids (Phe, Leu, Tyr, and Trp) (Friesema et al., 2003; Lafrenière et al., 1994; Visser et al., 2011).

On the other hand, OATP1C1 (also known as OATP14 or OATP-F) is a protein with 12 transmembrane domains encoded by the *SLCO1C1* gene. OATP1C1 contributes to the membrane transport of THs (T3, T4, rT3, and T4 sulfate) (Pizzagalli et al., 2002; Sugiyama et al., 2003).

Both MCT8 and OATP1C1 are expressed in most tissues including the brain, liver, kidney, heart, thyroid, gastrointestinal tract, and testes (Cheng et al., 2005; Friesema et al., 2003; Kirat et al., 2013; Muzzio et al., 2014; Nishimura and Naito, 2008). Nevertheless, there is limited information about the expression of THs transporters in the mammal ovary and the cellular localization of MCT8 or OATP1C1 in the rat ovary remains unclear. Therefore, the aim of this study was to determine the expression, cellular localization, and immunoreactivity of MCT8 and OATP1C1 in the ovary of adult virgin rats.

2. Materials and methods

2.1. Animals and tissue preparation

Six adult virgin female Wistar rats (150–200 g) were maintained under a 14:10 h light/dark cycle (lights on 06:00 h) with food and water available *ad libitum* for this study. Their estrous cycle was determined by vaginal smears and after two regular consecutive cycles were chosen during the diestrus-II phase. Ovaries from rats were collected immediately after euthanized with an overdose of sodium pentobarbital (50 mg/kg, i.p., Pisa). Samples from ovaries for Reverse Transcription-PCR were frozen in liquid nitrogen and stored at −80 °C. For their use in immunohistochemistry, the samples were fixed in 4% paraformaldehyde in phosphate buffered saline (PBS) for 24 h, dehydrated, embedded in paraffin, serially sectioned at 7 µm and mounted on poly-L-lysine-coated slides. All procedures were conducted in accordance with the Mexican Law for Production, Care and Use of Laboratory Animals (NOM-062-ZOO-1999) under the approval and supervision of Universidad Autónoma de Tlaxcala, whose internal Bioethical Committee carefully reviewed and approved this research protocol.

2.2. RNA isolation and reverse Transcription-PCR

Total RNA was extracted from the right ovaries (n = 6) using TRI reagent (Sigma-Aldrich) followed by DNase treatment (RQ1 RNase-Free DNase; Promega), according to the manufacturer´s instructions. The RNA concentration was determined spectrophotometrically at 260 nm (6715 UV/Vis; Jenway), purity was assessed from the 260/280 absorbance ratio, where ratios obtained were between 1.9 and 2.0. The RNA integrity was electrophoretically evaluated on 1% agarose gel staining with ethidium bromide.

For each sample, cDNA was synthesized from 2 µg total RNA using 1 µl M-MLV Reverse Transcriptase (Promega, USA) mixed with 1 µl Oligo (dT) 10 µM (Sigma-Aldrich, USA), 1 µl dNTP Mix10 mM (Promega, USA) and RNase-free water (Sigma-Aldrich, USA) in a total volume of 20 µl according to the manufacturer's instructions. The reverse transcription reaction was performed, in a single run, in a Verity Thermal Cycler (Applied Biosystems) for 5 min at 70 °C followed for 60 min at 42 °C and finally for 15 min at 70 °C.

Table 1
Primers for PCR used in this study.

Gen /# Accession	Primer sequences (5´- 3´)	Length bp
SLC16A2 (MCT8)	F: CCCAAGCAAGAGAGGCGCCC	94
NM_147216.1	R: CGGTAGGTGCGCTGGCGAAA	
SLCO1C1 (OATP1C1)	F: GGATCCCCAGTGGGTCGGGG	82
NM_053441.1	R: ACCAGAAAGGCACGGCTGCA	
PPIA (CYCLOPHILIN A)	F: CCGCTGTCTCTTTTCGCC	128
NM_017101.1	R: GCTGTCTTTGGAACTTTGTCTG	

To investigate the mRNA expression of MCT8 and OATP1C1, PCR analysis was performed in triplicate and in different runs for each sample. Primers sequences for amplification of THs transporters were obtained from the literature (MCT8 and OATP1C1: de Souza et al., 2017; and PPIA, housekeeping gene: de Souza et al., 2015), and purchased from Sigma-Aldrich (USA). Details of the primers used in this study are shown in Table 1. PCR was performed with 1 µg of cDNA incubated with 1 µl of *Taq* DNA polymerase (Sigma-Aldrich, USA) and 1 µl of 10 µM specific primers. Thermal cycling conditions were established as follows: 94 °C for 3 min for initial denaturation; followed by 35 cycles of 94 °C for 30 s, with an annealing temperature of 55 °C for 30 s and 72 °C for 30 s; the final elongation step was set at 72 °C for 10 min. The cDNA was omitted for the negative control. PCR end products were detected by electrophoresis on 3% agarose gels stained with ethidium bromide and visualized on an UV-transilluminator (UVP). The relative levels of expression of MCT8, OATP1C1 and PPIA were analyzed by densitometry, determining the intensity of the bands by the area under its intensity profile curve using ImageJ software (NIH, USA). The results are expressed as the relative expression (average of three repetitions for each sample) and all results were normalized to the expression of the PPIA.

2.3. Immunohistochemical analysis

The avidin-biotin-peroxidase (ABC) method was performed on tissue sections to localize the THs transporters MCT8 and OATP1C1. We previously reported the immunostaining procedure (Anaya-Hernández et al., 2014), briefly, one slide per ovary and per rat was deparaffinized and incubated in a microwave oven in 10 mM sodium citrate (pH 6) to retrieve antigens. Endogenous peroxidase was quenched with 3% hydrogen peroxide at room temperature, and endogenous binding sites were blocked with 5% normal goat serum diluted in PBS with 0.3% Triton X-100 (PBST). The slides were incubated with the primary antibody (rabbit polyclonal anti-MOT8, Abcam, Cat. ab136980, 1:200; or rabbit polyclonal anti-SLCO1C1, ThermoFisher Scientific, Cat. PA5-42469, 1:200) diluted with PBST in a humidified chamber for 24 h at 4 °C. Subsequently, they were rinsed with PBST and incubated with the secondary antibody (biotinylated goat anti-rabbit IgG, ThermoFisher Scientific, Cat. 65–6140, 1:200) diluted in PBST for 2 h at room temperature in the humidified chamber, and then washed with PBS. Negative controls were done omitting the primary antibodies and incubated only with the secondary antibody. Immunostaining was developed using Vectastain ABC kit (Vector Labs, Burlingame, CA, USA), and 0.05% 3,3-diaminobenzidine with 0.03% H_2O_2 until a brown color was observed. Slides were counterstained with Mayer's hematoxylin, dehydrated, and were covered with the mounting medium and a coverslip. The preparations were examined under light microscope (Leica DM750), and images were acquired with 4×, 10×, 40× or 100× objectives (Camera Leica ICC50E, 5 M P). A semi-quantitative analysis of immunoreactivity to THs transporters in ovary cells was scored independently by 3 observers. Immunoreactivity to MCT8 and

INFORME DE LABORES 2019

OATP1C1 (separately) was done based on the intensity of brown color. Thus, dark-brown was considered as strong immunoreactivity (+++), light-brown was considered as weak immunoreactivity (+), and an intermediate color between dark-brown and light-brown was considered as moderate immunoreactivity (++) (Thongrod et al., 2019).

2.4. Statical analysis

All data of the relative gene expression were tested for normality (Kolmogorov-Smirnov), and analyzed by a *T*-test. Data are presented as mean ± SEM values (of three experiments). GraphPad Prism version 5.01 software (La Jolla, CA, USA) was used and differences were considered statistically significant at $P \leq 0.05$.

3. Results

3.1. Expression of MCT8 and OATP1C1

In the ovarian tissue, Reverse Transcription-PCR detected mRNA amplification products for MCT8 and OATP1C1. In this tissue, MCT8 gene expression level was significantly higher than that of OATP1C1 ($P < 0.01$; Fig. 1). No PCR products were detected in samples without mRNA (negative control).

3.2. Cellular immunolocalization of MCT8

All ovarian cell types showed immunoreactivity to MCT8 (Fig.1A; Table 2). Oocyte and follicular epithelium of primordial (Fig.1B), oocytes, theca and granulosa cells of primary (Fig.1C) and secondary follicles (Fig.1D, E), as well as stroma cells (Fig.1L) and tunica albuginea (Fig.1K) showed moderate labeling to MCT8; while in tertiary (Fig.1F, G) and Graafian follicles (Fig.1H, I) the intensity of immunoreaction in oocytes, theca, and granulosa cells was very high. In addition, the cells from corpus luteum (Fig.1J), the germinal epithelium (Fig.1K), blood vessels (Fig.1L), and adipose tissue (Fig.1M) showed very strong immunoreactivity. No immunoreactivity was seen in negative control ovary sections (Fig.1N).

Table 2
Immunoreactivity of MCT8 and OATP1C1 in the different ovarian cells of the virgin rat. Strong (+++), moderate (++) and weak (+) immunoreactivity.

	Cell type	MCT8	OATP1C1
Follicles	Primordial		
	oocyte	++	++
	follicular epithelium	++	++
	Primary		
	oocyte	++	+
	granulosa	++	+
	Secundary		
	oocyte	++	+
	granulosa	++	++

	Stroma	++	+++
	Tunica albuginea	++	+++
	Germinal epithelium	+++	+
	Blood vessels	+++	+++
	Adipose tissue	+++	+++

All ovarian cell types showed immunoreactivity to MCT8 (Fig. 2A; Table 2). Oocyte and follicular epithelium of primordial (Fig. 2B), oocytes, theca and granulosa cells of primary (Fig. 2C) and secondary follicles (Fig. 2D, E), as well as stroma cells (Fig. 2L) and tunica albuginea (Fig. 2K) showed moderate labeling to MCT8; while in tertiary (Fig. 2F, G) and Graafian follicles (Fig. 2H, I) the intensity of immunoreaction in oocytes, theca, and granulosa cells was very high. In addition, the cells from corpus luteum (Fig. 2J), the germinal epithelium (Fig. 2K), blood vessels (Fig. 2L), and adipose tissue (Fig. 2M) showed very strong immunoreactivity. No immunoreactivity was seen in negative control ovary sections (Fig.2N)

3.3. Cellular immunolocalization of OATP1C1

Ovarian cell types showed variable immunoreactivity to OATP1C1 (Fig. 3A; Table 2). Very weak immunoreactivity was observed in oocytes of primary (Fig. 3C), secondary (Fig.3D, E) and tertiary follicles (Fig.3F), and granulosa cells of primary (Fig. 3D), corpus luteum (Fig. 3J), and germinal epithelium (Fig.3K). Oocytes of primordial (Fig. 3B) and Graafian follicles (Fig. 3H), as well as granulosa and theca cells of secondary (Fig. 3G), tertiary and Graafian follicles showed moderate immunoreactivity. Cells from stroma (Fig. 3B), tunica albuginea (Fig. 3K), blood vessels (Fig.3L), and adipose tissue (Fig. 3M) showed very strong immunoreactivity. No immunoreactivity to OATP1C1 was seen in negative control ovary sections (Fig. 3N).

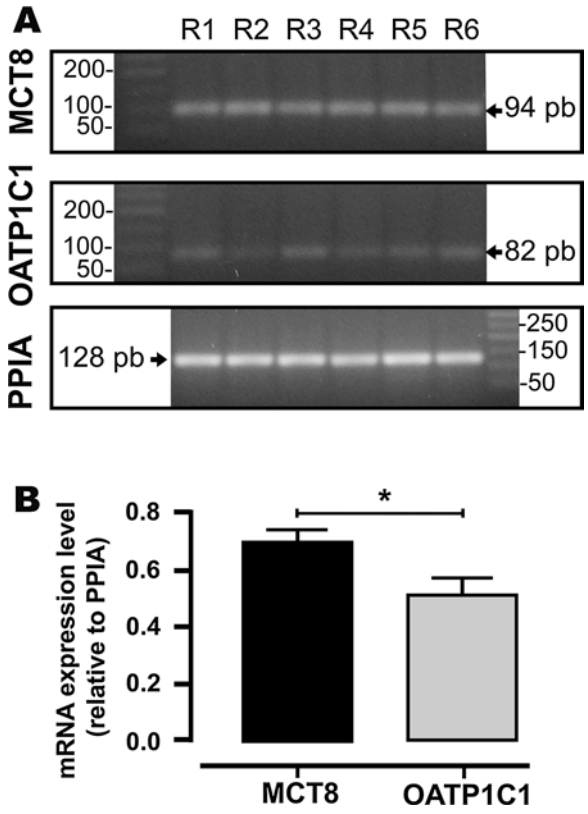

Fig. 1. Relative mRNA expression of MCT8 and OATP1C1 in the ovary from six rats (R1–R6). A) Representative PCR-amplified products in agarose gel stained with ethidium bromide. B) Densitometry analysis of gene expression, the results were normalized with the reference gene PPIA. Each bar represents the mean ± SEM of each gen (*$p \leq 0.01$).

INFORME DE LABORES 2019

4. Discussion

4.1. Expression of MCT8 and OATP1C1

This study shows that the ovary of the rat expresses the THs transporters MCT8 and OATP1C1. This is in accordance to the results reported for the ovary of other species (zebrafish, fathead minnow, mouse and human) where the presence of MCT8 mRNA (Arjona et al., 2011; Muzzio et al., 2014; Nishimura and Naito, 2008) and mRNA of OATP1C1 (Cheng et al., 2005; Muzzio et al., 2014) has been proved. In this study, we found that the MCT8 gene expression level was higher than that of OATP1C1, in contrast to what was reported in the ovary of teleost fish, fathead minnow (Muzzio et al., 2014). No data are available on the comparison of the expression of MCT8 and OATP1C1 in mammalian ovaries. In other reproductive tissue, such as the placenta of the Wistar rat, the expression of MCT8 is also higher than the expression of OATP1C1 (Sun et al., 2014).

Although MCT8 is part of the family of the MCTs, it has been characterized as an exclusive transporter of THs, specifically T3 and T4 (Bernal et al., 2015; Friesema et al., 2003). This suggests that the expression of MCT8 shown by the ovarian tissue is given as a function of the thyroid status as seen in other tissues (Engels et al., 2015). On the other hand, OATP1C1 has an average affinity for transporting THs, and sulfated T3 and T4 (Bernal et al., 2015; Visser et al., 2011). In addition to transporting THs, OATP1C1 can also transport sulfated estrone-3-sulfate and estradiol-17β-glucuronide (Visser et al., 2011). In this case, the functional role of the OATP1C1 transporter is very important, allowing not only the efflux of THs but also of metabolites of steroid hormones.

This study is the first to show the cellular localization and the differential immunoreactivity of both THs transporters in all ovarian cell types of the adult virgin rat.

4.2. Cellular immunolocalization of MCT8

The immunoreactivity of MCT8 was found in all ovarian structures. The fact that antral follicles, as well as the corpus luteum, show an abundant immunoreactivity of MCT8 may be related to the function of THs in these structures. The ovarian follicles (primordial, primary, secondary, tertiary and Graaf) are susceptible to the action of THs. Therefore, by synergizing with follicle-stimulating hormone (FSH), THs regulate the development and maturation of granulosa, theca and oocyte cells, as well as the regulation of steroidogenesis (Fedail et al., 2014; Liu et al., 2017; Zhang et al., 2013). Due to this, both the oocyte and the granulosa cells (including the radiated corona and the oophorous cumulus) and the theca express the TRα and TRβ (Aghajanova et al., 2009; Rodríguez-Castelán et al., 2017a; Wakim et al., 1994). In this study, we found an abundant immunoreactivity of MCT8 in tertiary and Graafian follicles, which could be related to the degree of maturity from several processes mediated by developmental thyroid hormone signal. Since this work is the first to demonstrate the cellular immunoreactivity of MCT8, comparison with previous studies is not possible. Nevertheless, research shows that in other mammal tissues the expression of MCT8 is also differentially influenced by cellular type, physiological condition and thyroid status (Alkemade et al., 2011; Alvarez-Salas et al., 2016; Arjona et al., 2011; Engels et al., 2015; Kirat et al., 2013).

It has been described that in the corpus luteum of mammals, THs have different functions, including regulating proliferation, apoptosis, and angiogenesis for luteal cells maintenance, and secretion of progesterone (Macchiarelli et al., 2013; Navas et al., 2014; Silva et al., 2013). In addition, the corpus luteum expresses the TRα and TRβ that help the THs carry out the functions described above (Aghajanova et al., 2009; Rodríguez-Castelán et al., 2017a; Wakim et al., 1994). The abundant immunoreactivity of the MCT8 transporter found in the corpus luteum of the rat demonstrates the importance of the THs in this structure. Adipose tissue also shows an abundant immunoreactivity of MCT8, this is because THs regulates adipogenesis, mobilization, and storage of lipids, inflammation and insulin sensitivity (Obregon, 2014; Panveloski-Costa et al., 2018).

4.3. Cellular immunolocalization of OATP1C1

The ovarian cells of the virgin adult rat show immunoreactivity to the OATP1C1 transporter. The ovarian structures that exhibit the highest immunoreactivity to OATP1C1 are the tertiary and Graafian follicles, as well as the stroma and tunica albuginea. This could be because these structures are targets of THs (Fedail et al., 2014; Zhang et al., 2013).

Likewise, the adipose tissue also has an abundant immunoreactivity to OATP1C1, possibly because adipocytes, like the ovary, secrete estrone and store it as sulfated estrone, which requires OATP1C1 to enter and leave the cell (Bernal et al., 2015; Ihunnah et al., 2014).

The higher immunoreactivity to MCT8 and OATP1C1 observed in the blood vessels can be explained by the fact that the molecules that transport these proteins (T4, T3, T2, T3S, T4S, rT3) must pass through the bloodstream to reach the cells that require them (Bernal et al., 2015; Visser et al., 2011).

In conclusion, our results provide evidence that the rat ovary expresses the THs transporters MCT8 and OATP1C1, which could play a key role in ovary responses to circulating THs. Furthermore, the results indicate that some alteration in these transporters could interfere with reproductive processes, such as ovulation and steroidogenesis, compromising the fertility of the female. In addition, our findings in the ovarian tissue provide a basis to the study of the THs transporters on different physiological conditions.

Author contributions

EL, YF, MA, AAH carried out the experiment. EL, MA, LJS, EGN contributed with reagents, materials, analysis tools, as well as to the interpretation of the results and helped supervise the project. EL and AAH contributed to the conception and design of the study and drafting the article. All authors discussed the results, contributed, and approved to the final manuscript.

CRediT authorship contribution statement

Enoch Luis: Conceptualization, Investigation, Resources, Supervision, Validation, Writing - review & editing. **Yesenia Fernández:** Investigation, Validation, Visualization, Writing - review & editing. **Mayvi Alvarado:** Investigation, Resources, Supervision, Validation, Writing - review & editing. **Libertad Juárez-Santacruz:** Resources, Supervision, Validation, Writing - review & editing. **Edelmira García-Nieto:** Resources, Supervision, Validation, Writing - review & editing. **Arely Anaya-Hernández:** Conceptualization, Formal analysis, Investigation, Methodology, Project administration, Supervision, Validation, Visualization, Writing - original draft, Conceptualization.

Declaration of Competing Interest

The authors declare no conflicts of interest.

Acknowledgments

Authors thank LANISAF (UACh-UATx) project. AAH, thanks to the postdoctoral fellowship PRODEP (511-6/17-3560) and to Fis. César Oliver Lara Figueroa (from Laboratorio Nacional de Canalopatías) for the excellent technical assistance. The language revision of Pamela Robles Martínez is also acknowledged.

ABSTRACT

Ribonucleoprotein (RNP) complexes and RNA-processing enzymes are attractive targets for antibiotic development owing to their central roles in microbial physiology. For many of these complexes, comprehensive strategies to identify inhibitors are either lacking or suffer from substantial technical limitations. Here, we describe an activity-binding-structure platform for bacterial ribonuclease P (RNase P), an essential RNP ribozyme involved in 5′ tRNA processing. A novel, real-time fluorescence-based assay was used to monitor RNase P activity and rapidly identify inhibitors using a mini-helix and a pre-tRNA-like bipartite substrate. Using the mini-helix substrate, we screened a library comprising 2560 compounds. Initial hits were then validated using pre-tRNA and the pre-tRNA-like substrate, which ultimately verified four compounds as inhibitors. Biolayer interferometry-based binding assays and molecular dynamics simulations were then used to characterize the interactions between each validated inhibitor and the P protein, P RNA and pre-tRNA. X-ray crystallographic studies subsequently elucidated the structure of the P protein bound to the most promising hit, purpurin, and revealed how this inhibitor adversely affects tRNA 5′ leader binding. This integrated platform affords improved structure-function studies of RNA processing enzymes and facilitates the discovery of novel regulators or inhibitors.

INTRODUCTION

Regulatory RNAs, ribozymes, and RNA-protein complexes are appealing antibiotic targets due to their essential functions in microbial metabolism (1–3). This clinical importance is exemplified by the ribosome, which is currently the target of roughly 50% of known antibiotics (4). The focus of this work is Ribonuclease P (RNase P), the only ribozyme other than the ribosome that is present in all three domains of life (see (5–8) for some reviews). This essential ribonucleoprotein complex remains to be exploited as a target for much-needed novel antibacterial agents (9).

The composition of RNase P varies across the three domains of life (10) and therefore may afford high selectivity in drug targeting (11,12). While in archaea and eukaryotes, RNase P is comprised of one RNA subunit and four to ten proteins (13), in bacteria, this complex is formed by an RNA subunit (P RNA, 350–400 nucleotides, 110–125 kDa) and a single protein (P protein, ∼110 amino acids, 13 kDa) (14). In all species, the P RNA serves as the primary biocatalyst (15) for the cleavage of the 5′-leader sequence of pre-tRNAs during tRNA maturation (16). The P protein, on the other hand, binds the distal 5′-leader region of the pre-tRNA substrate, enhances the affinity of metal ions, and assists in product release (17–20). RNase P is dependent on divalent metal ions (Mg^{2+} is needed for proper folding and activity (21–23)) and *in vitro*, high concentrations of Mg^{2+} are sufficient to allow P RNA catalysis, even in the absence of the protein subunit (15,24,25).

There are several known inhibitors of RNase P (reviewed in (12,26,27)), with iriginol hexaacetate and methylene blue being the most recently discovered (26,28). However, to date, neither natural nor highly specific RNase P inhibitors have been identified. The dynamic and flexible nature of the RNase P complex may have hindered the evolution of specific binders (29) and moreover, the protein subunit has some features of intrinsically disordered proteins, which

INFORME DE LABORES 2019

could hamper the stable binding of ligands (30). There also may be an inherent limitation for small molecules to compete with the protein for binding to the P RNA, depending on the relative affinity of the P RNA:P protein pair.

Monitoring RNase P activity has traditionally relied on using radiolabeled RNA substrates (31). In this method, radiolabeled RNA is mixed with RNase P. The reaction is then monitored by denaturing polyacrylamide gel electrophoresis (Urea-PAGE) followed by auto-radiography (31). Very recently, alternatives to measure the kinetics of RNase P on pre-tRNA substrates have emerged. A recent paper developed a fluorescence polarization-based activity assay to monitor RNase P activity on a full-length substrate (26).

To expand the repertoire of inhibitors that may serve as clinical leads as antibiotics, a robust platform for assessing RNase P activity in high throughput is essential. Current activity protocols are either inhibited by 1% (v/v) DMSO or not amenable to high-throughput screening. Additionally, validation methods to verify efficacious RNase P inhibition are lacking. Recognizing these shortcomings, we aimed to create improved methods for discovering small molecule inhibitors of RNase P. To accomplish this goal, we focused on the following strategy: (i) developing a novel method to measure real-time RNase P activity in solution; (ii) obtaining real-time measurements of the binding of the RNase P holoenzyme, P RNA and P protein to their native substrate and inhibitors and (iii) obtaining structural information, *in silico* and through X-ray crystallography, on the binding of potential inhibitors to the P protein.

In this work, we present an RNase P activity assay that exploits a previously reported minimal model substrate (pMini3bpUG, herein referred to as Minihelix or Mh) (32,33). This substrate utilizes a FRET mechanism in which the RNase P substrate couples both a 3′ fluorophore and a 5′ non-fluorescent quencher. Cleavage and release of the quencher molecule by RNase P enables the detection of enzymatic activity by measuring fluorescence emission over time, which is amenable for monitoring steady-state kinetics and for high-throughput screening assays.

We then implemented this method to assess a compound library of 2560 small molecules and found four compounds that inhibit RNase P activity. These inhibitors were effective in the presence of both a canonical pre-tRNA substrate and a novel pre-tRNA-like substrate (herein referred to as 'bipartite pre-tRNA') that is composed of two RNA oligonucleotides and monitors the reaction in an analogous way to the Mh substrate. To avoid the sensitivity of RNase P processing to organic solvents using the bipartite pre-tRNA substrate, we dissolved the hits in PEG 200 rather than DMSO. This procedure allowed us to validate the inhibitory properties of these molecules under varied conditions.

Positive hits were then verified and characterized using biolayer interferometry (34), which allowed us to perform the following tasks: (i) define the affinity parameters of the RNase P holoenzyme, P RNA and P protein to the RNA substrates, (ii) discriminate between the interactions of a given compound with the holoenzyme, P RNA, P protein or the substrate and (iii) determine if a given compound hinders the binding of the holoenzyme to pre-tRNA or the P protein to the 5′-leader.

Once validated, we performed docking and molecular dynamics simulations with each hit and identified putative binding sites for two inhibitors on the P protein. Furthermore, purpurin, a competitive inhibitor which behaved as the most consistent hit across our assays, was shown to bind the P protein by X-ray crystallography, with its binding site corresponding to part of the 5′-leader binding site.

MATERIALS AND METHODS

Selection of bacterial RNase P

We chose to work with RNase P from the thermophilic bacterium *Thermotoga maritima* for several reasons. First, it represents the ancestral and most common 'type A' ribozyme, the same that is present in *Escherichia coli* (35). Second, the crystal structure of the RNase P holoenzyme from *T. maritima* in complex with tRNA (19) as well as the apo-structure of the RNA subunit (36) are known, thus facilitating structure-function studies. Third, the folding protocol of the RNase P holoenzyme from *T. maritima* (described below) leads to crystals that present a functional and homogeneous molecular complex (19). Fourth, although the RNase P from *T. maritima* has optimal activity at 50°C (37), the holoenzyme is active in a temperature range of 20–55°C.

RNase P production

The preparation of P RNA and pre-tRNA from *T. maritima* was carried out by *in vitro* transcription and purified by denaturing 6% urea-PAGE with standard protocols as described previously (19,38). The P protein was purified according to (39). The A260/A280 ratio was between 0.6 and 0.7 for each preparation of purified protein.

RNase P reconstitution

The reconstitution of the RNase P holoenzyme was performed as described in (40,19). This protocol produces a homogeneous and functional ribozyme that can be crystallized by mixing P RNA and P protein in a 1:1.1 molar ratio in 1× TH buffer (33 mM Tris–HCl, 66 mM HEPES, pH 7.4) and 400 mM ammonium acetate (AmOAc). The mixture was heated to 95°C for 2 min in a water bath, then chilled on ice for 2 min, after which $MgCl_2$ was added to a final concentration of 100 mM. Although RNase P from *T. maritima* is catalytically active at 10 mM $MgCl_2$ (19), we found that for our minihelix substrate, 100 mM $MgCl_2$ demonstrated more robust activity. This higher concentration was used in all experiments described herein. The holoenzyme was further incubated at 50°C for 10 min and 37°C for 40 min. The final concentration of holoenzyme was 333 nM (35.6 μg/ml of P RNA and 4.7 μg/ml of P protein).

Substrate minihelix (Mh)

The minihelix (Mh) substrate (Figure 1A) was adopted from a previously characterized RNase P substrate, pMini3bpUG (32,33) and coupled to either Black Hole Quencher 1 (BHQ1) or Black Hole Quencher 2 (BHQ2) at the 5′-end and Alexa Fluor 488 at the 3′-end. This probe was

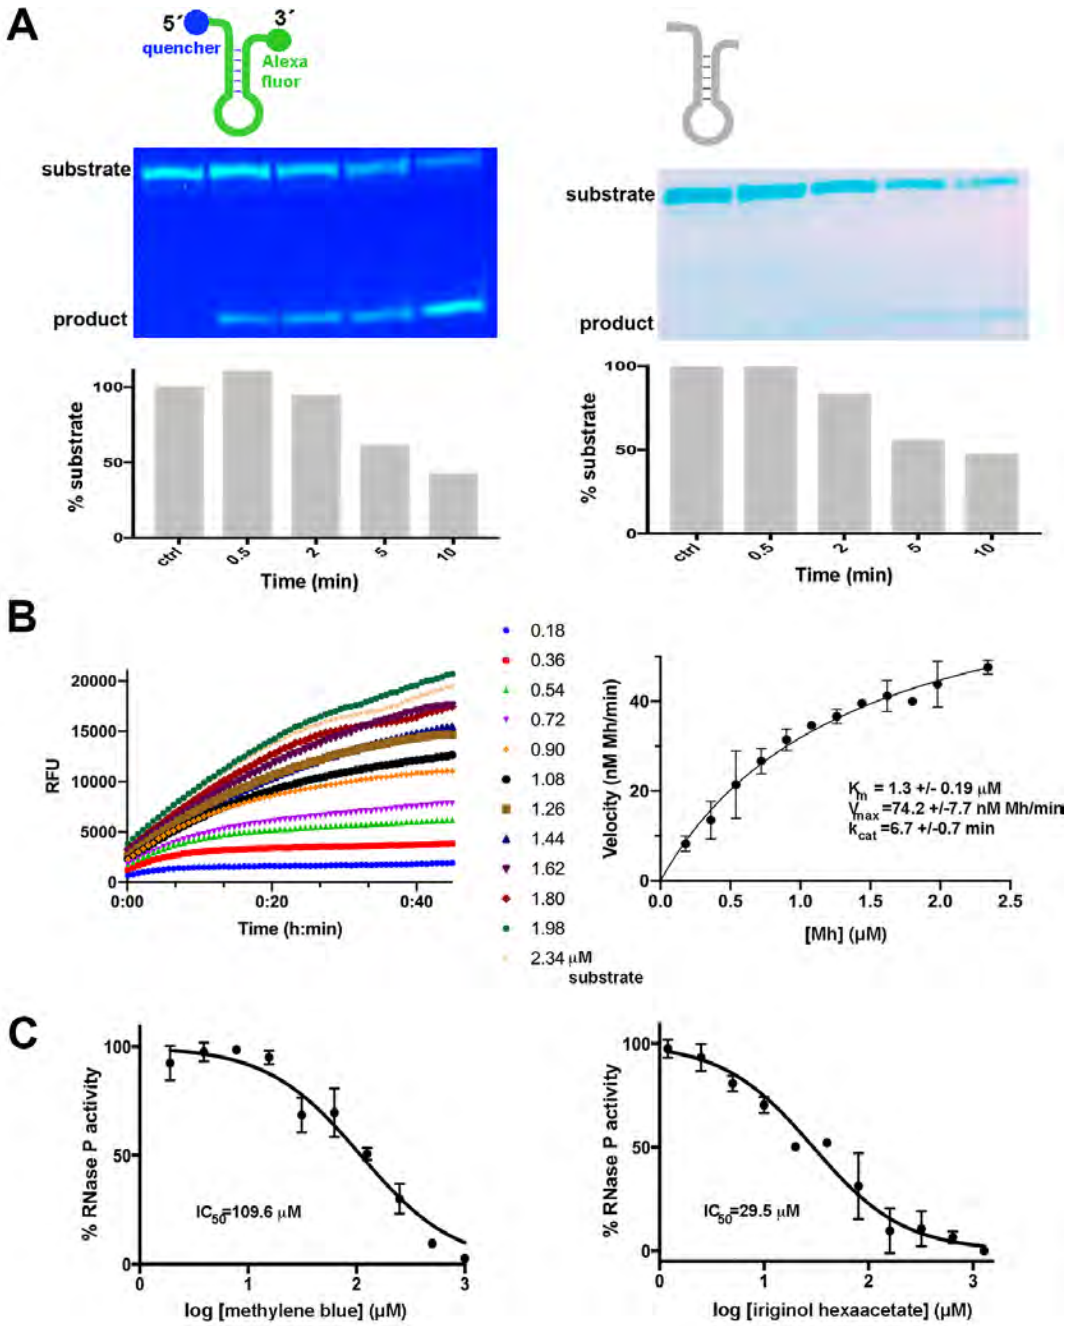

Figure 1. Validation of the fluorescent minihelix (Mh) substrate. (**A**) Cleavage by bacterial RNase P. Top. Schematic representation of the 24-nucleotide fluorescent (left) or non-fluorescent (right) minihelix (Mh) substrate with the predicted secondary structure according to Brannvall et al. (32). Middle left. RNase P holoenzyme from *Thermotoga maritima* cleaves the fluorescent Mh substrate, as visualized by 20% urea-PAGE under UV light. The fluorescence detected from both the substrate (upper band) and the product (lower band) is due to the unfolding of the Mh probe under the denaturing gel conditions. The time-dependent disappearance at 55°C of the 24 nt Mh fluorescent substrate (5 ng), with a simultaneous accumulation of the 15 nt product, confirms the catalytic cleavage of RNase P on the proposed minihelix. Middle right. FRET-pair addition does not affect the cleavage of RNase P on the fluorescent probe as visualized by UV after PAGE and ethidium bromide staining. Bottom. Similar time courses of substrate conversion are observed for the fluorescent (left) and non-fluorescent (right) Mh substrates. (**B**) Kinetic assays of RNase P with the fluorescent substrate show a typical Michaelis-Menten enzymatic behavior. Left. Representative plots of kinetic assays are shown. RNase P holoenzyme was incubated at 20°C at 11 nM, with increasing Mh concentrations as indicated. Right. Michaelis-Menten model fitting ($R^2 = 0.9368$). Initial velocities from three independent trials were plotted against substrate concentration; error bars indicate the standard error for each plot. (**C**) The reported RNase P inhibitors methylene blue and iriginol hexaacetate inhibit bacterial RNase P from *Thermotoga maritima*. Left. The inhibition of RNase P by methylene blue. Dose-response curve ($R^2 = 0.9543$) calculated from the normalized slope values from the linear portions of the kinetic assays in triplicate shown in Supplementary Figure S5. The reported K_i value using a conventional pre-tRNA substrate and the RNA subunit of different bacterial RNase P′s is between 14 and 28 μM (28). Right. Inhibition of RNase P by iriginol hexaacetate. Dose–response curve ($R^2 = 0.9556$) calculated from the normalized slope values from assays in triplicate. The reported IC_{50} value using a fluorescent pre-tRNA substrate is 0.8 μM for *Bacillus subtilis* RNase P (26).

INFORME DE LABORES 2019

purchased either from Sigma-Aldrich or Integrated DNA Technologies (IDT). A requested scale of 0.05 mmol yielded between 6.3 and 20 nmol (57.5 to 181 μg, enough for 1300–4000 reactions depending on the experimental substrate concentration). Before use, the minihelix was diluted from a 100 μM stock (dissolved in water) to 3.6 μM in activity buffer H (33 mM Tris–HCl, 66 mM HEPES, pH 7.4, 400 mM AmOAc and 100 mM $MgCl_2$).

Substrate bipartite pre-tRNA

The bipartite pre-tRNA substrate derived from pre-$tRNA^{Phe}$ from *T. maritima* (Supplementary Figure S13) was designed for the ease of chemical synthesis and conceived from the fact that the anticodon loop is not required for RNase P recognition (Reiter *et al.*). As for the Mh substrate, fluorescent bipartite pre-tRNA was coupled to Black Hole Quencher 1 (BHQ1) at the 5′-end of the 5′ oligo, and to Alexa Fluor 488 at the 3′-end of the 3′ oligo (see Supplementary Table S1). The probes were purchased from Integrated DNA Technologies (IDT). A requested scale of 250 nmol yielded 27.4 nmol (0.36 mg) for the 5′ oligo and 3.8 nmol (50 μg) for the 3′ fluorescent oligo. Before use, the probes were diluted from a 100 μM stock (dissolved in water) and assembled by mixing and heating to 3.6 μM in activity buffer L (Tris–HCl pH 7.4 33 mM, HEPES 66 mM, 100 mM AmOAc and 10 mM $MgCl_2$).

Fluorescence-based activity assay

Reactions were performed in a total volume of 20 μl. Pipetting was done by hand using multichannel pipettes. First, an 18 μl reaction mixture containing 16.5 μl of activity buffer (H for Mh or L supplemented with 10% PEG 200 for bipartite pre-tRNA) and 270 nM (Mh) or 135 nM (bipartite pre-tRNA) (1.5 or 0.7 μl of the 3.6 μM stock) of the fluorescent substrate probe was pre-incubated on ice for at least 5 m in a black polystyrene 384-well microtiter microplate with a flat transparent bottom (Corning ref 3540). The holoenzyme was then added at a final concentration of 33 nM (2 μl of a 333 nM stock) in 1× TH buffer and mixed. Kinetic activity was monitored in a Synergy MX Multimode Detector (BioTek) at 37°C with rapid agitation. At least 20 readings were taken per well every 15 s. The probe was excited at 485 nm, and its emission was monitored at 535 nm with an integration time of 1 s. From the plots of relative fluorescent units (RFU) versus time, linear regression was used to determine the slopes in the linear portion of the curves, using at least 12 data points to obtain initial velocities. Non-linear fitting to obtain the Michaelis–Menten parameters was performed using GraphPad Prism® 6.01 software.

Gel-based activity assay

For gel-based activity assays, reactions were prepared as described in the previous section (fluorescence activity assay), incubated for 1–15 min at 37–50°C, then loaded onto a denaturing 7 M urea–20% acrylamide gel in the case of the Mh substrate or 19% acrylamide (40% acrylamide/bisacrylamide 38.5:1.5) for the bipartite pre-tRNA substrate. The activity conditions for the gel reported in Figure 3A, to monitor the cleavage of the holoenzyme and P RNA, were under 100 mM AmOAc and 10 mM $MgCl_2$. The gels (13 × 16 × 0.15 cm) were electrophoresed at 20 V/cm for 2–3 h. UV shadowing or ethidium bromide staining was used to visualize RNA cleavage. Detection of minihelix fluorescence was achieved without staining using a UV lamp with excitation at ∼254 nm.

Library screening

Screening was performed with the Spectrum Collection (MicroSource Discovery Systems, Inc), which comprises 2560 compounds, each dissolved in DMSO at 10 mM. For our initial screening, compounds from this collection were tested in cocktails; eight compounds were tested per well in 384-well format. The final concentration of each compound in the cocktail was 1.25 mM. For the activity assay, reactions were set up in a total volume of 20 μl (13.5 μl of activity buffer, 1.5 μl of fluorescent Mh at 3.6 μM, 3 μl of DMSO or cocktail). This set-up resulted in a final concentration of 187.5 μM for each compound. The control wells included for each experiment series were: (i) reaction with twice (3 μl) the fluorescent Mh amount to avoid a signal saturation for the rest of the wells, (ii) two reactions with 10% DMSO (no cocktail), (iii) Mh substrate only, with no ribozyme, (iv) reaction with 100 mM $CaCl_2$, which it is used as a negative control as it competes with $MgCl_2$ (EDTA was not used because metal ions are essential to maintaining the structure of P RNA (41)). The reaction was initiated by adding 2 μl of holoenzyme at 333 nM and monitored as described above. Each round of experiments contained twenty different cocktails corresponding to one row of a 384-well plate (Supplementary Figures S6 and S24). Cocktails that showed inhibition (those with a slope value lower than any of the positive controls in the same plate) were verified (Supplementary Figure S7) and deconvoluted (Supplementary Figure S8) to determine the individual fragment or fragments responsible for the inhibition. At this stage, each compound from the inhibitory cocktails was tested at a final concentration of 1 mM (2 μl of the 10 mM stock). We performed a gel-based assay for the nine selected compounds to qualitatively verify the results obtained by the fluorescence assay (Supplementary Figure S9). After deconvolution, each of the final four potential positive compounds was purchased individually from a different provider (Sigma-Aldrich) and tested inhibition using the *T. maritima* Mh, pre-tRNA and bipartite pre-tRNA substrates (Figure 2 and Supplementary Figures S10–S12 and S14).

Expression and purification of His-tagged P protein for binding assays

The gene encoding the P protein from *T. maritima* (gene synthesis performed by DNA 2.0 ATUM) was cloned into the expression vector TmP-pD454-GST as a Glutathione S-transferase (GST) fusion protein, with a TEV protease cleavage site and a His_6-tag at the N-terminus. This vector was transformed into *E. coli* BL21(DE3)pLysS cells. Cells were then used to inoculate 3 l of Luria-Bertani media and incubated with orbital shaking at 250 rpm and 37°C until

Downloaded from https://academic.oup.com/nar/article/47/12/6425/5475076 by UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO user on 20 October 2020

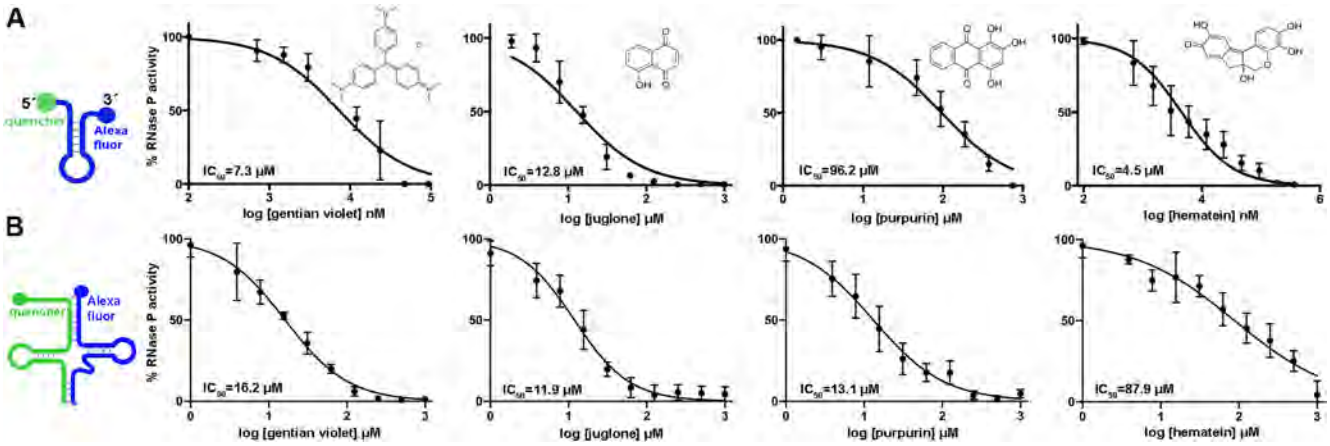

Figure 2. Four validated hits inhibit RNase P holoenzyme from *Thermotoga maritima* in the micromolar range using the substrates Mh and bipartite pre-tRNA. After the screening step (Supplementary Figures S6–S9), four compounds inhibit RNase P using substrates Mh (**A**) and bipartite pre-tRNA (**B**). See Supplementary Figure S13 for a description and validation of the bipartite pre-tRNA substrate. Experiments were performed using compounds from Sigma Aldrich in standard conditions and as described in Supplementary Figures S10 and S14. The four hits are gentian violet (tris(4-(dimethylamino)phenyl)methylium chloride), juglone (5-hydroxy-1, 4-naphthoquinone)., purpurin (1,2,4-trihydroxyanthraquinone) and hematein (3,4,6a,10-tetrahydroxy-6a,7-dihydroindeno[2,1-*c*]chromen-9(6H)-one. A brief description of some properties found of these compounds is given in the Supplementary Information.

the OD_{600} reached 0.6. Protein expression was then induced with IPTG at 1 mM for 6 h. The cell pellet was collected and sonicated in 40 ml of lysis buffer (20 mM sodium phosphate monobasic, pH 8.0, 500 mM NaCl, 20 mM imidazole, 10% glycerol, 1 mM TCEP). TEV protease (700 μg) was then added directly to the lysate and incubated for 16 h at 34°C. The lysate was centrifuged at 13 000*g* and solid urea was added to the supernatant to reach a final concentration of 5 M. The sample was then purified by Ni-NTA affinity chromatography column (HisTrap FF crude, GE Healthcare) equilibrated with binding buffer (20 mM sodium phosphate monobasic, 500 mM NaCl, 5 M urea, 30 mM imidazole, pH 8.0). A 30 min wash at 5 ml/min was performed after which the protein was eluted in 20 mM sodium phosphate monobasic, 500 mM NaCl, 5 M urea, 2 M imidazole, pH 8.0. The elution was then loaded onto a gel filtration column (HiPrep 26/10 desalting, GE Healthcare) equilibrated with desalting buffer (20 mM sodium phosphate monobasic, pH 8.0, 500 mM NaCl). The eluted protein was concentrated to 5 mg/ml and stored at 19°C until needed.

Biolayer interferometry assays (P RNA and holoenzyme)

Real-time binding assays of the holoenzyme, P RNA, P protein, the substrate minihelix and the 5′-leader to individual compounds were performed by biolayer interferometry using an Octet RED96 system (ForteBio). For the holoenzyme or P RNA, a 5′ biotinylated RNA oligonucleotide with the sequence 5′biotin-CAU**UCCAGACGAU** was immobilized on Super Streptavidin (SSA) biosensors. Then, a modified P RNA or holoenzyme was added. The P RNA modification consisted of a sequence with part of the P1 stem sequence complementary to the biotinylated oligonucleotide (AUCGUCUGGA) (Supplementary Figure S23A). P1 is far from the active site or other regions involved in specific interactions (Supplementary Figure S23B) (19). The activity of this construct was indistinguishable from the wild-type holoenzyme. Alternatively, the holoenzyme was immobilized through the His-tagged P protein from *T. maritima* at 0.05 mg/ml (3.4 μM) on Ni-NTA biosensors. Control biosensors were used to subtract non-specific binding of compounds to the biosensor surface. All assay steps (immobilization, wash, baseline, association, and dissociation) were performed in 20 mM HEPES pH 7.4, 100 mM ammonium acetate, 10 mM $MgCl_2$, 2.5% DMSO. The assays were performed on black bottom 96-well microplates (Greiner Bio-One 655209) in a total volume of 200 μl, at 30°C with orbital shaking at 1000 rpm. Experiments were controlled with the software Data Acquisition 8.2 (ForteBio, Inc.). Kinetic binding parameters were calculated using Data Analysis 8.2 (ForteBio, Inc.). After subtraction of reference biosensors, the binding curves were aligned to the X- and Y-axis and the association-dissociation inter-step curve in order to get a common baseline for the association and dissociation phases.

Biolayer interferometry assays (P protein)

Immobilization of the His-tagged P protein from *T. maritima* at 0.05 mg/ml (3.4 μM) was performed on Ni-NTA biosensors. For the initial binding tests to the P protein, a compound concentration of 1 mM was used. Periods for each step of the assay were as follows: immobilization (400 s), wash (100 s), baseline establishment (100s), association (250 s), dissociation (250 s). For each titration curve, six points were used corresponding to the 125, 62.5, 31.25, 15.6 and 7.8 μM compound concentrations. Control biosensors were used to subtract non-specific binding of compounds to the biosensor surface. All assay steps (immobilization, wash, baseline, association, and dissociation) were performed in 20 mM HEPES pH 7.4, 100 mM ammonium acetate, 10 mM $MgCl_2$, 5% DMSO. The assays were performed on black bottom 96-well microplates (Greiner Bio-One 655209) in a total volume of 200 μl, at 30°C with orbital shaking at 1000 rpm. Experiments were controlled with the software Data Acquisition 8.2 (Forte-

INFORME DE LABORES 2019

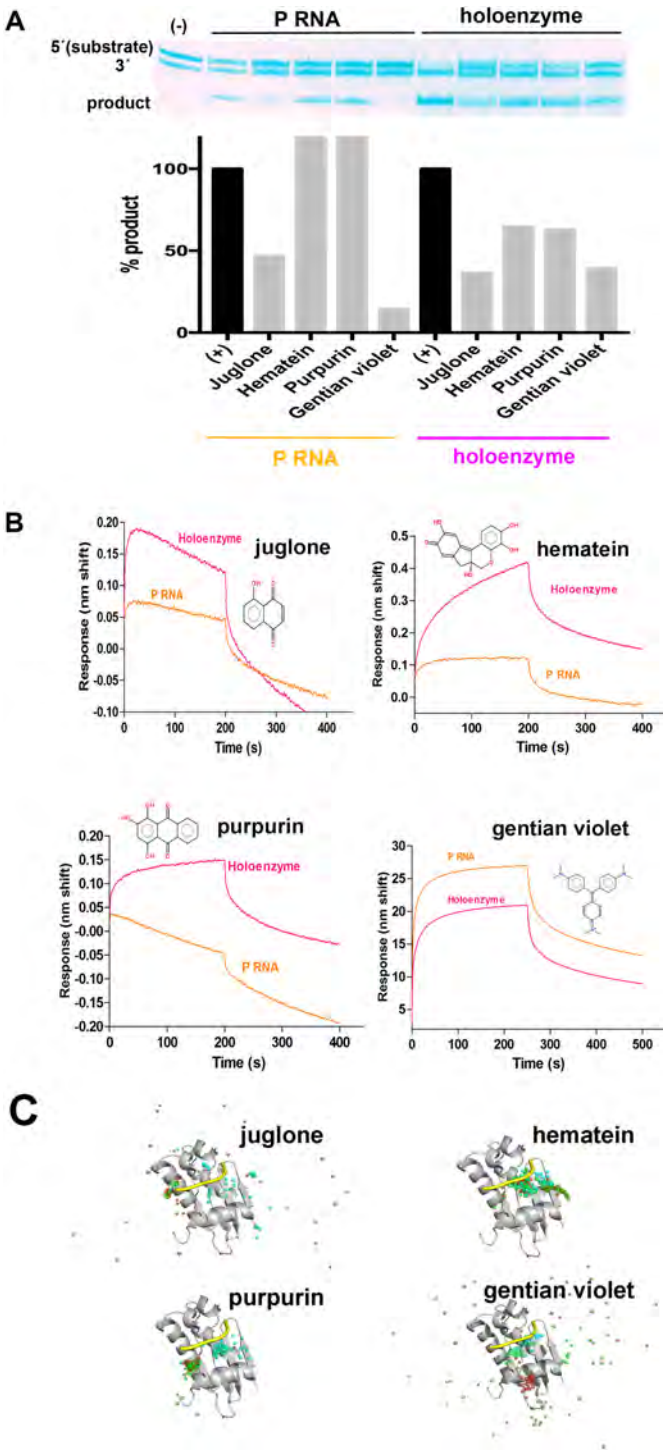

Figure 3. The inhibitors purpurin and hematein bind to the holoenzyme. (**A**) Top. 19% urea-PAGE demonstrates bipartite pre-tRNA substrate is processed with either P RNA or the RNase P holoenzyme from *T. maritima*. Bottom. Comparison of RNase P activity using P RNA (left) or the holoenzyme (right), indicates that purpurin and hematein do not inhibit the P RNA reaction, as derived by densitometry analysis of the lower band (product). (**B**) The relative affinities of the inhibitors for the P RNA or the holoenzyme differ. Binding sensorgrams obtained by biolayer interferometry (BLI). P RNA or RNase P holoenzyme was immobilized on super streptavidin (SSA) biosensors through a 5′-biotinylated RNA oligonucleotide complementary to a region on the P1 stem of P RNA (see Materials and Methods). Remarkably, purpurin does not bind to P RNA (orange). In contrast, gentian violet binds not only to P RNA but also to the Mh substrate (Supplementary Figure S16). (**C**) Molecular Dynamics (MD) simulations of RNase P protein in complex with the validated inhibitors. In each panel, semitransparent spheres represent the geometric center, over a 200 ns trajectory, of the corresponding tested compound. The 5′-leader (yellow) is shown for reference purposes only; it was not included in the simulation. Sphere color coding indicates the starting and final positions in blue and red, respectively. The starting complex conformation for gentian violet, juglone and hematein correspond to the best pose suggested by docking simulations. Purpurin's starting conformation corresponds to that observed in the crystal structure in complex with the P protein (PDB code: 6MAX. See Figure 5). Hematein and purpurin remain bound to the P protein throughout the dynamics protocol.

Bio, Inc.). Kinetic binding parameters were calculated using Data Analysis 8.2 (ForteBio, Inc.). After subtraction of reference biosensors, the binding curves were aligned to the X- and Y-axis and the association-dissociation inter-step curve in order to get a common baseline for the association and dissociation phases.

Biolayer interferometry assays (minihelix substrate)

3′-Biotinylated minihelix was purchased from Integrated DNA Technologies (IDT) (24-mer RNA sequence, 5′-GAUCUGAAUGCGGAAACGCGCCAC-3′-Biotin).
The biotinylated minihelix was immobilized on Super Streptavidin (SSA) biosensors at a concentration of 10 μM. An initial screening of compounds at 1 mM yielded a binding signal only for two compounds: gentian violet and methylene blue. For the titration experiments, 10 μM of 3′-biotinylated minihelix was immobilized for 300 s on Super Streptavidin (SSA) biosensors, followed by a wash step of 100 s and association and dissociation steps of 200 s in the presence of 6 different concentrations of compound ranging from 500 to 15.6 μM. SSA biosensors with no minihelix were used to measure non-specific binding of compounds. All other parameters (buffer, instrument control, analysis) are as described above.

Binding of the P protein to the 5′ RNA leader and binding hindrance

A 5′ RNA leader sequence with 10-bases 5′-GGAAAAAGAU-3′ was purchased from IDT and used at a concentration of 5 μM. This sequence is the same used to obtain the crystal structure of the RNase P holoenzyme (19). The His-tagged P protein was immobilized on Ni-NTA biosensors at 0.05 mg/ml (3.4 μM). The 5′ RNA leader does not bind to the Ni-NTA biosensor surface. The steps performed on the assay and their periods were: P protein immobilization (400 s), wash (100 s), baseline (100ms) (1000 rpm), compound association (800 s), compound dissociation (200 s) (500 rpm), baseline (100 s), 5′ leader association (200 s), 5′ leader dissociation (200 s) (1000 rpm). The assay was performed at 30°C. The compounds were used at 100 μM throughout. All assay steps were performed in 20 mM HEPES pH 7.4, 100 mM ammonium acetate, 10 mM $MgCl_2$, 5% DMSO.

INFORME DE LABORES 2019

Molecular docking

In silico molecular docking of gentian violet, juglone, purpurin and hematein were performed on the RNase P protein from *Thermotoga maritima* (PDB code 1NZ0). The analysis was conducted using AutodockVina 1.2 (42). Protein and small molecule compounds' structures were prepared by employing scripts from AutoDockTools (43). Two search boxes, with sizes 30 Å × 30 Å × 30 Å, were explored, aiming to cover the tRNA 5′-leader binding region (PDB code 3Q1R). These two boxes were centered at (x = 51.45, y = –23.71, z = –3.4) and (x = 49.01, y = –18.63, z = –8.04). When indicated, side chain flexibility was considered for F17, K51, K53 and K90. Search parameters were set to their default values. The best-suggested pose from the two searches for each ligand was selected as a starting position to perform Molecular Dynamics simulations.

Molecular dynamics simulation

Molecular dynamics simulations were performed on the best binding modes (according to the docking score), for gentian violet, juglone and hematein. Purpurin's starting conformation corresponded to that observed in the crystal structure (PDB code: 6MAX). All systems were simulated with GROMACS 5.0.3 (44) using the AMBER99SB-ILDN all-atom force field (45) in an explicit water solvent scheme with periodic boundary conditions. The topology and force field parameters files for the gentian violet and purpurin compounds were generated with ACYPE (46). The protein protonation was performed with Molprobity (47). The water molecule model used was based on the transferable intermolecular potential with three sites (48). The solvent also included sodium chloride (NaCl) at 0.15 mM plus a small surplus of ions for electric charge neutralization. The long-range electrostatic interactions were computed using fast Particle-Mesh Ewald (PME) (49), using a grid spacing of 1.2 Å. The van der Waals and short-range electrostatic interactions were computed using a cutoff of 1.1 Å for both parameters. The neighbor list was updated every 20 steps using the Verlet cut-off scheme. All bonds were constrained using LINCS (50), enabling a simulation time step of 0.002 ps. The following startup protocol was applied to all modeled systems: Firstly, two following minimization processes with (i) 1000 steps under the steepest descendant algorithm and (ii) 500 steps using the conjugate gradient algorithm. Subsequently, the following two simulations were carried out to equilibrate the system at 300 K: (i) 500 ps in the canonical ensemble at 300 K using a V-rescale thermostat (τ = 0.1 ps) (51) and (ii) 500 ps in the isobaric-isothermal ensemble using Berendsen (52) pressure coupling at 1 bar (τ = 2.0 ps). During these processes, a restraint constant of 1000 kJ mol^{-1} nm^{-2} was applied to all heavy protein atoms and all main chain heavy atoms for the temperature and pressure equilibrations, respectively. An additional 500 ps were simulated within the isobaric–isothermal ensemble without restraints. Finally, 100 ns of molecular dynamics simulation was performed in the isobaric–isothermal ensemble using the Parrinello–Rahman barostat with no restraints (53). For all systems, the protocol was repeated three times starting from the minimized structures with a new assignment of velocities.

Protein crystallization, fragment screening, and structure determination

P protein from *T. maritima* in 50 mM Tris–HCl pH 7.5, 0.2 mM EDTA was crystallized at 3 mg/mL in 12% PEG-1000, 100 mm sodium acetate, pH 4.8, and 200 mM potassium sulfate by vapor diffusion in a sitting drop configuration in 96-well crystallization plates (Swissci™), where 1 μl of P protein plus 1 μl of mother liquor were mixed thoroughly. Crystals appeared in 3 days at 19°C with approximate dimensions of 300 × 200 × 90 μm. Due to the frequent appearance of salt crystals of similar morphology, the presence of protein crystals was checked under a CrystaLight™ 100 UV Source (Molecular Dimensions). P protein crystals were severely damaged at concentrations of DMSO as low as 5%. Thus, purpurin was solubilized in 50% PEG-400, which proved useful in dissolving this compound entirely and maintaining the integrity of P protein crystals. From this stock, a cryoprotectant solution was prepared at a final concentration of 20 mM purpurin, which additionally contained 35% PEG-1000, 100 mM sodium acetate, pH 5.2, 20 mM potassium sulfate and 1 mM DTT. Crystals were soaked for 3 months using the solution with purpurin. Crystals were flash-frozen and stored in liquid nitrogen until needed. Diffraction data were collected at 100 K at a wavelength of 0.9785 Å at the Life Sciences Collaborative Access Team (LS-CAT) 21-ID-F and 21-ID-G beamlines at the Advanced Photon Source (Argonne National Laboratory, Argonne, IL, USA). Data were indexed and processed with XDS (54) and reduced with Aimless (55).

For fragment screening, the reference structure was solved by molecular replacement using Phaser (56), with a search model based on the structure of the P protein from *Thermotoga maritima* (PDB entry: 1NZ0). There is one monomer in the asymmetric unit, with a crystal solvent content of 40%. The presence of purpurin was initially confirmed by difference Fourier maps calculated using the structure of the wild-type enzyme.

The ligand was manually fit, and the restraints for refinement were generated using the eLBOW program of the PHENIX suite (57) using the SMILES string C1 = CC = C2C(= C1)C(= O)C3 = C(C2 = O)C(= C(C = C3O)O)O. Refinement was alternated with manual building/refinement in COOT (58), PHENIX and the PDB_REDO server (59).

The B-factor of the ligand is 42.5 versus 16.0, 25.4 and 21.1 Å^2 for the surrounding residues Val33 Gln28 and Arg89, respectively and the density of the ligand is evident in the 2mF_o – DF_c map at a contour level of 1.5σ. σA-weighted, 2F_o – F_c simulated annealing omit maps (Supplementary Figure S19) were used to validate the presence of the ligand further.

The model presents no Ramachandran outliers. Data collection and refinement statistics are summarized in Supplementary Table S2. Figures were prepared with Pymol (The PyMOL Molecular Graphics System, Version 1.7.4, Schrödinger, LLC). The atomic coordinates and structure factors of the RNase P protein from T. maritima in the complex with purpurin have been deposited in the Protein Data Bank (PDB) with the accession code 6MAX.

INFORME DE LABORES 2019

RESULTS

A new fluorescent probe as an RNase P substrate

In this work, we designed a synthetic oligonucleotide substrate probe with a fluorophore and a non-fluorescent quencher (NFQ) at the two termini (Figure 1A, Supplementary Table S1) based on a FRET detection mechanism. If the substrate is cleaved, physical separation of the quencher from the fluorophore allows light emission that can be detected with a fluorometer (60–62). A short RNase P substrate candidate that fulfills the assay design requirements was the minihelix (Mh) pMini3pbUG (Figure 1A), whose cleavage kinetics were previously characterized (32,33) and confirmed in the present study. Substrate functionality was first tested in a polyacrylamide gel-based assay (Figure 1A) to ascertain uniform cleavage of the substrate by the RNase P holoenzyme and ensure that the appended fluorophore and quencher did not hinder catalysis. After testing the RNase P activity on the modified FRET substrate and confirming the specific cleavage (Figure 1A), we also tested the minihelix construct without the fluorescent label. The same RNase P processing pattern was observed in both cases (Figure 1A) thus supporting that the fluorophore and the quencher do not affect the ability of this substrate to be enzymatically processed by RNase P. Finally, the titration of the Mh fluorescent substrate using unlabeled pre-tRNA or Mh (Supplementary Figure S1) in solution activity assays (described below) led to a decrease in the relative fluorescence in time-course measurements.

The Mh substrate can be used in a novel, real-time in-solution RNase P fluorescence-based assay.

The in-solution activity assays were performed at 37°C in a total volume of 20 μl on a fluorescence microplate reader in 384-well plates (Figures 1B, C, 2 and Supplementary Figures S1–S10). Supplementary Figure S2A demonstrates the stability over time and the FRET quenching efficiency of the substrate (fluorescent substrate or holoenzyme with $CaCl_2$ added as a negative control). Using the Mh substrate, we did not observe RNase P activity (Supplementary Figure S2A) at 10 mM $MgCl_2$. The kinetic analysis further demonstrated that this is indeed a viable and useful assay for monitoring RNase P activity (Figure 1B, left and Supplementary Figure S2B). A Michaelis–Menten fit was performed, and the kinetic parameters were calculated (Figure 1B, right). The obtained K_M and k_{cat} values are 1.3 μM and 6.7 min^{-1}, respectively. The only previously reported values for this substrate are $K_D = 2.8$ μM and $k_{obs} = 0.86$ min^{-1} using the RNase P from *E. coli* (33).

The novel fluorescence assay using Mh Is reproducible, tolerant of DMSO, sensitive to known RNase P inhibitors and amenable for high-throughput screening

Before performing this assay in a large-scale setup, we first assessed its reproducibility in 10–12 reactions usually performed in a single run (Supplementary Figure S3). To evaluate the robustness of the assay, we used a *Z*'-factor scoring method (63) for both the end-point of the assay (Supplementary Figures S3A, C) and the initial velocities of the reaction (Supplementary Figure S3B, D) (*Z*'-factor = 0.73). The linear responses in all cases were 3–5 min long (Figure 1B and Supplementary Figures S3–S10). In subsequent experiments, we considered the kinetics information given by the linear parameter to calculate the IC_{50} values for the inhibitors described in Figures 3 and 4. Most notably, we found that DMSO does not decrease the activity of RNase P on the cleavage of the Mh substrate up to a concentration of 30% (v/v) (Supplementary Figure S4). For the assays involving inhibitors (Figure 2A and Supplementary Figures S5–S10), we used a concentration of 10% DMSO.

To benchmark our assay against known inhibitors, we tested the activity of two newly-described RNase P inhibitors, methylene blue (33) (Figure 1C, left and Supplementary Figures S5A, B) and iriginol hexaacetate (26) (Figure 1C, right and Supplementary Figures S5C, D). Notably, we detected inhibition for both compounds, and IC_{50} values are in reasonable agreement with the published data (109 μM versus 62 μM (reported) for methylene blue and 29.5 μM versus 0.8 μM (reported) for iriginol hexaacetate). As expected, we did not detect inhibition by neomycin B or kanamycin B, as it is known that high Mg^{2+} concentrations nullify their effects on RNase P (64). These results corroborate the validity of the assay as we were able to detect inhibition in the same range as previously reported inhibitors and exclude non-specific interactors. Our chosen RNase P system and the developed assay (regarding substrate, real-time monitoring, volume, buffer composition, [E]/[S] ratio and DMSO tolerance) are a reliable platform to search for new inhibitors in a high-throughput manner.

Library screening and hit validation identifies four potential inhibitors of RNase P

We performed a screen of the Spectrum Collection library (Discovery Systems, Inc.) comprising 2560 compounds (Supplementary Figure S6). A schematic view of the overall workflow and results is presented in Supplementary Figure S22. In our setup, the screening strategy involved initial testing of cocktails with eight compounds per assay/well. To select a positive hit, we considered the inhibition of the initial velocity of the reaction based on its *Z*-factor robustness (Supplementary Figures S3B and D). Several cocktails exhibited initial velocity changes that were significantly decreased (Supplementary Figure S6). In general, we further analyzed the compounds that demonstrated an initial velocity slope lower than the positive control or a negative slope (Supplementary Figure S6. Red bar corresponds to the positive control). We verified the selected cocktails by a second round of selection (Supplementary Figure S7) and finally deconvoluted to identify active compounds (Supplementary Figure S8). The potential hits were further verified at this stage by the correspondence between the fluorescence-based assay and the canonical gel-based inhibition test using lower concentrations of compounds (Supplementary Figure S9).

Using this strategy, after the initial screening (Supplementary Figure S6), 37 cocktails were selected and verified again for inhibition (Supplementary Figure S7). Of these, ten cocktails with evident inhibition were retained and then deconvoluted to deduce the 10 active compounds in each

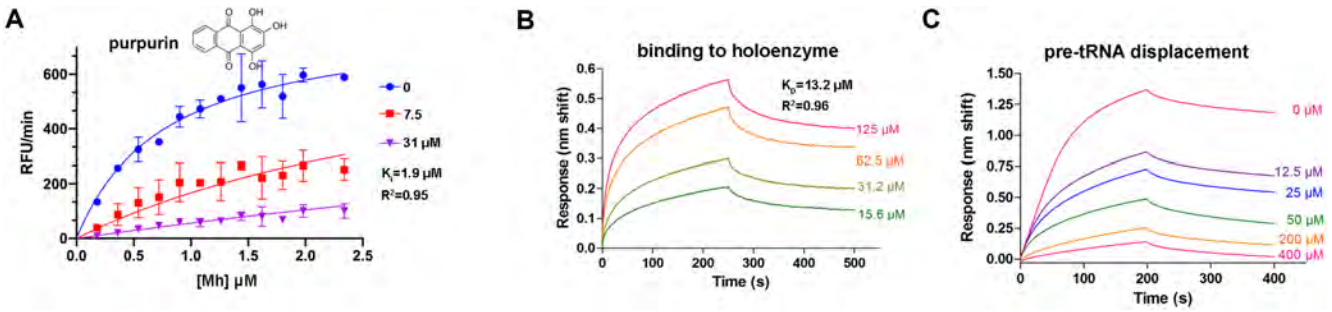

Figure 4. Characterization of the inhibition of *T. maritima* RNase P by purpurin. (**A**) Best global fit for inhibition of RNase P in the presence of varying concentrations of fluorescent Mh substrate. A competitive inhibition model best fit the data ($R^2 = 0.9549$) with $K_i = 1.9 \pm 0.5$ μM. Symbols represent the mean ± standard error as determined from three independent experiments at each concentration. See also Supplementary Figure S18. (**B**) The affinity of purpurin for the RNase P holoenzyme comparable to its K_i. Binding sensorgrams obtained by biolayer interferometry (BLI). RNase P holoenzyme at 400 nM was immobilized on Ni-NTA. (**C**) Purpurin displaces bound pre-tRNA in a dose-response behavior. Binding sensorgrams obtained by biolayer interferometry (BLI). RNase P holoenzyme was immobilized on Ni-NTA biosensors, incubated with purpurin at varying concentrations (0–400 μM), and then the association and dissociation pre-tRNA was monitored. Of the four inhibitors found in this study, only purpurin exhibited a dose–response behavior in this experiment. See also Supplementary Figure S17.

(Supplementary Figure S8). One compound, ethidium bromide, was discarded due to its known non-specific effects on nucleic acids. We thus proceeded with 9 compounds for confirmation of inhibition at a lower concentration (Supplementary Figure S9).

A gel-based inhibition assay was performed in parallel for the nine selected compounds to qualitatively verify the results obtained by the fluorescence-based assay of Supplementary Figure S9A for the nine selected compounds (Supplementary Figure S9B) (250 and 500 μM at this stage versus 1 mM for the deconvolution stage shown in Supplementary Figure S8). In this assay, the compound iodoquinol resulted in a false positive (the inhibition does not correlate in both assays, Supplementary Figures S9A and B). Pararoseaniline and emodin did not inhibit RNase P under the conditions tested in these assays (Supplementary Figure S9), nifursol is a weak inhibitor (Supplementary Figure S9), and alexidine hydrochloride seems to precipitate the holoenzyme (Supplementary Figure S9B and Supplementary Figure S8C). These results excluded five more compounds.

After this more restrictive analysis, four remaining compounds were pursued further: gentian violet (Tris(4-(dimethylamino)phenyl)methylium chloride), juglone (5-hydroxy-1, 4-naphthoquinone), purpurin (1,2,4-trihydroxyanthraquinone) and hematein (3,4,6a,10-tetrahydroxy-6a,7-dihydroindeno[2,1-*c*]chromen-9(6H)-one. We purchased these reagents from a different provider (Sigma Aldrich) and used these compounds to generate dose-response curves (Figure 2A and Supplementary Figure S10). The range of IC_{50} values was between 4.5 and 96.2 μM (Figure 2A).

Pre-tRNA and a pre-tRNA-like substrate allow validation of the four identified hits using gel and fluorescence-based assays

First, we qualitatively validated the results obtained using the fluorescent Mh substrate by gel-based assays using a canonical pre-tRNA substrate (Supplementary Figures S11 and S12). Next, to mimic a substrate similar to the natural pre-tRNA, we designed a new probe consisting of two individual oligonucleotides (39 and 38 nucleotides for the 5′ and 3′ components, respectively) (Figure 2B, right, Supplementary Figure S13 and Supplementary Table S1). This probe, named bipartite pre-tRNA, differs from a canonical pre-tRNA in the sense that it lacks the anticodon loop and it is composed of two oligonucleotides (Supplementary Figure S13A). Binding experiments of pre-tRNA and bipartite pre-tRNA substrates to the holoenzyme using biolayer interferometry show that their affinity is comparable (K_D values of 1.8 and 3.5 nM, Supplementary Figure S13B). For the binding experiments, we tested the agreement of the affinity values obtained by BLI with previous K_D determinations of the RNase P holoenzyme:pre-tRNA and the P RNA:P protein pairs (65,40). These K_D values are in excellent agreement with the published data (Supplementary Figure S15A, B). Finally, titration of fluorescent bipartite pre-tRNA, with a similar design to fluorescent Mh, in time-course fluorescence emission experiments using unlabeled substrates shows highly similar profiles (Supplementary Figure S13C). Thus, we used fluorescent bipartite pre-tRNA as an analog that is highly similar to pre-tRNA, and we obtained dose-response curves using this substrate in the presence of the four hits obtained using fluorescent Mh (Figure 2B and Supplementary Figure S14). As the sensitivity to DMSO for this assay using the bipartite pre-tRNA substrate was very high (no more than 2% DMSO was tolerated, similar to (26,17), we used 10% PEG 200 instead.

Overall, the fluorescent screening strategy—using both a model substrate, tolerant to high DMSO concentrations and a pre-tRNA-like substrate, useful to demonstrate the inhibition properties under low monovalent and Mg^{2+} conditions—demonstrates its utility to find new small molecule inhibitors directed against RNase P.

Purpurin and hematein bind to the RNase P holoenzyme

Gel-based assays performed using the bipartite pre-tRNA substrate (Figure 3A) under a single buffer condition where both P RNA and the holoenzyme display activity demon-

Downloaded from https://academic.oup.com/nar/article/47/12/6425/5475076 by UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO user on 20 October 2020

INFORME DE LABORES 2019

strated that the hits purpurin and hematein inhibit the reaction catalyzed by the RNase P holoenzyme but not the P RNA alone (Figure 3A). The gel-assay using the bipartite pre-tRNA substrate allowed us to distinguish this behavior clearly. In agreement with this result, binding assays with immobilized P RNA or holoenzyme using a 5′ biotinylated RNA oligonucleotide (Figure 3B) show that purpurin does not bind to P RNA and hematein binds only slightly to P RNA (Figure 3B). In contrast with the behavior of these two hits, gentian violet inhibits the reaction *via* P RNA (Figure 3A) and also binds more strongly to it (Figure 3B). Moreover, unlike the other three hits, gentian violet binds to the biotinylated minihelix substrate in the micromolar range (Supplementary Figure S16). The hit juglone displayed a less clear behavior in these assays (Figure 3A, B).

Given that the main difference between P RNA and the holoenzyme is the presence of the P protein, we performed a preliminary interrogation of potential inhibitor interactions between the P protein and each of the four hits using docking and Molecular Dynamics (MD) (Figure 3C and Supplementary Figure S18). Small molecule docking studies of gentian violet, juglone and hematein were performed on the model obtained from crystallographic data of the RNase P protein from *T. maritima* (PDB codes 1NZ0, 3Q1R). Next, Molecular Dynamics (MD) simulations were performed on the four compounds with the best-scoring docking poses or the purpurin position as observed in complex with the P protein by X-ray crystallography (Figure 5C, PDB code: 6MAX). While the dynamics preserve the overall protein structure, the binding modes of the tested compounds were affected (Figure 3C and Supplementary Figure S20). While hematein and purpurin rearranged themselves into a new binding mode around the initial docking or crystallographic pose around the P protein (Figure 3C and Supplementary Figure S20), juglone and gentian violet did not adopt a stable arrangement (Figure 3C and Supplementary Figure S20).

Overall, the activity, binding, docking and MD experiments point to gentian violet as a non-specific inhibitor that binds to RNA, juglone as an inhibitor with an ambiguous mechanism and hematein and purpurin as inhibitors of *T. maritima* RNase P holoenzyme which may specifically target the P protein.

Purpurin inhibits RNase P holoenzyme through a competitive mechanism and shows a dose-response relationship on its binding to the holoenzyme and pre-tRNA displacement

We tested whether any of the four validated hits were capable of displacing the canonical substrate pre-tRNA from the holoenzyme in a binding assay. Purpurin displays a dose-response relationship and remarkably, none of the other three hits demonstrated this behavior (Figure 4C, Supplementary Figure S17). Together, all of the data collected for purpurin are in agreement with the activity and binding criteria to validate an RNase P inhibitor (Table 1). Further characterization shows that the K_i value of purpurin (Figure 4A, Supplementary Figure S18), obtained from an adjustment to a competitive inhibition model, is in general agreement with the K_D value obtained for RNase P holoenzyme-purpurin (Figure 4B, Table 1).

Purpurin has a binding site on the P protein in a region important for substrate binding

To further explore the possible binding of purpurin to the P protein, we tested the binding interference of an RNA oligonucleotide with the sequence of a 5′leader in the presence of this compound (Figure 5A). Remarkably, purpurin interferes with the binding of the leader to the P protein (Figure 5A). The three other hits were also tested in this manner (Supplementary Figure S19). Juglone and gentian violet do not impede the leader binding (Supplementary Figure S19). We discounted hematein because, although it displayed leader-binding hindrance (Supplementary Figure S19), unlike purpurin, it lacked a dose-response relationship on pre-tRNA displacement in the presence of the holoenzyme (see Figure 4C for purpurin). We next determined that purpurin binds to the P protein with micromolar affinity in a dose-response relationship (Figure 5B). Finally, the crystal structure of *T. maritima* P protein in complex with purpurin (Figure 5C, D Supplementary Figure S21 and Table S2) shows a binding region of the compound located in a hydrophobic patch formed by residues Val 33, Leu 35 and Ile 87. Additional hydrogen-bonding interactions are observed between purpurin and Gln 28 and Arg 89. Arg 89 is a conserved protein residue, essential for efficient *T. maritima* RNase P activity, that potentially contacts the pre-tRNA leader binding region (Figure 5D) (38). Taken together, the binding and X-ray crystallography results indicate the existence of a region in the P protein that is sensitive to the binding of inhibitory compounds of *T. maritima* RNase P and that this region is also crucial for substrate binding.

DISCUSSION

In this work, we developed and implemented novel methods to discover and validate inhibitory compounds against bacterial RNase P and gain insight into the structure and function of this ribozyme. Although FRET assays have been used for high-throughput screening of RNA-based targets (66,61,62), this is the first description of this type of method tailored for RNase P. The most noteworthy differences between the proposed method compared to the recent advances described by (26) are the DMSO tolerance (provided by the use of the Mh substrate), the salt tolerance (which reduces non-specific binding) and the development of a novel bipartite pre-tRNA substrate (which allows hit validation). In particular, the DMSO tolerance of the new assay allows for additional chemical space to be probed beyond what was previously explored. It should be noted however that, given the assay design, inhibitors that alter the fidelity of processing might appear as false negatives in the fluorescence-screening step. It should also be considered that there might be a quenching effect from cleaved 5′ leader that could lead to an underestimation of the catalytic activity. Despite these potential issues, the presented method offers a powerful way to discover new inhibitors under a variety of conditions and substrates.

Additionally, this work presents the first binding screening method amenable for high-throughput for RNase P. The method may be useful for enhanced characterization of known inhibitors (26) or to demonstrate specific binding to the holoenzyme, P RNA or P protein (67,68). Notably,

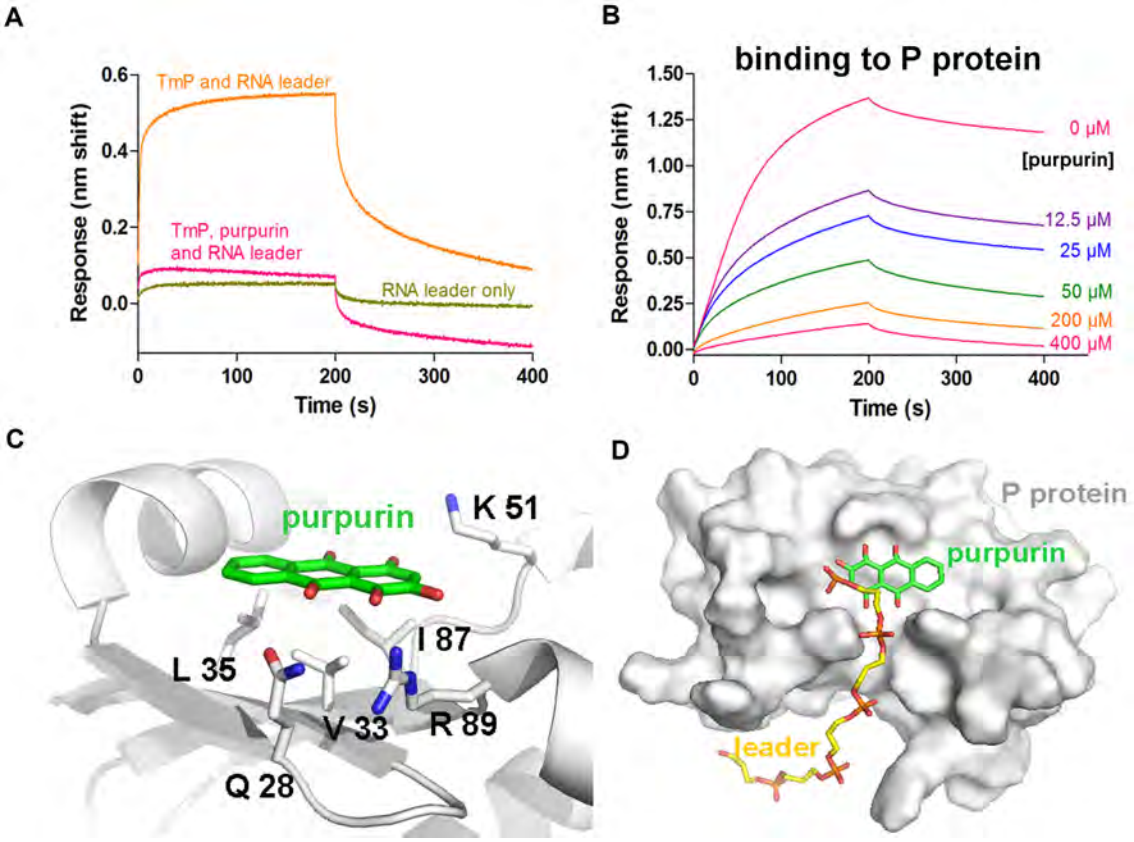

Figure 5. Purpurin binds the P protein. (**A**) Purpurin hinders the binding of the P protein to the 5′ RNA leader. Association and dissociation of the 5′ RNA leader to the P protein (TmP) is measured over time. P protein was immobilized on Ni-NTA biosensors while purpurin was assayed at 100 μM and the 5′ RNA leader at 5 μM. A 10-nt leader was used for these experiments. See Supplementary Figure S10 for the experimental design and testing of the other three inhibitors. (**B**) Purpurin binds to the P protein from *T. maritima* in a dose-response manner ($K_D = 6.8$ μM). Binding sensorgrams obtained by BLI. P protein was immobilized on Ni-NTA biosensors after which its association and dissociation from indicated compounds were monitored. Sensorgrams were fit to a 1:1 Langmuir binding model. (**C**) Location of purpurin (green) on the *T. maritima* P protein as determined by X-ray crystallography (PDB code: 6MAX; see Supplementary Figure S19 and Supplementary Table S2). (**D**) Location of the 5′ RNA leader (yellow) on the P protein in the context of the RNase P holoenzyme in complex with tRNA (19) (PDB code: 3Q1R). In both cases, residue Arg 89 (labeled in panel C) forms interactions with the different ligands.

Table 1. Summary of inhibition and affinity parameters for the four identified hits

Compound name	Mh IC_{50} (μM)	Bipartite pre-tRNA IC_{50} (μM)	Targets RNA	Dose–response displacement of pre-tRNA	K_i and K_d (holoenzyme) (μM)
Gentian violet	7.3 ± 1.6	16.2 ± 2.1	++ (substrate)	No	ND
Juglone	12.8 ± 1.9	11.9 ± 1.7	+	No	ND
Purpurin	96.2 ± 21.7	13.1 ± 2.3	-	Yes	1.9 ± 0.4, 13.2 ± 2.6
Hematein	4.5 ± 0.9	87.9 ± 19.7	-	No	ND

this method provided insights into the inhibitory mode of action via monitoring the pre-tRNA or the leader binding hindrance to the holoenzyme or the P protein. Overall, the results obtained point to the P protein as a promising target for the yet undiscovered inhibitors.

We also used molecular docking, molecular dynamics, and X-ray crystallography to elucidate the possible site of action for the validated hits. P protein is an ideal target for these techniques. Due to its small size (117 aa, 14 kDa), efficient MD protocols are executed successfully. The protein crystallizes in 3 days, the crystals diffract to high resolution (~1.5 Å), a structure of the holoenzyme is known, and the critical binding sites have been identified (19). Most importantly, the crystallization precipitant (PEG 1000) is fully compatible with the solvent used to solubilize fragments (PEG 400 50%). However, it has been challenging to obtain complexes of the P protein with different ligands, probably due to steric hindrance in the crystal packing. Nonetheless, we succeeded in obtaining the crystal structure of the P protein in complex with purpurin, which binds in a region important for the 5′-leader interaction with the protein (38). This region includes R89, a highly conserved residue that makes putative contacts with the phosphate backbone of N-5 of the pre-tRNA leader. The mutation of this residue has substantial effects on RNase P activity (38). These re-

Downloaded from https://academic.oup.com/nar/article/47/12/6425/5475076 by UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO user on 20 October 2020

INFORME DE LABORES 2019

sults point to the P protein as an attractive component for targeted inhibition.

Table 1 shows a summary of the four validated hits and some parameters analyzed in this work. Most importantly, purpurin is the only compound that shows similar IC_{50} values using the fluorescent substrates Mh and bipartite pre-tRNA and presented a dose-response relationship on the pre-tRNA displacement assay. Moreover, the obtained K_D value to the holoenzyme and the K_i are in reasonable agreement. Holistically, this work demonstrates the necessity to consider several corroborating approaches before committing to an initial small-molecule inhibitor hit. While purpurin binds somewhat weakly, its relatively low molecular weight (256 Da), may allow its further optimization.

Three of the found hits—juglone, hematein, and purpurin—have characteristics of known non-specific inhibitors in drug screens, specifically catechol and quinone groups that are known to undergo addition reactions, complex with divalent metal ions, or act as redox cyclers (69–71). On the other hand, several lines of evidence point to purpurin as a potential inhibitor amenable to further optimization. This compound maintains inhibition even at remarkably high concentrations of $MgCl_2$ (100 mM) and ammonium acetate (400 mM), shows a dose–response relationship in binding the holoenzyme, binding P protein and displacing pre-tRNA, and it presents a specific binding site on the P protein, as revealed by the co-crystal structure.

Taken together, this work offers the following technological advances that may be more widely applied to the study of RNA-protein complexes: (i) establishment of biolayer interferometry as a real-time technique for measuring ligand interactions with all the components of RNase P (P RNA, P protein and substrate); (ii) demonstrating the utility of a novel, pre-tRNA-like substrate, which may be useful for the study of other tRNA-processing enzymes and (iii) highlighting the use of low molecular PEGs as substitutes for DMSO in the study of small ligands in complex with macromolecules. This work offers a multi-technique platform for inhibitor discovery and indicates, for the first time, that the P protein is a promising target for future antibiotics.

DATA AVAILABILITY

Hippocampal neurogenesis regulates recovery of defensive responses by recruiting threat- and extinction-signalling brain networks

Received: 16 October 2018
Accepted: 18 January 2019
Published online: 27 February 2019

Alonso Martínez-Canabal[1], Grecia López-Oropeza[1], Abril Gaona-Gamboa[1], Paola Ballesteros-Zebadua[2], Olinca Galvan de la Cruz[2], Sergio Moreno-Jimenez[2] & Francisco Sotres-Bayon[1]

Safe exposure to a context that was previously associated with threat leads to extinction of defensive responses. Such contextual fear extinction involves the formation of a new memory that inhibits a previously acquired contextual fear memory. However, fear-related responses often return with the simple passage of time (spontaneous fear recovery). Given that contextual fear and extinction memories are hippocampus-dependent and hippocampal neurogenesis has been reported to modify preexisting memories, we hypothesized that neurogenesis-mediated modification of preexisting extinction memory would modify spontaneous fear recovery. To test this, rats underwent contextual fear conditioning followed by extinction. Subsequently, we exposed rats to an enriched environment or focal X-irradiation to enhance or ablate hippocampal neurogenesis, respectively. Over a month later, rats were tested to evaluate spontaneous fear recovery. We found that enhancing neurogenesis after, but not before, extinction prevented fear recovery. In contrast, neurogenesis ablation after, but not before, extinction promoted fear recovery. Using the neuronal activity marker c-Fos, we identified brain regions recruited in these opposing neurogenesis-mediated changes during fear recovery. Together, our findings indicate that neurogenesis manipulation after extinction learning modifies fear recovery by recruiting brain network activity that mediates the expression of preexisting contextual fear and extinction memories.

To survive in a dynamic environment, animals must be able to distinguish between a dangerous and a safe place. When a place is associated with an aversive consequence (e.g. a foot-shock) the brain forms a threat memory to that context (contextual fear memory), representing a dangerous place. After repeated re-exposure to the same context but without the aversive consequence (i.e. without foot-shock), the brain forms an extinction memory to that context, representing a safe place[1,2]. Later, exposure to the context evokes the extinction memory rather than fear memory, as indicated by low defensive responses to the threat. However, with the simple passage of time after extinction learning, expression of the fear memory returns, as indicated by high defensive responses to the threat[3–5]. This time-dependent phenomenon, known as spontaneous recovery of fear[6,7], is accentuated in patients with fear-related disorders[8]. Despite the importance of spontaneous fear recovery to study how animals distinguish between safe and dangerous contexts over time and how dysregulation of this phenomenon may relate to psychopathology, its underlying brain mechanisms are not clear.

Neural activity in the hippocampus is crucial for encoding contextual memories in rodents as in humans[1]. Recent reports show that the addition of new neurons (neurogenesis) to the adult dentate gyrus of the hippocampus can modify preexisting hippocampal-dependent memories[9–12]. Contextual memory that is hippocampus-dependent, and that is crucial for survival, involves encoding the association of a place with its

biological significance, as in fear and extinction memories[1,3,13]. It has been suggested that hippocampal neurogenesis modulates the expression of fear-related memories. Yet the accumulated evidence that supports this notion is conflicting. On one hand, evidence shows that facilitation of neurogenesis can increase fear context-specificity[14], decrease context-mediated fear-related responses[9,10] or have no effect[15]. On the other hand, there is evidence that blockade of neurogenesis can increase fear-related responses in infants[10], decrease fear-related responses in adults[16] or have no effect[17–19]. It is not clear whether the conflicting evidence in these different studies is due to neurogenesis manipulations being performed at different time points with respect to the formation of contextual fear and extinction memories. Thus, the time at which new neurons are added or not to the hippocampus circuitry may be crucial to understand its contribution to regulation of fear-related behaviours.

Spontaneous recovery of fear may be a particularly relevant phenomenon to study fear-related behaviours and contextual memory discrimination[2,5,20]. Testing memory retrieval during spontaneous recovery may allow to evaluate a time point when fear and extinction memories compete for the control of fear-related behaviours. Thereby this time point denotes a moment where the individual is required to distinguish between a dangerous and a safe place that may share some features[2,21]. Notably, this cognitive function (pattern separation), important for survival and mental health, has been associated with the addition of new neurons to the hippocampal circuits[22,23]. We hypothesized that a change in the hippocampal circuitry mediated by the addition or ablation of new-born neurons would modify the circuits that support fear expression during spontaneous recovery. Indeed, we found that increasing neurogenesis using environmental enrichment (EE) after, but not before or in absence of, fear extinction learning prevents spontaneous fear recovery. Consistently, we found that ablating hippocampal neurogenesis using focal X-irradiation[15] after, but not before or in the absence of, fear extinction learning promotes spontaneous fear recovery. Notably, using c-Fos expression as a neuronal activity marker, we identified that underlying brain activity involved in neurogenesis-mediated control of fear recovery levels involves opposing recruitment in the prefrontal-amygdala-habenula network.

Results

Environmental enrichment after extinction increases neurogenesis and prevents fear recovery. To test the hypothesis that adding more adult-born hippocampal neurons prevents fear recovery, we compared spontaneous fear recovery levels (freezing and bar presses per minute) before and after a month of either living in EE or in a standard home cage (non-EE). On day 1, rats were conditioned to fear a context (chamber) by pairing it with an aversive consequence (mild foot-shocks). The next day (day 2), rats extinguished their fear to the conditioned context by not receiving any aversive consequence. One day later (day 3), rats were tested for memory retrieval to the context. We used this first retrieval test to match groups (experimental and control) based on similar fear response levels. This matching allows for a fair comparison of fear response levels before and after living in an EE or non-EE. After matching, fear-related behaviours (freezing and presses per minute) were similar between groups during conditioning (day 1; freezing: $F_{(1,19)} = 1.80$, $p = 0.31$; bar-pressing: $F_{(1,19)} = 0.31$, $p = 0.58$), extinction (day 2; freezing: $F_{(1,19)} = 1.15$, $p = 0.29$; bar-pressing: $F_{(1,19)} = 1.24$, $p = 0.30$) and retrieval test (test 1 on day 3; freezing: $t_{(19)} = 0.52$, $p = 0.60$; bar-pressing: $t_{(19)} = 0.4$, $p = 0.96$). Over a month later rats were evaluated for a second retrieval test (day 38).

Rats either lived in an EE or in a non-EE for more than a month (35 days), the time that has been shown to be sufficient for adult-born new neurons to incorporate into hippocampal circuits[24]. On day 38, to evaluate spontaneous recovery of fear, rats were tested in the same context for a second retrieval test (test 2). We found, that rats that lived in an EE showed significantly lower levels of fear-related responses during test 2 as compared to rats that lived in a non-EE (freezing: EE: 23.72%; non-EE: 50.78%; $t_{(19)} = 2.33$, $p = 0.03$; bar-pressing: EE: 6.34 press/min; non-EE: 0.55 press/min; $t_{(19)} = 3.56$, $p = 0.002$), suggesting prevention of fear recovery (Fig. 1A). Moreover, rats that lived in an EE showed a robust increase in hippocampal neurogenesis, indicated by significantly higher numbers of doublecortin (DCX) positive cell density (+/mm^2), compared to rats that lived in a non-EE (Fig. 1B,C; EE: 475.47 DCX+/mm^2; non-EE: 212.70 DCX+/mm^2; $t_{(19)} = 3.56$, $p = 0.002$). Importantly, this effect was associated with specific local increase of hippocampal neurogenesis by EE as indicated by lack of effect on neurogenesis in the rostral migratory stream (EE: 0.53 ± 0.09 optical density units (OD), non-EE: 0.58 ± 0.03 OD; $t_{(14)} = 0.33$, $p = 0.74$). Further, we found that during test 2, fear response levels and levels of neurogenesis were related, as indicated by DCX+ neurons correlation with freezing ($R = -0.59$, $p = 0.0018$) and bar-pressing ($R = 0.52$, $p = 0.014$) (Fig. 1D). Together, these findings indicate that EE-mediated increase of hippocampal neurogenesis after extinction prevents fear recovery.

Hippocampal irradiation after extinction ablates neurogenesis and promotes fear recovery. Even though we showed that EE-mediated neurogenesis after extinction is sufficient to prevent fear recovery, it is possible that neurogenesis is not necessary to modulate fear recovery. To test this possibility, we ablated hippocampal neurogenesis by focal X-irradiation. To evaluate the effect of neurogenesis ablation on fear recovery, we compared spontaneous fear recovery levels (freezing and bar presses per minute) before and after three irradiation (IRR) or sham irradiation (non-IRR) sessions that occurred during a 35-day period to be comparable to the EE experiment above. Thus, on day 1, rats were conditioned to fear a context (chamber) by pairing it with an aversive consequence (mild foot-shocks). The next day (day 2), rats extinguished their fear to the conditioned context by not receiving any aversive consequence. One day later (day 3), rats were tested for memory retrieval to the context. We used this first test to match groups (experimental and control) based on similar fear response levels. This matching allows for a fair comparison of fear response levels before and after IRR or non-IRR. After matching, fear-related behaviour (freezing and presses per minute) was similar between groups during conditioning (day 1; freezing: $F_{(1,19)} = 0.47$, $p = 0.79$; bar-pressing: $F_{(1,19)} = 0.38$, $p = 0.95$), extinction (day 2; freezing: $F_{(1,19)} = 0.13$, $p = 0.73$; bar-pressing: $F_{(1,19)} = 0.20$, $p = 0.65$) and retrieval test (test 1 on day 3; freezing: $t_{(19)} = 0.28$, $p = 0.77$; bar-pressing: $t_{(19)} = 1.27$, $p = 0.21$). Then rats received either IRR or non-IRR.

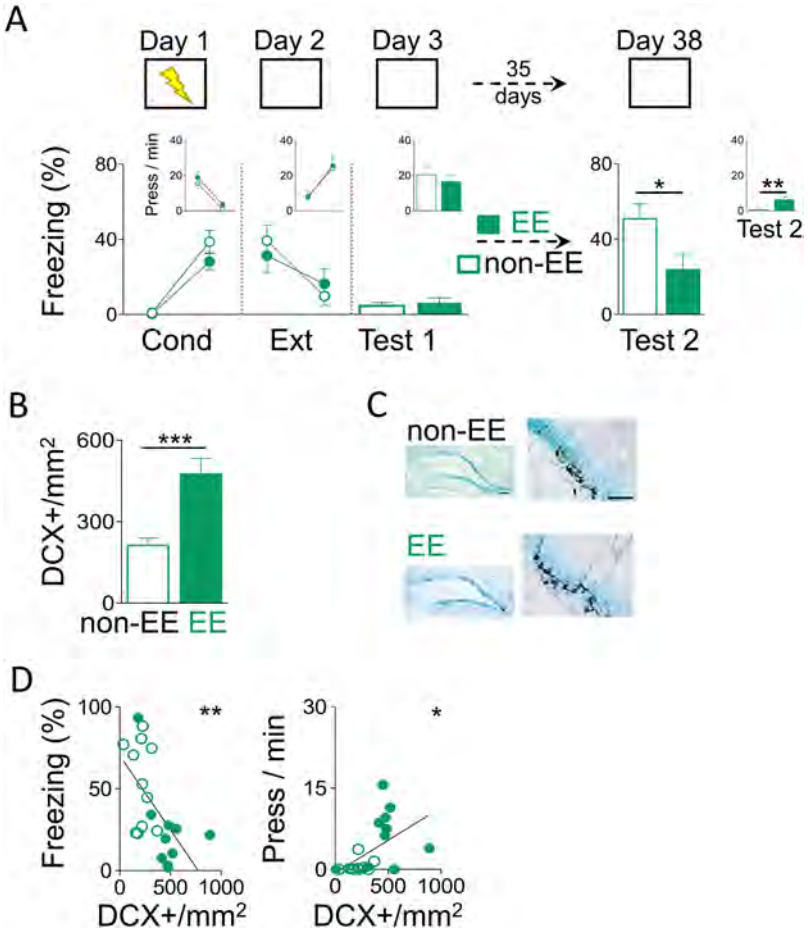

Figure 1. EE-mediated neurogenesis increase after extinction prevented spontaneous fear recovery. (**A**) Top, Rats were trained to associate a context with foot-shocks (day 1; conditioning). One day later, rats were trained to associate the same context with the absence of foot-shocks (day 2; extinction). The next day, rats were placed in the same context without foot-shocks (day 3; test 1). Then, rats were housed for over a month (35 days) either in an EE or a non-EE. Finally, rats were placed again in the same context alone to test for fear recovery (day 38; test 2). Bottom, EE after extinction training prevented spontaneous fear recovery, as indicated by low freezing and high bar presses per minute, when comparing EE with non-EE (EE: n = 10; non-EE: n = 11). Insets: bar-pressing behavior (press/min) across the different phases of the behavioral protocol. Data are shown for first block (early) and last block (late) of conditioning and extinction (5-minute blocks), and as a single block in test sessions (10-minute block). (**B**) Rats that lived in an EE for over a month showed more number of immature cells (DCX+) per area (mm^2) in the dentate gyrus of the hippocampus than rats that lived in a non-EE. (**C**) Representative immunohistochemically stained immature cells (DCX+; black) in the dentate gyrus of the hippocampus after EE or non-EE. Low magnification scale bar = 200 µm (left) and high magnification scale bar = 50 µm (right). (**D**) Negative correlation between number of DCX+/mm^2 and percent freezing response in Test 2 (R = −0.59; $p < 0.01$). Positive correlation between number of DCX+/mm^2 and presses per min in Test 2 (R = 0.52; $p < 0.05$). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$. Error bars indicate SEM. EE: enhanced environment; Cond: conditioning; Ext: extinction; DCX+: doublecortin positive cells.

On day 38, over a month after the first retrieval test, to evaluate spontaneous recovery of fear, rats were tested in the same context for a second retrieval test (test 2; Fig. 2A). We found that rats treated with IRR showed significantly higher levels of fear-related responses during test 2 as compared to rats treated with non-IRR (freezing: IRR: 62.64%; non-IRR: 30.34%; $t_{(19)} = 3.41$, $p = 0.003$**;** bar-pressing: IRR: 0.31 press/min; non-IRR: 9.39 press/min; $t_{(19)} = 3.41$, $p = 0.003$), suggesting promotion of fear recovery. Importantly, and consistent with previous reports[25], irradiated rats showed a robust decrease in hippocampal neurogenesis as compared to non-IRR rats, as indicated by significantly lower DCX+ neurons in the hippocampus of IRR-treated rats compared to non-IRR control rats (Fig. 2B,C; IRR: 350 DCX+/mm^2; non-IRR: 56.85 DCX+/mm^2; $t_{(19)} = 8.40$, $p < 0.0001$). Further, we found that this effect was due to specific local increase of hippocampal neurogenesis as indicated by lack of effect on neurogenesis in the rostral migratory stream (non-IRR: 0.64 ± 0.81 OD, IRR: 0.56 ± 0.06 OD; $t_{(14)} = 0.34$, $p = 0.74$). Further, we found that during test 2, fear response levels and levels of neurogenesis were related, as indicated by DCX+ neurons correlation with freezing (R = −0.58, $p = 0.03$) and bar-pressing (R = 0.47, $p = 0.03$)

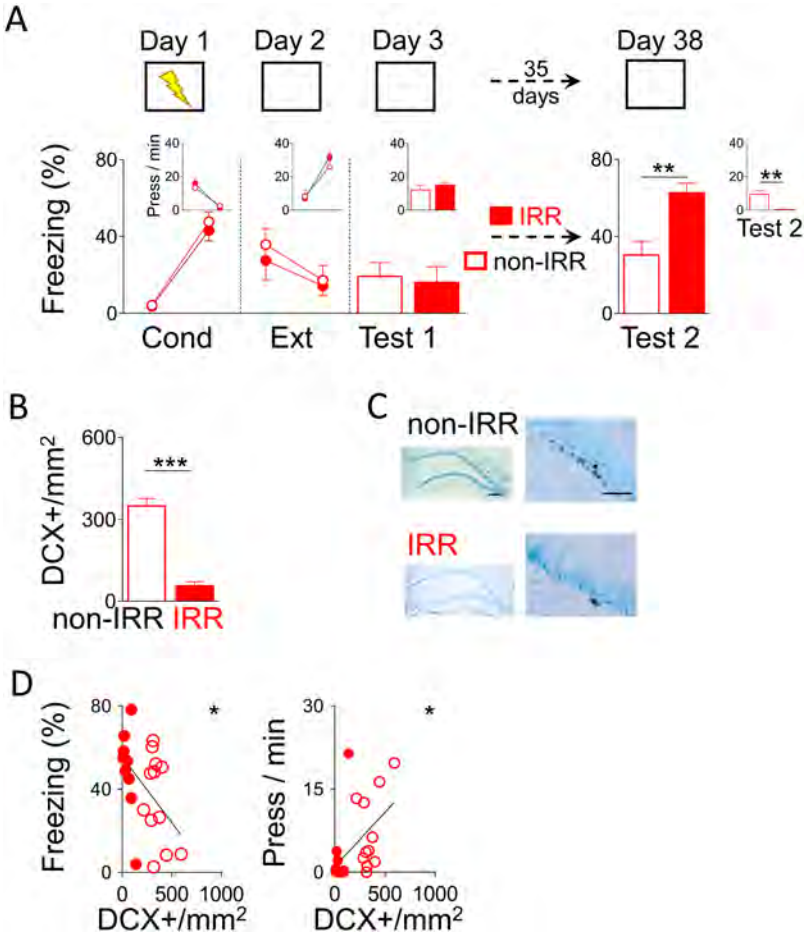

Figure 2. IRR-mediated neurogenesis ablation after extinction promoted spontaneous fear recovery. (**A**) Top, Rats were trained to associate a context with foot-shocks (day 1; conditioning). One day later, rats were trained to associate the same context with the absence of foot-shock (day 2; extinction). The next day, rats were placed in the same context without foot-shocks (day 3; test 1). Then, rats received three IRR or non-IRR sessions during a 35-day period. Finally, rats were placed again in the same context alone to test for fear recovery (day 38; test 2). Bottom, IRR after extinction training promoted spontaneous fear recovery, as indicated by high freezing and low bar presses per minute (inset), when comparing IRR with non-IRR (IRR: n = 9; non-IRR: n = 12). Insets: bar-pressing behavior (press/min) across the different phases of the behavioral protocol. Data are shown for first block (early) and last block (late) of conditioning and extinction (5-minute blocks), and as a single block in test sessions (10-minute block). (**B**) Rats subjected to IRR showed less number of immature cells (DCX+) per area (mm^2) in the dentate gyrus of the hippocampus than non-IRR. (**C**) Representative immunohistochemically stained immature cells (DCX+; black) in the dentate gyrus of the hippocampus after IRR or non-IRR. Low magnification scale bar = 200 µm and high magnification scale bar = 50 µm. (**D**) Negative correlation between DCX+/mm^2 and percent freezing response in Test 2 ($R = -0.58$; $p < 0.05$). Positive correlation between number of DCX+/mm^2 and presses per min in Test 2 ($R = 0.47$; $p < 0.05$). $^{**}p < 0.01$, $^{***}p < 0.001$. Error bars indicate SEM. IRR: irradiation; Cond: conditioning; Ext: extinction; DCX+: doublecortin positive cells.

(Fig. 2D). Together, these findings indicate that IRR-mediated ablation of hippocampal neurogenesis after extinction promotes fear recovery.

Neurogenesis-mediated fear recovery is associated with opposite changes in brain network activity. Our results of the manipulation of neurogenesis levels after extinction, using EE to increase it and IRR to ablate it, suggest that the amounts of adult-born neurons that are incorporated into the hippocampus is crucial to regulate spontaneous fear recovery. During fear recovery, both fear and extinction memories compete for the control of fear-related behaviour[21]. Interestingly, recent studies show that neurogenesis modifies pre-existing memories[10]. One way to evaluate whether neurogenesis manipulations modify preexisting memories is by assessing the recruitment of neuronal activity in structures involved in signalling threat and extinction memories[26]. To address this recruitment issue, rats from the previous experiments (EE vs. non-EE and IRR vs. non-IRR) were sacrificed and perfused 90 minutes after the second retrieval test (day 38). We used expression of the *c-fos* immediate early gene as a marker of recent neuronal activity (Fig. 3A). To directly compare c-Fos protein expression between candidate brain structures (hippocampus, amygdala, prefrontal cortex and dorsal

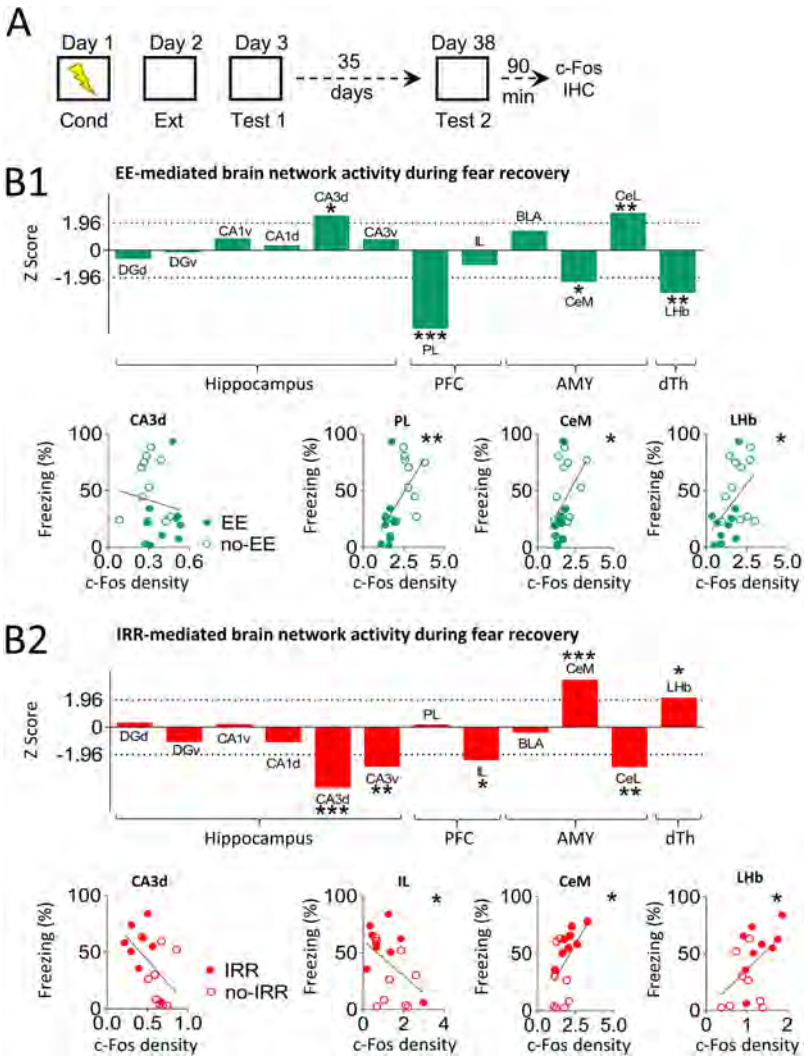

Figure 3. Opposing brain network recruitment during fear recovery mediated by neurogenesis manipulations. (**A**) Top, Rats were trained to associate a context with foot-shocks (day 1; conditioning). One day later, rats were trained to associate the same context with the absence of foot-shocks (day 2; extinction). The next day, rats were placed in the same context without foot-shocks (day 3; test 1). Then, separate groups of rats received different treatments to induce opposing neurogenesis effects (EE to enhance it or IRR to ablate it) during a 35-day period. After neurogenesis manipulations rats were placed again in the same context alone to test for fear recovery (day 38; test 2). Ninety minutes following this test, brains were removed and expression of activity-regulated gene *c-fos* was evaluated immunohistochemically. (**B**) Data represent normalized contrast of c-Fos immunoreactive cells in treated rats (EE and IRR) as compared to its control group (non-EE and non-IRR, respectively) (z-score). (**B1**) Top, Z-scores of c-Fos expression shows that EE, as compared to non-EE, increased recruitment (positive z-scores that exceeded 1.96; $p < 0.05$) of dorsal CA3 (CA3d) and centrolateral amygdala (CeL), while decreasing neuronal activity (negative z-scores that exceeded −1.96; $p < 0.05$) in prefrontal (PFC) prelimbic cortex (PL), centromedial amygdala (CeM) and lateral habenula (LHb). Bottom, Correlation analysis between percent freezing response during fear recovery (day 38) and c-Fos density (c-Fos positive cells per 100 µm^2) shows a positive correlation for PL ($R = 0.57$; $p < 0.01$), CeM ($R = 0.45$; $p < 0.05$) and LHb ($R = 0.48$; $p < 0.05$). (**B2**) Top, Z-scores of c-Fos expression shows that IRR, as compared to non-IRR, increased recruitment (positive z-scores that exceeded 1.96; $p < 0.05$) of centromedial amygdala (CeM) and lateral habenula (LHb), while decreasing neuronal activity (negative z-scores that exceeded −1.96; $p < 0.05$) in prefrontal (PFC) infralimbic cortex (IL), dorsal and ventral CA3 (CA3d and CA3v) as well as centrolateral amygdala (CeL). Bottom, Correlation analysis between percent freezing response during fear recovery (day 38) and c-Fos density (c-Fos positive cells per 100 µm^2) shows a positive correlation for LHb ($R = 0.48$; $p < 0.05$), CeM ($R = 0.49$; $p < 0.05$) and a negative correlation for CA3d ($R = -0.51$, $p < 0.05$) and IL ($R = -0.47$, $p < 0.05$). Both in z-score and correlation analysis: *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$.

thalamus) and experiments (EE-mediated increase of neurogenesis and IRR-mediated ablation of neurogenesis), data were normalized using z-scores. On the one hand, we found that increased neurogenesis mediated by EE, (as compared with non-EE) was associated with c-Fos expression changes in specific brain sub-regions

related to threat and extinction signalling. This is indicated by the increase of c-Fos activity in the lateral region of the central amygdala (CeL) and dorsal cornu ammonis 3 (CA3d), as well as decreased c-Fos activity in the prelimbic region of the prefrontal cortex (PL), medial region of the central amygdala (CeM) and lateral region of the habenula (LHb) (Fig. 3B1; CeL: $z = 2.59$, $p = 0.01$; Ca3d: $z = 2.40$, $p = 0.016$; PL: $z = -5.52$, $p < 0.001$; CeM: $z = -2.16$, $p = 0.03$; LHb: $z = -2.94$, $p = 0.003$). This pattern of brain activity suggests that prevention of fear recovery behaviour, mediated by increased neurogenesis, recruits an amygdala subregion associated with decreased fear-related behaviour (CeL)[27,28], while at the same time engages inhibition of brain regions associated with increased fear-related behaviour (PL[29,30], CeM[27] and LHb[31]). Consistent with this interpretation, we found that brain activity pattern and freezing behaviour were inversely correlated (negative correlation) with CeL ($R = -0.44$, $p = 0.047$) and were directly correlated (positive correlation) with PL, CeM and LHb (PL: $R = 0.57$, $p = 0.006$; CeM: $R = 0.45$, $p = 0.042$; LHb: $R = 0.48$, $p = 0.03$) (Fig. 3B1).

On the other hand, we found that neurogenesis ablation mediated by IRR (as compared with non-IRR) was associated with c-Fos expression changes in brain regions related to fear and extinction memories, as indicated by increases of c-Fos activity in CeM and LHb, as well as decreased c-Fos activity CA3d, CA3v, IL and CeL (Fig. 3B2; CeM: $z = 3.29$, $p = 0.0009$; LHb: $z = 2.01$, $p = 0.044$; CA3d: $z = -4.21$, $p < 0.0001$, CA3v: $z = -2.72$, $p = 0.006$; IL: $z = -2.24$, $p = 0.024$; CeL: $z = -2.75$, $p = 0.006$). This pattern of brain activity suggests that promotion of fear recovery behaviour, mediated by ablated neurogenesis, recruits amygdala and dorsal thalamus subregions associated with increased fear-related behaviour (CeM[32] and LHb[33]), while at the same time engages inhibition of brain regions associated with decreased fear-related behaviour (IL[34], CeL[32] and CA3[35]). Consistent with this interpretation, we found that brain activity pattern and freezing behaviour were related, as indicated by direct correlation (positive correlation) of freezing behaviour and c-Fos expression in CeM and LHb (CeM: $R = 0.49$, $p = 0.041$; LHb: $R = 0.49$, $p = 0.041$), as well as inverse correlation (negative correlation) in IL, CA3 and CeL (IL: $R = -0.47$, $p = 0.045$; CA3d: $R = -0.51$, $p = 0.03$; CeL: $R = -0.29$, $p = 0.26$) (Fig. 3B2). Together, these findings indicate that neurogenesis manipulations to increase (using EE) and ablate (using IRR) neurogenesis after extinction modify, in opposing manner, the neuronal activity of brain subregions related to preexisting fear and extinction memories.

Neurogenesis after extinction is necessary for environmental enrichment-mediated prevention of fear recovery. We showed that EE-mediated neurogenesis increase after extinction prevents spontaneous fear recovery and IRR-mediated neurogenesis ablation after extinction promotes spontaneous fear recovery. However, despite hippocampal neurogenesis being one of the most notorious effects observed at molecular level due to EE[36], living in an EE could affect brain activity that is not limited to the hippocampus[37]. To exclude the possibility that the observed EE-mediated prevention of fear recovery is independent of hippocampal neurogenesis, we subjected rats with ablated hippocampal neurogenesis (using IRR) to an EE for over a month (35 days) after extinction and evaluated spontaneous fear recovery (day 38). As in our previous experiments in this study, rats were matched for similar levels of fear-related behaviour during the first retrieval test (day 3) (freezing: $t_{(14)} = -1.26$, $p = 0.23$; bar-pressing: $t_{(14)} = 0.76$, $p = 0.45$). This matching resulted in similar fear-related response levels between groups during conditioning (day 1; freezing: $F_{(1,14)} = 0.47$, $p = 0.49$; bar-pressing: $F_{(1,14)} = 0.02$, $p = 0.88$) and extinction (day 2; freezing: $F_{(1,14)} = 0.32$, $p = 0.58$; bar-pressing: $F_{(1,14)} = 2.271$, $p = 0.15$). We found that, rats treated with IRR followed by EE (IRR/EE) showed significantly higher levels of fear-related responses during test 2 as compared to rats treated with non-IRR followed by EE (non-IRR/EE) (Fig. 4A; freezing: IRR/EE: 51.66%; non-IRR/EE: 21.7%; $t_{(14)} = 2.79$, $p = 0.015$; bar-pressing: IRR/EE: 2.96 press/min; non-IRR-EE: 11.04 press/min; $t_{(14)} = 220$, $p = 0.045$), excluding the possibility that the observed EE-mediated effect on prevention of fear recovery is independent of hippocampal neurogenesis. Further, we confirmed that IRR decreases hippocampal neurogenesis as compared to non-IRR rats, as indicated by significantly lower DCX+ neurons in the hippocampus of IRR/EE-treated rats compared to non-IRR/EE control rats (Fig. 4B; IRR/EE: 126.34 DCX+/mm^2; non-IRR/EE: 389.62 DCX+/mm^2; $t_{(14)} = 5.66$, $p < 0.0001$); and that this neurogenesis ablation effect was specific to the hippocampus as indicated by lack of effect on neurogenesis in the rostral migratory stream (non-IRR: 0.58 ± 0.03 OD, IRR: 0.62 ± 0.02 OD; $t_{(10)} = 0.77$, $p = 0.45$). Consistently, we found that during test 2, freezing response and levels of neurogenesis are related, as indicated by DCX+ neurons correlation with freezing responses (freezing: $R = -0.57$, $p = 0.02$) (Fig. 4C). Together, these findings indicate that EE-mediated increase in neurogenesis after extinction, that in turn prevents spontaneous fear recovery, is dependent on hippocampal neurogenesis.

Neurogenesis manipulations before extinction do not affect fear recovery. In the present study, we have shown that neurogenesis manipulations after extinction learning, regulates the expression of spontaneous fear recovery: increased neurogenesis leads to low fear recovery and decreased neurogenesis leads to high fear recovery. However, it is possible that neurogenesis manipulations at other time points, besides after extinction, also have an impact on fear-related behaviour. To test this possibility, neurogenesis manipulations (EE-mediated increase or IRR-mediated ablation of neurogenesis) were performed before, rather than after extinction learning. Rats were matched for similar fear-related behaviour levels during conditioning (day 1; freezing: EE vs non-EE: $F_{(1,14)} = 0.02$, $p = 0.88$; IRR vs non-IRR: $F_{(1,11)} = 0.015$, $p = 0.9$; bar-pressing: EE vs non-EE: $F_{(1,14)} = 0,32$, $p = 0.84$; IRR vs non-IRR: $F_{(1,11)} = 1.25$, $p = 0.28$). The next day four different groups of rats were subjected to four different treatments: EE or non-EE and IRR or non-IRR. Over a month (35 days) after conditioning, rats extinguished fear to the context (day 36) and were tested for retrieval in two consecutive days (days 37 and 38). We found that neither increasing nor decreasing neurogenesis (using EE (Fig. 5A) or IRR (Fig. 5C), respectively) before extinction (after conditioning) affected fear expression, extinction learning or spontaneous fear recovery, as indicated by similar levels of fear-related behaviour during extinction between groups (freezing: EE vs non-EE: $F_{(1,14)} = 0.85$, $p = 0.37$; IRR vs non-IRR: $F_{(1,11)} = 0.84$, $p = 0.38$; bar-pressing: EE vs non-EE: $F_{(1,14)} = 0.42$,

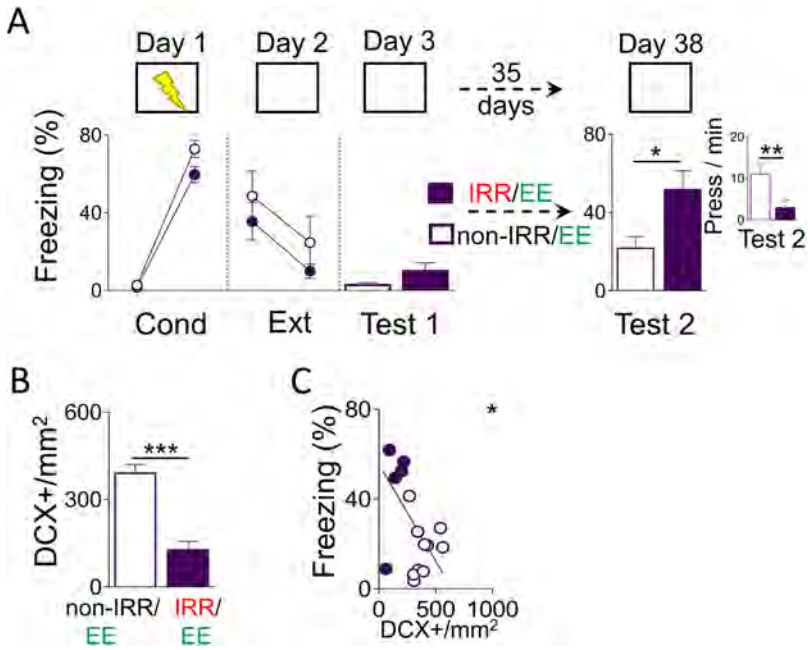

Figure 4. Irradiation arrest of EE-mediated neurogenesis increase after extinction restores spontaneous fear recovery. (**A**) Top, Rats were trained to associate a context with foot-shocks (day 1; conditioning). One day later, rats were trained to associate the same context with the absence of foot-shock (day 2; extinction). The next day, rats were placed in the same context without foot-shocks (day 3; test 1). Rats were housed for over a month (35 days) in an EE. At the beginning of EE rats received three IRR or non-IRR sessions. Finally, rats were placed again in the same context alone to test for fear recovery (day 38; test 2). Bottom, rats subjected to both IRR and EE (IRR/EE: n = 6) after extinction showed high spontaneous fear recovery, as indicated by high freezing and low bar pressing rate (inset) compared with rats subjected to both non-IRR and EE (non-IRR/EE: n = 12) after extinction. Data are shown for first block (early) and last block (late) of conditioning and extinction (5-minute blocks), and as a single block in test sessions (10-minute block). (**B**) Rats subjected to non-IRR/EE showed more number of DCX+ per area (mm^2) in the hippocampus than EE/IRR-treated rats. (**C**) Negative correlation between number of DCX+ per area (mm^2) and percent freezing response in Test 2 (R = −0.57; $p < 0.05$). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$. Error bars indicate SEM. EE: environmental enrichment; IRR: irradiation; Cond: conditioning; Ext: extinction; DCX+: doublecortin positive cells.

$p = 0.84$; IRR vs non-IRR: $F_{(1,11)} = 0.14$, $p = 0.71$) and two retrieval tests (test 1; freezing: EE vs non-EE: $t_{(14)} = 0.18$, $p = 0.88$; IRR vs non-IRR: $t_{(11)} = 0.11$, $p = 0.91$; bar-pressing: EE vs non-EE: $t_{(14)} = 0.28$, $p = 0.77$; IRR vs non-IRR: $t_{(11)} = 0.46$, $p = 0.65$; test 2: freezing: EE vs non-EE: $t_{(14)} = 1.353$, $p = 0.11$; IRR vs non-IRR: $t_{(14)} = 1.41$, $p = 0.18$; bar pressing: EE vs non-EE: $t_{(11)} = 0.88$, $p = 0.39$; bar-pressing: IRR vs non-IRR: $t_{(11)} = 1.57$, $p = 0.14$). Yet, as expected, we found significantly more DCX+ neurons in EE-treated rats as compared to non-EE rats (Fig. 5B; $t_{(14)} = 3.88$, $p = 0.043$) and significantly less DCX+ neurons in IRR-treated rats as compared to non-IRR rats (Fig. 5B; $t_{(11)} = -4.82$, $p = 0.02$), supporting the notion that EE increases neurogenesis and IRR ablates it, independently of when it occurs. Together these results indicate that for neurogenesis to influence spontaneous fear recovery it must occur after, but not before, extinction learning.

To assess whether the neurogenesis-mediated effect on fear expression we observed (low with EE and high with IRR) is dependent on the experience of extinction, rats were tested in a behavioural protocol that includes conditioning (day 1) and two different retrieval tests (day 2 and 38) separated by over a month (35 days), but without an extinction training session. After proper group matching during the first conditioning retrieval test (day 2; EE vs non-EE: $t_{(12)} = 1.08$, $p = 0.3$; IRR vs non-IRR: $t_{(10)} = 0.4$, $p = 0.69$), we found that neither EE nor IRR altered fear expression, as indicated by similar fear-related behaviours during the second retrieval test (day 38) (Fig. 5E,G; freezing: EE vs non-EE: $t_{(12)} = -1.55$, $p = 0.15$; IRR vs non-IRR: $t_{(10)} = 0.46$, $p = 0.64$; bar-pressing: EE vs non-EE: $t_{(12)} = 0.1.26$, $p = 0.23$; IRR vs non-IRR: $t_{(10)} = 0.14$, $p = 0.88$). Again, despite not having a behavioural effect, both manipulations used (EE and IRR) were effective at modifying neurogenesis levels (increase and ablate, respectively) (Fig. 5F,H; EE vs non-EE: $t_{(12)} = 4.54$, $p = 0.007$; IRR vs non-IRR: $t_{(10)} = 4.03$, $p = 0.0024$). These results indicate that neurogenesis-mediated effect on fear expression is dependent on extinction. Moreover, all together these findings highlight the importance of timing neurogenesis manipulations after extinction to influence the expression of spontaneous fear recovery.

Increased neurogenesis after extinction does not prevent cued fear recovery. Fear-related behaviour regulation can be triggered by context or specific environmental cues such as a tone. Contextual fear-related behaviour is dependent on the hippocampus, but cued fear-related behaviour is dependent on the amygdala[38]. Thus, to test whether neurogenesis-mediated prevention of spontaneous fear recovery is hippocampus dependent,

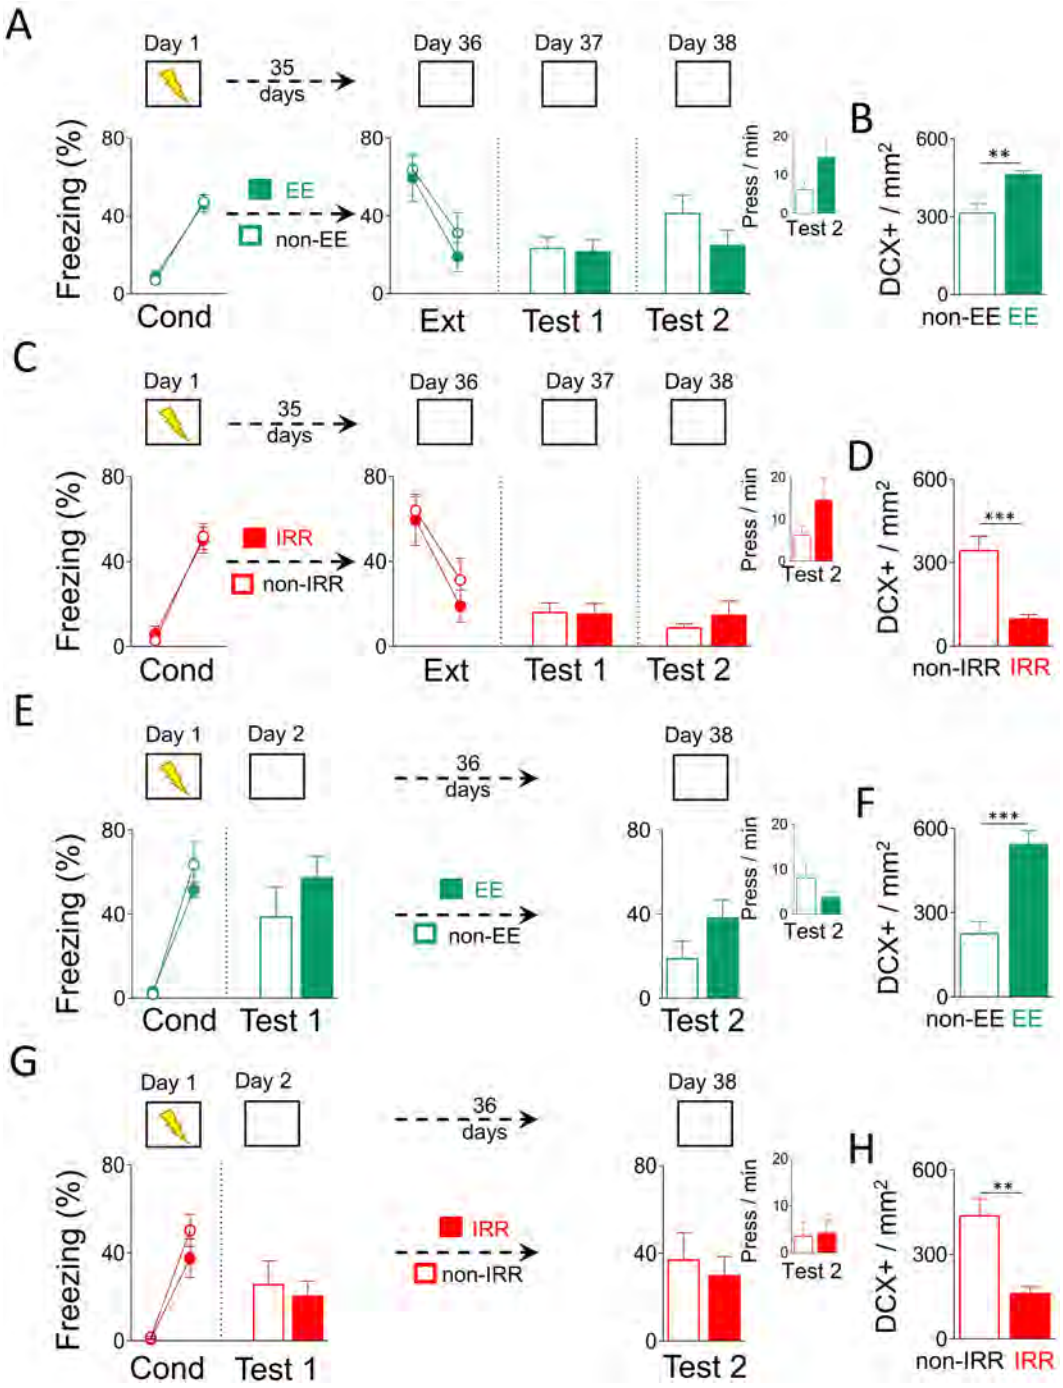

Figure 5. Neurogenesis increase by EE or decrease by IRR before or without extinction training does not alter fear-related behaviors. (**A**,**C**) Top, Rats that previously associated a context with foot-shocks (day 1; conditioning) were either housed in an EE or non-EE, or subjected to three IRR or non-IRR sessions, in a 35 day-period. On day 36, rats were exposed to the conditioning context without foots-shocks (extinction). The following two days, rats were exposed again to the same context alone (days 37 and 38; tests 1 and 2). Data are shown for first block (early) and last block (late) of conditioning and extinction (5-minute blocks), and as a single block in test sessions (10-minute block). (**A**) Bottom, EE before extinction training did not alter fear-related behaviors during extinction or test sessions, as compared to non-EE (EE: n = 8; non-EE: n = 8), as indicated by similar freezing responses and bar presses per minute (inset). (**B**) Rats that lived in an EE for over a month, before extinction training, showed more number of DCX+ per area (mm^2) in the hippocampus than non-EE. (**C**) Bottom, IRR before extinction training did not alter fear-related behaviors during extinction or test sessions, as compared to non-IRR (IRR: n = 7; non-IRR: n = 6), as indicated by similar freezing responses and bar presses per minute (inset). (**D**) Rats that were subjected to IRR, before extinction training, showed less number of DCX+/mm^2 in the hippocampus than non-IRR. (**E**,**G**) Rats that were trained to associate a context with foot-shocks (day 1; conditioning) were exposed to the conditioning context alone the next day (day 2; test 1). Then after over month (36 days) of either living in an EE or non-EE, or subjected to three IRR or

non-IRR sessions, rats were again exposed again to the conditioning context alone (day 38; test 2). (**E**) Bottom, EE after conditioning and a retrieval test (without extinction) did not alter fear-related behaviors during test sessions, as compared to non-EE (EE: n = 8; non-EE: n = 6), as indicated by similar freezing responses and bar presses per minute (inset). (**F**) Rats that lived in an EE for over a month, after conditioning and a retrieval test (without extinction), showed more number DCX+/mm^2 in the hippocampus than non-EE. (**G**) Bottom, IRR after conditioning and a retrieval test (without extinction) did not alter fear-related behaviors during test sessions, as compared to non-IRR (IRR: n = 6; non-IRR: n = 6), as indicated by similar freezing responses and bar presses per minute (inset). (**H**) Rats that were subjected to IRR, after conditioning and a retrieval test (without extinction), showed less number of DCX+/mm^2 in the hippocampus than non-IRR. Data are shown for early and late conditioning and extinction (5 min blocks) and for test sessions (10 min average). $^{**}p < 0.01$., $^{***}p < 0.001$. EE: environmental enrichment; IRR: irradiation; Cond: conditioning; Ext: extinction; DCX+: doublecortin positive cells.

we used a non-hippocampus dependent conditioning procedure (auditory fear conditioning). We compared spontaneous tone-elicited fear recovery before and after a month of either living in an enriched environment (EE) or a standard home cage (non-EE). On day 1, rats were conditioned to fear a sound (tone) by pairing it with an aversive consequence (mild foot-shocks). The next day (day 2), rats extinguished their fear to the conditioned tone by not receiving any aversive consequence. One day later (day 3), rats were tested for fear memory retrieval to the tone. After proper group matching during the first retrieval test (day 3; $t_{(13)} = 0.91$, $p = 0.92$), rats spent over a month in EE or non-EE until tested for a second retrieval test (day 38). We found that rats that lived in an EE showed similar tone-elicited fear-related behaviour levels during test 2 as compared to rats that lived in a non-EE (Fig. 6A; freezing: EE: 70.02%; non-EE: 55.36%; $t_{(13)} = 1.15$, $p = 0.26$; bar-pressing: EE: 1.031 press/min; non-EE: 3.43 press/min; $t_{(13)} = 0.99$, $p = 0.3$). Despite the consistent EE-induced increase of neurogenesis after extinction (Fig. 6B; $t_{(13)} = 3.13$, $p = 0.008$), our behavioural results indicate that neurogenesis-mediated prevention of spontaneous fear recovery is hippocampus dependent and amygdala independent.

Discussion

We investigated when adult hippocampal neurogenesis affects spontaneous fear recovery and its underlying brain network activity. We found that EE-mediated enhancement of neurogenesis prevented fear recovery. Consistently, we found that IRR-mediated ablation of neurogenesis promoted fear recovery. Interestingly, these opposing neurogenesis manipulations affected fear-related behaviours only if manipulations occurred after, but not before or in the absence of, extinction learning. These behavioural findings indicate that neurogenesis effect on fear-related behaviour during fear recovery is time- and extinction-dependent. Notably, assessment of neural activity revealed that recruitment of distinct prefrontal-amygdala-habenula networks correlates with opposing neurogenesis manipulations and fear-related response during fear recovery. These findings add to a growing body of evidence showing that neurogenesis regulates fear-related behaviour by altering activity in fear-signalling brain regions[9,10] and highlight the importance of timing neurogenesis manipulations after extinction learning.

New neurons are generated in the adult dentate gyrus of the hippocampus in mammals[39]; however, the functional impact of these adult-born neurons on hippocampus-dependent functions is still unclear. For instance, although the impact of neurogenesis on hippocampal-dependent contextual fear memories has been largely explored, current results are conflicting. Neurogenesis manipulations (using different methods to enhance or ablate it) can either increase[16], decrease[10] or have no effect[17] on fear-related responses. Here we show that identifying *when* neurogenesis is crucial and irreplaceable may be key to understand the role it plays in fear-related behaviour. We found that neurogenesis modulations alter the of expression fear-related behaviours only if neurogenesis manipulations occurred after, but not before, extinction training, suggesting a time-dependent effect. This post-training effect is consistent with the long-held notion that the hippocampus plays a key role in memory consolidation and its retrieval[13,40]. More interestingly, our behavioural findings are consistent with the recently emerged notion that neurogenesis is crucial to alter preexisting hippocampal-dependent memories[11,41]. It has been suggested that targeting neurogenesis after memory formation (post-training) is more disruptive because these memories are already committed to memory traces[42]. Further, recent studies have shown that neurogenesis manipulations after memory formation can alter the expression of the fear memory by either promoting memory consolidation[15] or forgetting[10]. But, we found that increasing neurogenesis after conditioning (before extinction) did not promote forgetting of fear memory. A possible explanation for the discrepancy with Akers *et al*., 2014 is twofold: stronger conditioning and saliency of bar-pressing across contexts in our study. The former explanation agrees with a recent report showing that spatial memory forgetting is prevented by long training[43]. The latter explanation agrees with another recent report showing spatial memory forgetting can be prevented by the addition of a salient retrieval reminder[44]. Although we cannot specify through which mechanism(s), our findings indicate that opposing neurogenesis manipulations timed after the formation of the extinction memory may alter the expression of fear-related contextual memories and thereby prevent or promote fear recovery.

Previous studies exploring the relationship between hippocampal neurogenesis and extinction of fear have shown conflicting data. One report found that neurogenesis ablation retards extinction learning[45], while another found the same manipulation had no effect[46]. Yet, the effect of manipulating neurogenesis after extinction learning had not been studied. By timing neurogenesis manipulation before or after extinction and evaluating spontaneous fear recovery, our findings reveal that neurogenesis manipulations after extinction learning, but not before, is crucial to modify fear levels during fear recovery. Notably, this effect on fear-related behaviours is not present in the absence of extinction training, suggesting it is an extinction-dependent effect. Given hippocampus' well-known role in consolidation[47], our results extend its role to neurogenesis-mediated consolidation of

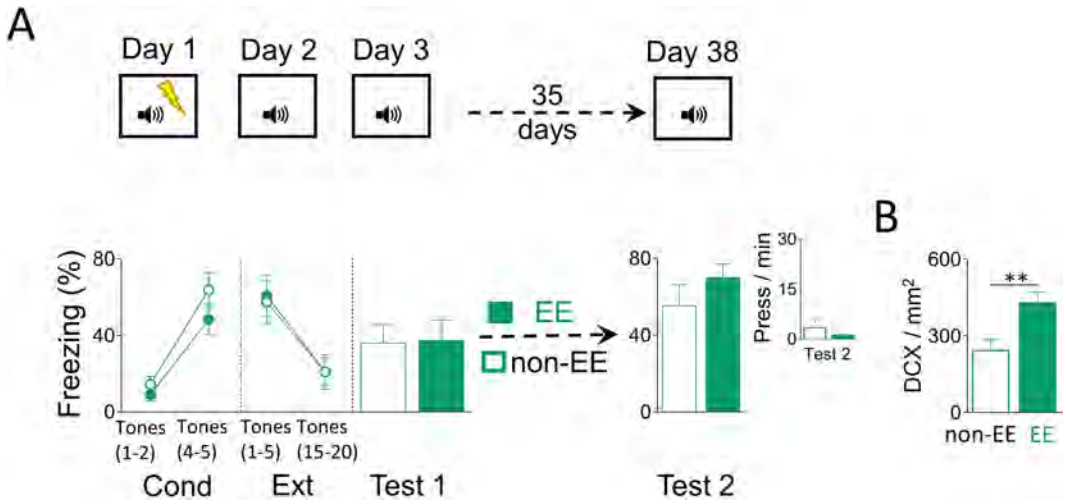

Figure 6. EE-mediated neurogenesis increase does not prevent tone-associated fear recovery. (**A**) Top, Rats were trained to associate a tone with foot-shock (five tone-shock pairings) (day 1; conditioning). One day later, rats were trained to associate the same tone (20 presentations) with the absence of foot-shock (day 2; extinction). The next day, rats were presented with the same tone without foot-shocks (day 3; test 1). Then, rats were housed for over a month (35 days) either in an EE or a non-EE. Finally, rats were presented with two tones alone in the same context to test for fear recovery (day 38; test 2). Data are shown for first block (early) and last block (late) of conditioning and extinction, and as a single block in test sessions (2-trial blocks). Bottom, EE after extinction training did not prevent tone-associated fear recovery, as indicated by similar freezing responses and bar presses per minute (inset), when comparing EE with non-EE (EE: n = 8; non-EE: n = 7). (**B**) Rats that lived in an EE for over a month showed more number of DCX+ per area (mm^2) in the dentate gyrus of the hippocampus than rats that lived in a non-EE. $^{**}p < 0.01$. Error bars indicate SEM. EE: enhanced environment; Cond: conditioning; Ext: extinction; DCX+ doublecortin positive cells.

extinction memory. Further, events that involve synaptic changes (including neurogenesis), mediated by hippocampal communication with the medial prefrontal cortex (mPFC) are necessary and recruited during consolidation of remote fear memory[15]. However, changes that mPFC undergoes (e.g. increased synaptic density) during remote memory consolidation[48,49] are reverted by extinction training, suggesting synaptic modifications in mPFC can be mediated by hippocampal neurogenesis during extinction. This is consistent with the presently observed PL decreased recruitment mediated by neurogenesis enhancement and IL decreased activity mediated by neurogenesis ablation during extinction consolidation.

It is also possible that the effect we observed is also due to modulation of other cognitive functions. It has been suggested that during fear recovery of extinguished fear, two memory traces (fear memory and extinction memory) compete for the control of fear-related behaviours[1,21]. Our results suggest that increasing neurogenesis may balance towards the expression of extinction memory and decreasing neurogenesis may balance towards the expression of fear memory. Given that in our study, both fear and extinction memories share the representation of the same context, it is possible that the observed neurogenesis-mediated effect on fear recovery also relies on a neurogenesis-dependent phenomenon known as pattern separation[50]. Neurogenesis may prevent fear recovery by facilitating the separation of similar contextual representations that may otherwise cause defensive responses based on ambiguous interpretations of the valence of the context (dangerous vs. safe environment)[51]. Further experiments are necessary to test this idea formally.

But what brain activity supports the observed neurogenesis-mediated time- and extinction-dependent effect on fear recovery? Consistent with previous results, we found that extinguished fear recovery involves recruitment of the canonical brain circuit involved in fear regulation (distinct regions of the hippocampus, medial prefrontal cortex and the amygdala[26,30,34]). Additionally, consistent with habenula´s role in signalling aversion[31], we found the habenula to be heavily correlated with fear recovery levels associated with opposing neurogenesis manipulations. Importantly, our findings suggest that modifications generated in the hippocampus mediated by adding new-born neurons modifies the activity of this circuitry. This is consistent with the idea that, through adulthood, new neurons are continuously generated and integrated into existing circuits in the hippocampus[52,53] modulating hippocampus-dependent information processing and associated circuitry[12]. Further, our brain activity findings are consistent with studies *in silico* that predict that neuronal plasticity mediated by adding new neurons alters brain activity associated to previously established memory traces[11,54]. Thus, together our results are consistent with the idea that hippocampal neurogenesis models (or remodels) connectivity of the brain network involved in fear-related behaviours linked to previous contextual experiences.

Fear-related disorders in humans are associated with high fear relapse rates[55], reduced hippocampal volume[56,57], hyperactivity in the dorsal anterior cingulate cortex[58] (a homolog of rodent PL[59]) and reduced activity in the ventromedial prefrontal cortex[60] (a homolog of rodent IL[61]). We found that high fear recovery mediated by neurogenesis ablation after extinction is associated with decreased hippocampal and IL activity, while low fear recovery mediated by increased neurogenesis is associated with conspicuously decreased PL activity.

Thus, targeting the promotion of neurogenesis (for example with regular aerobic exercise programs[62]) after extinction-based therapy may help restore activity of the fear regulation brain network and thereby prevent fear relapse in humans.

Methods

Subjects. A total of 107 male Wistar rats (180–220 g; Instituto de Fisiología Celular breeding colony) were housed in polyethylene cages and maintained on a standard 12 h light/dark schedule with *ad libitum* access to standard laboratory rat chow and water until bar-press training. All manipulations and behavioural procedures were performed during the light phase between 7:00 and 19:00 h. Animals were housed in groups of 2–3 per cage in a temperature-controlled environment (24 °C). All procedures were approved by the Institutional Animal Care and Use Committee of the Cellular Physiology Institute at the National Autonomous University of Mexico (FSB35–14 and FSB98-35), in compliance with the National Ministry of Health guidelines for the care of laboratory animals.

Behaviour. Food was restricted to 18 g/day of standard laboratory rat chow until rats reached 85% of their free-feeding weight. Rats were trained to press a lever for food (dustless precision pellets, 45 mg Bioserve, New Jersey) on a variable interval reinforcement schedule (VI 60 s). All rats received six bar-press training sessions until they reached a minimum of 12 presses per minute (each session lasted 30–35 min). Pressing maintains a constant level of activity against which freezing can be reliably measure. Bar-press training, fear conditioning, extinction and retrieval tests were performed in standard operant chambers (Coulbourn Instruments, Whitehall, PA) located inside sound-isolated cubicles (Med Associates, Burlington, VT). Bar-press training and fear conditioning protocols were performed in different conditions to control for potential context pre-exposure. Bar-press and fear conditioning contexts differed considerably. While fear conditioning context included a grid floor, white house light, clear plastic walls and constant background white noise, bar-press training context included a plastic floor, no house light, striped plastic walls and no background noise. The only element in common between operant and classical conditioning contexts was the lever-feeder. Between experiments, shock grids and floor trays were cleaned with soap and water, and the chamber walls were cleaned with wet paper towels.

Contextual fear conditioning, extinction and retrieval tests were performed in the same chambers. Rats were exposed to 5 min of habituation to the context immediately followed by conditioning consisting of five foot-shocks (2 s, 1 mA; inter shock interval was variable with an average of 2 min) during 15 min exposure to the context. Contextual extinction of fear consisted of 50 min exposure to the context in the absence of foot-shocks. Contextual memory retrieval test consisted of 10 min exposure to the context alone. Food pellets were available in the conditioning chambers on a VI 60 s schedule throughout all phases of the experiment. Freezing data were calculated as mean freezing per minute and expressed in graphs as average of 5 minutes in blocks (first block (early) and last block (late) of conditioning and extinction) or a 10-minute block (test sessions). Bar-pressing data were calculated as mean bar presses per minute and expressed in graphs as 5-minute blocks (first block (early) and last block (late) of conditioning and extinction) or a 10-minute block (test sessions).

Auditory fear conditioning, extinction and retrieval tests were performed in the same chambers. Auditory conditioning consisted on the presentation of five tones (30 s, 4 kHz, 75 dB) that co-terminated with foot-shocks (1 s, 0.8 mA). Auditory extinction of fear consisted on 20 tone-presentations in the absence of foot-shocks. Auditory fear memory retrieval test consisted on the presentation of 2 tones alone. In all sessions, the interval between tones was variable with an average of 2 min. Freezing and bar-pressing during the tone were used as a measure of cued fear. Food pellets were available in the conditioning chambers on a VI 60 s schedule throughout all phases of the experiment. Freezing data were calculated as mean freezing per minute during tone presentation (trial) and expressed in graphs as average of 2 trial in blocks (first block (early) and last block (late) of conditioning and extinction, and a single block in test sessions). Bar-pressing data were calculated as mean bar presses per minute during tone presentation (trial) and expressed in graphs as 2-trial blocks (first block (early) and last block (late) of conditioning and extinction, and a single block in test sessions).

Neurogenesis manipulations. Environmental enrichment: This procedure is used as an experimental tool to enhance adult hippocampal neurogenesis[37,62]. Rats were separated in two groups: those that lived in an enriched environment (EE) and those that lived in standard environment (non-EE). EE rats were housed in groups of 2–3 rats in standard large cages equipped with a running wheel for aerobic exercise (always available), an opaque plastic tunnel and chewing woods. Non-EE rats were also housed in groups of 2–3 rats in standard large cages but with no other material.

X–Irradiation: This procedure is used as an experimental tool to ablate adult hippocampal neurogenesis[16,25]. Rats were separated into two groups: those that were irradiated (IRR) and those that received sham-irradiation (non-IRR). All rats were anesthetized (ketamine 90 mg/kg and xylazine 10 mg/kg, i.p.). First, we obtained a cranial tomography to obtain the specific target coordinates to locally irradiate the hippocampus specifically. Then, rats were placed in a stereotaxic apparatus. The whole procedure was performed using a 6MV linear accelerator (Novalis, Brainlab-Varian). IRR rats received three arcs of circular irradiation per each side of the hippocampus; X-rays were confined to the hippocampus shape using a circular collimator (6 mm-Brainlab). Non-IRR rats were anesthetized in the same conditions and placed in the stereotaxic apparatus in the irradiation room, however, no X-irradiation was applied. For each rat, this process was repeated three times per session in three separate sessions distributed in 35 days. On each session, a dose of 5 Greys (Gy; Gy = J/kg) was applied, with a total dosage of 15 Gy for the three sessions. At the beginning and the end of each session vital signs were monitored. After each session, rats were put back in their home cages.

Immunohistochemistry. Ninety minutes after the final behavioural test, rats were overdosed with chloral hydrate (400 mg/Kg, Sigma) and transcardially perfused with cold saline solution (0.9%), and paraformaldehyde (PFA, 4%). Brains were collected and post-fixed in the same perfusate. One week later, brains were transferred into a 30% sucrose (Sigma) in PBS. Brains were mounted and cut (50 µm) using a cryostat (Leica, CM 1520) at −25 °C. Sections were collected into tissue culture plates with antifreeze (40% glycerol, 10% ethylene glycol in PBS). Then, brain sections were mounted into gelatinized slides. On the first immunohistochemistry day, the antigen retrieval protocol was performed. Slides were placed through an alcohol gradient. Then, slides were placed in citrate buffer solution (10 mM Citric Acid, 0.05 Tween 20, pH 6.0) and subsequently in a pressure cooker during 20 min. Next, tissue underwent endogenous peroxidases blocking (Hydrogen peroxide 3%, Sigma) for 10 min. Tissue was removed from slides and placed freely floating in a blocking solution (Bovine Serum Albumin, 1%, Santa Cruz Biotechnology, NGS 1%, Jackson Immunoresearch in TBS-T) during 1 hr. Tissues were then transferred to the primary antibody (1:2500, anti c-Fos, Ab-5, Polyclonal Rabbit, Millipore/Calbiochem or 1:5000, rabbit monoclonal anti-DCX, #4604 S, Cell Signaling Technology) for 48 h at 120 rpm. The second immunohistochemistry day, sections were washed six times with TBS-T for 10 min. Then, tissue was incubated in the secondary antibody (1:1000, anti-rabbit, Jackson Inmunoresearch) for 1 h at 120 rpm. Afterwards, six TBS-T washes were performed for 10 min and then incubated in ABC complex (1:250) (kit ABC-peroxidase, elite VECTASAN®, Vector) during 1 h. Next, six more TBS-T washes for 10 min were done. DAB-Ni (Sigma) solution was used as chromogen, forming a purple-black precipitate. Sections were mounted and counterstaining with methyl green (Sigma).

Cell counting and analysis. We quantified the number of c-Fos positive nuclei in the prelimbic (PL) and infralimbic cortex (IL), lateral habenula (LHb), basolateral (BLA) and central amygdala (CeA) as well as CA1, CA3 and dentate gyrus (DG) of the hippocampus. DCX positive cells (DCX+) were quantified in DG. The DCX+ cells were counted in all DG with a 40x objective (N.A 0.7) and images to measure the complete area were taken with 1X objective (N.A 0.04). Multiple images were captured for each brain region for c-Fos positive nuclei. All c-Fos images were taken with a microscope (Nikon Eclipse) with 10X objective (N.A 0.30) using the QCapturePro Program (7.05 v). For each region, the number of c-Fos positive nuclei were counted using the freely available image analysis software (ImageJ, 1.48 v, National Institutes of Health, US). Parameters we used to include c-Fos positive nuclei were: 52–250 µm area and 0.6–1 circularity. To directly compare c-Fos immunoreactivity in brain regions with different baselines, the expression of c-Fos was evaluated as a normalized contrast of c-Fos immunoreactive cells in treated rats (EE and IRR) relative to its control group (non-EE and non-IRR, respectively) (z-score; as in[63]). To obtain the density (numbers of cells per mm^2) of c-Fos positive nuclei and DCX+, we obtained the weighted mean of all the cells per area unit using ImageJ.

To control for DCX staining in the X-irradiation experiments, we quantified immunostained DCX+ cells in the rostral migratory stream (RMS). RMS can be found in the region that comprises the ependymal/olfactory ventricle (E/OV) at the level of the prefrontal cortext in the rat brain. Given the high concentration and entangled configuration of immature cells in RMS, it is not possible to reliably quantify immature cells one by one using the same methods described above for the hippocampus. Thus, we used optical density (OD) values to provide a quantitative and unbiased measurement of the density of immunostained doublecortin positive (DCX+) cells in RMS. OD values represent a standardized measurement of the intensity of dark deposit in an image. To obtain an effective contrast to quantify OD, DCX+ cells were immunostained in purple/black (stains the whole cell body, dendrites and axon) whereas DCX− cells appeared as a light green nuclear counterstaining. The dramatic contrast that resulted from this staining allowed to clearly differentiate between DCX+ and DCX− congregate cells, as evidenced by very distinct grey levels in images taken with a microscope equipped with a digital camera. Finally, we converted grey levels to quantifiable standard OD unit values using a software calibration tool (ImageJ).

Data collection and analysis. Behaviour was recorded with digital video cameras. Freezing was quantified from digitized video images using commercially available software (ANY-maze; Stoelting Co., IL, USA). The amount of time spent freezing per minute (contextual conditioning protocol) or per tone (auditory conditioning protocol) was expressed as a percentage of context exposure time or tone presentation, respectively. Bar-pressing was also used as conditioned fear-related response during context exposure or tone presentation. Groups were compared by using, when appropriate, unpaired Student's two-tailed *t* tests or repeated-measures analysis of variance (ANOVA; STATISTICA; StatSoft, Tulsa, OK).

Phasin PhaP1 is involved in polyhydroxybutyrate granules morphology and in controlling early biopolymer accumulation in *Azospirillum brasilense* Sp7

María de los Angeles Martínez-Martínez[1], Bertha González-Pedrajo[2], Georges Dreyfus[2], Lucía Soto-Urzúa[1] and Luis Javier Martínez-Morales[1*]

Abstract

Phasins are amphiphilic proteins involved in the regulation of the number and size of polyhydroxybutyrate (PHB) granules. The plant growth promoting bacterium *Azospirillum brasilense* Sp7 accumulates high quantities of bioplastic PHB as carbon and energy source. By analyzing the genome, we identified six genes that code for proteins with a Phasin_2 domain. To understand the role of *A. brasilense* Sp7 PhaP1 ($PhaP1_{Abs}$) on PHB synthesis, the *phaP1* gene (AMK58_RS17065) was deleted. The morphology of the PHB granules was analyzed by transmission electron microscopy (TEM) and the PHB produced was quantified under three different C:N ratios in cultures subjected to null or low-oxygen transfer. The results showed that $PhaP1_{Abs}$ is involved in PHB granules morphology and in controlling early biopolymer accumulation. Using RT-PCR it was found that phasin genes, except *phaP4*, are transcribed in accordance with the C:N ratio used for the growth of *A. brasilense*. *phaP1*, *phaP2* and *phaP3* genes were able to respond to the growth conditions tested. This study reports the first analysis of a phasin protein in *A. brasilense* Sp7.

Keywords: *Azospirillum brasilense* Sp7, Phasins, C:N ratio, Oxygen stress, PHB accumulation

Introduction

Since it was reported for the first time in 1926 (Lemoigne 1926), polyhydroxybutyrate (PHB) has been the best studied bacterial biopolymer. PHB exhibits similar characteristics with respect to petrochemical plastics in addition to its biodegradability and biocompatibility properties. These characteristics enable PHB convenient to reduce the use of petrochemical plastic derivatives (Madison and Huisman 1999; Anjum et al. 2016). Besides the significant advantages of PHB, it is currently not used in large quantities because of the high production costs (US$ 5.5/kg) (Brigham and Riedel 2018; Pavan et al. 2019), mainly caused by the expensive carbon sources and the ineffective recovery process. A solution for improve the large-scale production of PHB could be the use of economic carbon substrates for PHB production such as food wastes (Brigham and Riedel 2018). Nonetheless, usage of cheaper carbon source combined with optimized processes for PHA accumulation and extraction could reduce the cost of biopolymer production and this could allow to address the large-scale production challenge. Since the demand in the health industry, the making of renewable materials and the advances in technologies, will make the market increase at a rate of 6.3%, reaching 119.15 million dollars by 2025 (Global Polyhydroxyalkanoate (PHA) Market Analysis & Trends—Industry Forecast to 2025).

More than 300 microorganisms have been reported to be PHB-producers (Koller et al. 2010; Alarfaj et al. 2015). PHB-producing microorganisms synthesize PHB by three enzymatic reactions. β-ketothiolase (PhaA) condenses two acetyl-CoA into acetoacetyl-CoA, then

INFORME DE LABORES 2019

acetoacetyl-CoA is reduced to 3-hydroxybutyril-CoA by an acetoacetyl-CoA reductase (PhaB) and finally, 3-hydroxybutyril-CoA monomers are polymerized to PHB by a PHB synthase (PhaC) (Madison and Huisman 1999; Sagong et al. 2018).

Once synthesized, PHB is packaged into granules named carbonosomes which contain PHB covered by granule associated proteins (GAP's) (Steinbüchel et al. 1995; Jendrossek 2009; Pfeiffer and Jendrossek 2012). Four main GAP's have been reported: PHB synthases (PhaC), PHB depolymerases (PhaZ), regulators (PhaR or PhaM) and phasins (PhaP) (Steinbüchel et al. 1995; Tirapelle et al. 2013). Synthases and depolymerases are involved in PHB accumulation and utilization, respectively (Juengert et al. 2018; Mezzolla et al. 2018). Phasins are small amphiphilic proteins that coat and stabilize PHB in the cytoplasm (Sznajder et al. 2015) and therefore, phasins are involved in regulate the number and size of carbonosomes (Pfeiffer and Jendrossek 2012; Hauf et al. 2015). Regulator proteins (PhaR) control phasin synthesis (Maehara et al. 2002; Pötter et al. 2002; York et al. 2002) and possibly granule localization (PhaM) (Pfeiffer et al. 2011; Pfeiffer and Jendrossek 2014).

It has been demonstrated that phasins are the main GAP's (Steinbüchel et al. 1995: Sznajder et al. 2015). Studies on phasins have suggested possible interactions with PHB polymerases and PHB depolymerases depending on the PHB-producing microorganism (York et al. 2001; Fukui et al. 2001; Handrick et al. 2004a, b; Tian et al. 2005; Ushimaru et al. 2014). In *Aeromonas hydrophila* the PHB content increased twofold when the only PhaP was overexpressed (Ushimaru et al. 2014), also changes in the monomer composition of poly(3-hydroxybutyrate-*co*-3-hydroxyhexanoate) [P(HB-*co*-HHx)] copolyester were documented (Tian et al. 2005). It has also been shown that PHB is easily degraded in the presence of PhaP in *Rhodospirillum rubrum* (Handrick et al. 2004a, b; Kuchta et al. 2007).

PHB synthesis has been poorly studied in the α-proteobacterium *A. brasilense* Sp7. This bacterium accumulates up to 70% of its dry-cell weight (DCW) as PHB. The PHB accumulated energizes metabolic processes that favor bacterial survival under stressful environments (Tal and Okon 1985; Itzigsohn et al. 1995). PHB accumulation in *A. brasilense* Sp7 requires an excess in carbon and limited nitrogen sources (Tal and Okon 1985; Itzigsohn et al. 1995). Malic acid and ammonium chloride are the best carbon and nitrogen sources to improve PHB accumulation in *A. brasilense* Sp7 (Itzigsohn et al. 1995). Biochemical analyses of the PHB synthase and PHB depolymerase in *A. brasilense* have been carried out (Tal et al. 1990; Kadouri et al. 2002, 2003). However, there are no reports dealing with phasin proteins.

Our goal in this study was to analyze the function of the $PhaP1_{Abs}$ on the morphology of PHB granules and PHB accumulation using carbon:nitrogen (C:N) ratios of 30:1, 60:1 and 90:1, in cultures subjected to null or low-oxygen transfer. By means of bioinformatics analyses we found six genes that code for proteins containing a Phasin_2 domain (PF09361). In this work we deleted *phaP1* gene and the resulting mutant was characterized. The results showed that $PhaP1_{Abs}$ controls the morphology of the PHB granules and is involved in the control of early PHB synthesis in some of the growth conditions evaluated.

Materials and methods

Bacterial strains, plasmids and growth conditions

Bacteria used in this study are listed in Table 1. *Escherichia coli* strains were grown in Luria Bertani (LB) broth supplemented with the appropriate antibiotics at 37 °C and 150 rpm. LB composition per liter: yeast extract 5 g, casein peptone 10 g and NaCl 10 g. For *A. brasilense*, a minimal medium supplemented with malic acid and ammonium chloride as carbon and nitrogen sources, was used. Minimal medium composition per liter: Malic acid 4.355 g, NH_4Cl 0.2 g, K_2HPO_4 1.67 g, KH_2PO_4 0.87 g, $MgSO_4$ 0.29 g, NaCl 0.48 g, $CaCl_2$ 0.07 g, $FeCl_3{\cdot}6H_2O$ 0.01 g, $Na_2MoO_4{\cdot}2H_2O$ 0.025 g and 10 mL of trace element solution (containing $MnSO_4{\cdot}H_2O$ 250 mg, $ZnSO_4{\cdot}7H_2O$ 70 mg, $CoSO_4{\cdot}7H_2O$ 14 mg, $CuSO_4{\cdot}5H_2O$ 12.5 mg and H_3BO_3 3 mg per liter). *A. brasilense* Sp7 strains were cultured, with the appropriated antibiotics, at 32 °C and 110 rpm. All incubations were carried out in a 25 mm amplitude orbital shaker (INO-650M SEV®).

Bioinformatics analyses

Proteins containing a Phasin_2 domain (PF09361) in the *A. brasilense* Sp7 genome were searched on National Center for Biotechnology Information (NCBI) (Geer et al. 2009), Simple Modular Architecture Research Tool (SMART) (Letunic and Bork 2017) and PFAM databases (Finn et al. 2015). Secondary structures were predicted using the PSI-blast based secondary structure PREDiction (PSIPRED) software (Buchan et al. 2013) and Protein Homology/AnalogY Recognition Engine (Phyre2) server (Kelley et al. 2015). Three-dimensional structures of putative phasins were predicted by using the Iterative Threading ASSEmbly Refinement (I-TASSER) (Roy et al. 2010; Yang and Zhang 2015; Zhang et al. 2017) and SWISS-MODEL (Waterhouse et al. 2018) servers. The obtained three-dimensional structures were evaluated by Qualitative Model Energy ANalysis (QMEAN) (Benkert et al. 2011) and Ramachandran plots at SWISS-MODEL Structure Assessment server. Alignments were done using Clustal X software (Larkin et al. 2007). Identity and similarity percentages were calculated on the Sequence

INFORME DE LABORES 2019

Table 1 Strains and plasmids used in this study

Bacteria	Characteristics	Reference

Manipulation Suite (Stothard 2000). For the phylogenetic analyses, 18 amino acid sequences of phasins from main PHB-producing microorganisms were aligned using Clustal X software (Larkin et al. 2007). The phylogenetic tree was inferred using the Neighbor-Joining method and the evolutionary distances were computed using the Poisson correction method at the Molecular Evolutionary Genetics Analysis software version 7.0 (MEGA 7.0) (Kumar et al. 2016). The number of replicates were 500. Amino acid sequences of *Ralstonia eutropha* phasins were used as outgroup for the tree.

DNA manipulation

DNA was obtained by the phenol:chloroform method as previously reported (Cheng and Jiang 2006). Briefly, bacterial cells were harvested by centrifugation (8000×*g* for 5 min), the supernatant was removed, and the pellet washed in Sodium chloride–Tris–EDTA (STE) buffer twice. Cells were recovered and resuspended in Tris–EDTA (TE) buffer. Tris-saturated phenol (pH 8) was added, and the samples were mixed by vortexing and centrifuged as above. Phenol traces and debris were cleaned by three chloroform washes and the aqueous phase containing nucleic acids was recovered. RNA was eliminated by adding RNase H (10 mg/mL) to the aqueous phase and incubating for 10 min at 37 °C followed by purification with phenol:chloroform (Invitrogen). Pure DNA was contained in the aqueous phase. Plasmid DNA was isolated by the miniprep technique (Sambrook et al. 1989). Cloning procedures such as PCR amplifications, digestions and ligations were performed according to the instructions provided by the manufacturer (ThermoScientific).

In frame deletion of the *phaP1* gene in *A. brasilense* Sp7

Upstream and downstream regions of the *phaP1* gene (AMK58_RS17065) were PCR amplified using the primers *phaP1*FA*Pst*I/*phaP1*RA*Xma*I (upstream) and *phaP1* FB*Xma*I/*phaP1*RB*Eco*RI (downstream) (Table 2). Primers were designed to contain *Pst*I/*Xma*I and *Xma*I/*Eco*RI restriction sites. PCR conditions consisted of an initial denaturalization step at 94 °C for 5 min, followed by 30

cycles of denaturing at 94 °C for 45 s, annealing at 58 °C for 45 s and extension at 72 °C for 1 min as suggested by the manufacturer (ThermoScientific). Finally, an additional extension of 5 min at 72 °C was carried out. Both PCR fragments were digested with the specified endonucleases and cloned into *Pst*I/*Eco*RI sites of the suicide vector pSUP202 generating the plasmid pSUPAB. Then, kanamycin resistance gene from pCR2.1TOPO vector was cloned into *Xma*I sites of pSUPAB. The resulting suicide vector, pSUPAKB, was mobilized into *A. brasilense* Sp7 using *E. coli* S17-1 as a donor strain as previously reported (Mishra et al. 2011). The *A. brasilense phaP1* deleted mutant strain (named *A. brasilense* Δ*phaP1*) was selected on minimal medium supplemented with kanamycin (50 μg/mL) and ampicillin (100 μg/mL).

Complementation of the *A. brasilense* Δ*phaP1* strain

The complementation of the *A. brasilense* Δ*phaP1* was done in two steps. First, the pMBA-2 vector was generated by cloning of the arabinose promoter and the *araC* gene from pGLO into *ApaI*/*EcoRI* sites of the expression vector pMMB206. Second, the *phaP1* gene was amplified by PCR using the primers *phaP1*-F*Mfe*I/*phaP1*-R*Sma*I and wild type total DNA as a template. The PCR product was digested and ligated into *Eco*RI/*Sma*I restriction sites of pMBA-2. The resulting pMBA-12 plasmid was mobilized into *A. brasilense* Δ*phaP1* using *E. coli* S17-1 as a donor strain. The complemented mutant (named *A. brasilense* PhaP1^{+++}) was selected on minimal medium supplemented with chloramphenicol (10 μg/mL), kanamycin (50 μg/mL) and ampicillin (100 μg/mL). Induction of the arabinose promoter for PhaP1$_{Abs}$ expression in pMBA-12 vector was carried out with 0.1% arabinose (Sigma-Aldrich).

Growth curves of *A. brasilense* strains

Flasks containing 50 mL of minimal medium supplemented with malic acid and ammonium chloride at C:N ratios of 30:1, 60:1 and 90:1 were inoculated with the *A. brasilense* strains to an optical density at 600 nm (OD600) of 0.01, then the cultures were grown at 32 °C at 110 rpm. The OD600 was determined every 3 h during 24 h.

PHB quantitation

Strains of *A. brasilense* were grown on minimal medium supplemented with malic acid and ammonium chloride at C:N ratios of 30:1, 60:1 and 90:1 in flasks subjected to null or low-oxygen transfer. To generate null-oxygen transfer condition, unbaffled Erlenmeyer flasks of 125 mL of capacity were filled with 25 mL of minimal medium and capped with a number 5 rubber stopper, which keep off from the atmospheric oxygen transfer throughout the assay. To generate low-oxygen transfer condition, unbaffled Erlenmeyer flasks of 125 mL of capacity were filled with 25 mL of minimal medium and capped with a 5 g cotton stopper, which keep off from the atmospheric oxygen transfer throughout the assay. The flasks containing the minimal medium were inoculated with an overnight culture to an OD600 of 0.01 and grown at 32 °C and 110 rpm. For each strain, four flasks with 25 mL of minimal medium were inoculated with the appropriated strain. One flask was uncovered at 24 h to determine PHB production, another flask was uncovered at 48 h and so on. This led us to maintain the oxygen conditions throughout the study. Samples of *A. brasilense* strains (10 mL) were taken at 24, 48, 72 and 96 h and harvested by centrifugation (6000×*g* for 5 min). Cells were washed with TE buffer twice, weighed and dried at 60 °C until weight was constant. PHB was extracted as reported elsewhere (Hahn et al. 1994) and quantified spectrophotometrically (Law and Slepecky 1961). Data were correlated with a commercial standard of PHB (Sigma-Aldrich). Determinations were carried out in triplicate. Results are shown as mean ± standard deviation of % PHB/DCW. Statistical analysis was performed in Statgraphics Centurion 18 software using One-way ANalysis Of VAriance (ANOVA) at 95% confidence level.

Transmission electron microscopy (TEM)

Samples of *A. brasilense* strains were grown at C:N ratios of 30:1, and 90:1, harvested (6000×*g* for 5 min) and washed with TE buffer twice. Cells were fixed in 2.5% (v/v) glutaraldehyde for 3 h, postfixed in 1% (w/v) OsO_4 for 2 h and rinsed 3 times in 50 mM of sodium cacodylate buffer (pH 7.2). Bacteria were dehydrated with a graded ethanol series and embedded in a low-viscosity epoxy resin that was subsequently dried at 60 °C for 24 h. Ultrathin sections were stained with uranyl acetate and examined on a Jeol JEM-1200 EX II transmission electron microscope.

RT-PCR analysis

RNA was extracted from cultures of *A. brasilense* strains (wild type, mutant and complemented) grown on minimal medium at C:N ratios of 30:1 and 90:1. The extraction was performed using the Trizol reagent method according to the instructions provided (Sigma-Aldrich). A mix consisting of: 1 μg of pure RNA, *phaP1* to *phaP6* gene-specific primers (RT-*pha*P1-R, RT-*pha*P2-R, RT-*pha*P3-R, RT-*pha*P4-R, RT-*pha*P5-R and RT-*pha*P6-R) (Table 2), dNTP mix, RNase inhibitor, RevertAid reverse transcriptase and the RevertAid reverse transcriptase buffer, was used to produce the cDNA according to the recommendations of the manufacturer (ThermoScientific). For the PCR amplification of each putative phasin gene (internal region of ~120 nucleotides), a mix

INFORME DE LABORES 2019

consisting of: cDNA (1 µL), dNTPs, gene specified pair of primers (RT-*pha*P1-F/RT-*pha*P1-R, RT-*pha*P2-F/RT-*pha*P2-R, RT-*pha*P3-F/RT-*pha*P3-R, RT-*pha*P4-F/RT-*pha*P4-R, RT-*pha*P5-F/RT-*pha*P5-R or RT-*pha*P6-F/RT-*pha*P6-R) (Table 2), Taq polymerase recombinant and Taq polymerase recombinant buffer, was utilized. PCR conditions consisted of an initial denaturalization step at 94 °C for 5 min, followed by 30 cycles of denaturing at 94 °C for 30 s, annealing at 58 °C for 30 s and extension at 72 °C for 1 min as suggested by the manufacturer (ThermoScientific). Finally, an additional extension of 5 min at 72 °C was carried out. 16S rRNA gene (AMK58_09830) was used as control. PCR products were analyzed by gel electrophoresis on 3% agarose gels and subsequent ethidium bromide staining. RT-PCR assays were repeated three times.

Results

A. brasilense Sp7 contains six putative *phaP* genes

In silico analyses of the *A. brasilense* Sp7 genome revealed six genes that code for proteins containing a Phasin_2 domain (PF09361). Two putative phasin genes are in plasmid 1: AMK58_RS17065 (Gene ID: 36110503) and AMK58_RS20955 (Gene ID: 36111302) and the other putative phasin genes are in the chromosome: AMK58_RS04265 (Gene ID: 36107916), AMK58_RS04270 (Gene ID: 36107917), AMK58_RS07520 (Gene ID: 36108566) and AMK58_RS13850 (Gene ID: 36109844) (Additional file 1). The putative phasin proteins were referred as $PhaP1_{Abs}$ to $PhaP6_{Abs}$ according to the e-value (Table 3) presented with respect to the Phasin_2 domain. The size of the PhaP proteins ranges from 15 to 29 kDa. Analysis of the predicted secondary structure showed that phasins $PhaP1_{Abs}$ to $PhaP5_{Abs}$ possess a high α-helix content (85 to 95%) in contrast to $PhaP6_{Abs}$ which shows a low percentage (14%) (Table 3).

The phasin amino acid sequences from other PHB-producing microorganisms [*R. eutropha* (PhaP1 to PhaP7 and PhaM), *Pseudomonas putida* (PhaI and PhaF), *Aeromonas hydrophila* (PhaP), *Herbaspirillum seropedicae* (PhaP1 and PhaP2) and *Azotobacter* FA8 (PhaP)] were used for protein alignment with the *A. brasilense* Sp7 phasins (Fig. 1a). The results obtained showed that some *A. brasilense* Sp7 phasins are moderately conserved among phasins previously reported, with identities ranging from 3 to 33.7% and similarities from 6 to 55.8% (Additional file 2). The low identity and similarity percentages between the analyzed phasins, occurs by the diversity of aligned amino acid sequences of phasins belonging to the α, β, and γ-proteobacteria classes and does not pretend to identify a phasin domain. Moreover, the entire amino acid phasin sequences from the above-mentioned microorganisms were used to make a Neighbor-Joining phylogenetic tree (Fig. 1b). The putative $PhaP2_{Abs}$, $PhaP3_{Abs}$, $PhaP4_{Abs}$ and $PhaP5_{Abs}$ were clustered together on the 500 bootstrap tree. $PhaP1_{Abs}$ maybe share a common

[b] Amino acids

[c] Amino acids

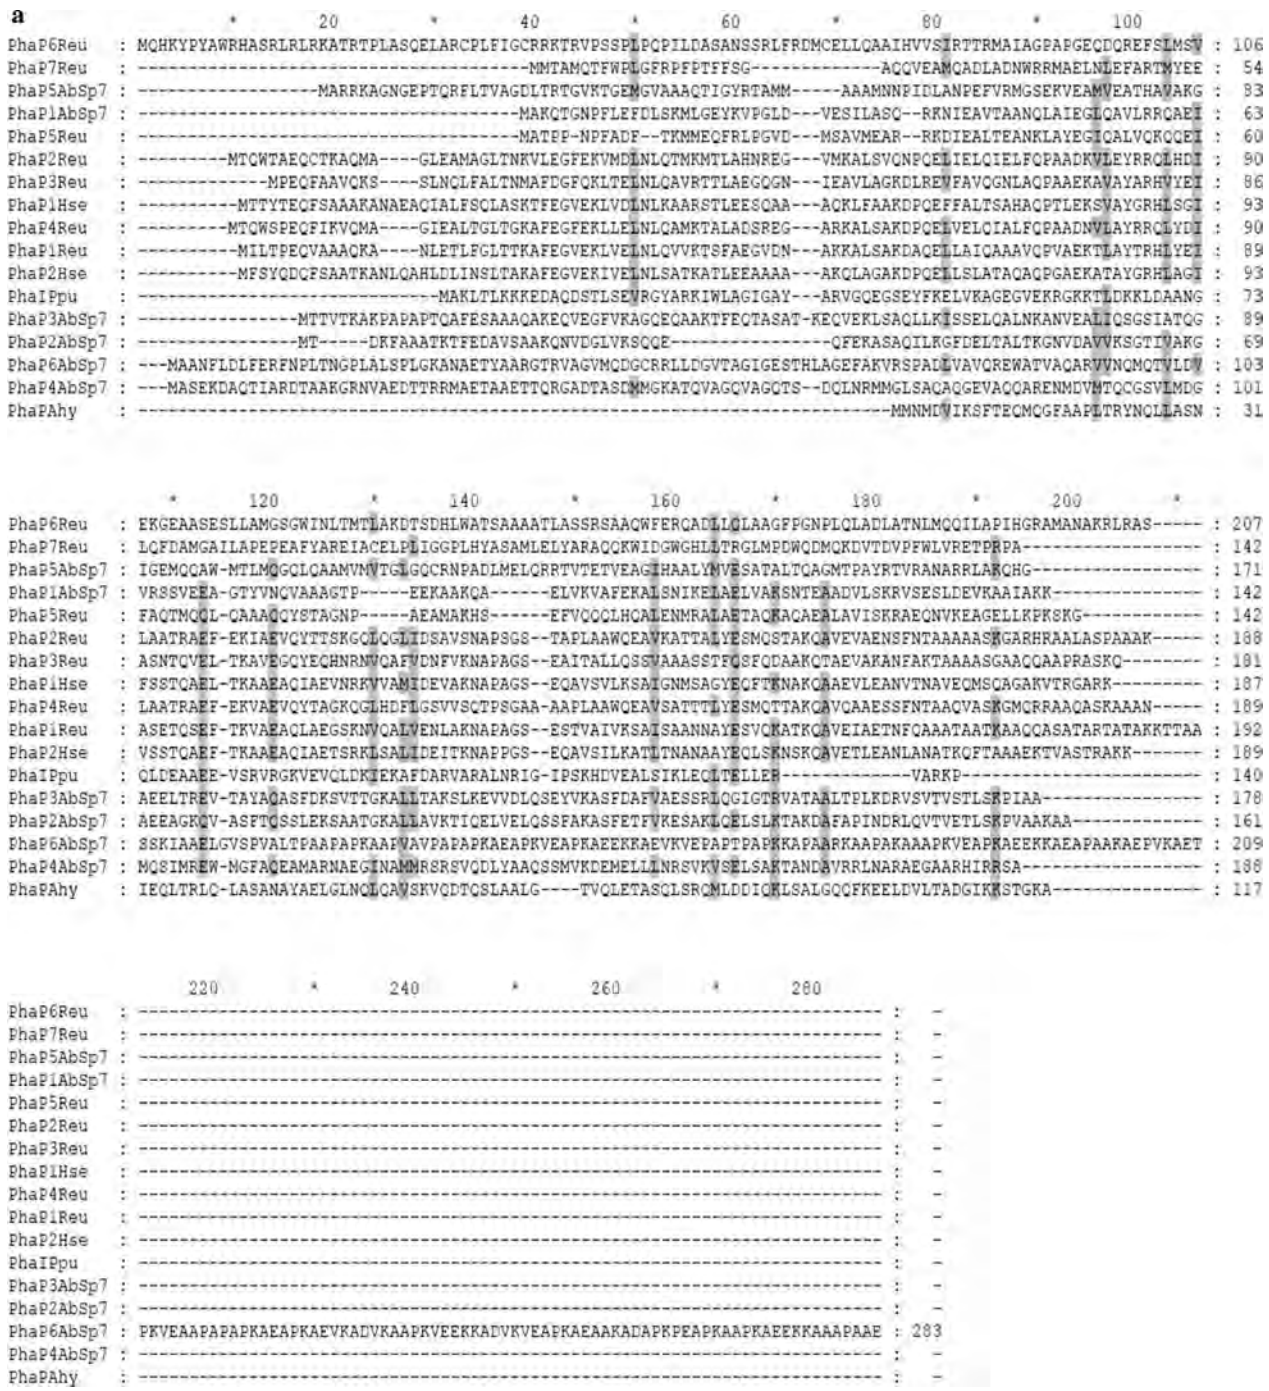

Fig. 1 Phylogeny of *A. brasilense* Sp7 phasin proteins. **a** The amino acids sequences of phasin proteins of PHB-producing microorganisms were aligned to *A. brasilense* Sp7 proteins containing a phasin domain (PF09361). The conserved residues are highlighted. **b** A phylogenetic tree based on amino acid sequences of phasins was inferred using the Neighbor-Joining method. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (500 replicates) are shown next to the branches. The evolutionary distances were computed using the Poisson correction method and are in the units of the number of amino acid substitutions per site. The analysis involved 18 amino acid sequences. All the positions containing gaps and missing data were eliminated. PhaP1AbSp7 to PhaP6AbSp7 denotes the *A. brasilense* Sp7 PhaP1 to PhaP6. PhaP1Reu to PhaP7Reu indicates the phasins PhaP1 to PhaP7 of *R. eutropha*. PhaIPpu and PhaFPpu are the phasins PhaI and PhaF, respectively, of *P. putida*. PhaP1Hse and PhaP2Hse are the *H. seropedicae* PhaP1 and PhaP2. PhaPAhy denotes the *A. hydrophila* PhaP

INFORME DE LABORES 2019

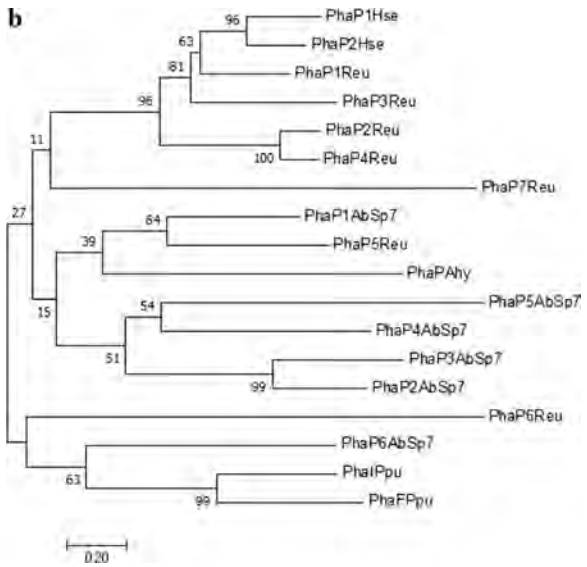

Fig. 1 (continued)

ancestor with this clade. The putative $PhaP6_{Abs}$ was clustered alone. A gene duplication event is suggested for $PhaP2_{Abs}$ and $PhaP3_{Abs}$. It is important to mention that was not possible enroot the phylogenetic tree due to the diversity of amino acid sequences of phasins used for tree construction.

Because of the non-existence of genetic, biochemical and structural information about phasin proteins of the most-well studied PHB-producing microorganisms, it was decided to analyze whether the putative *A. brasilense* Sp7 phasins share any structural homology with the crystal structure of $PhaP_{Ahy}$ (*Aeromonas hydrophila*) (PDB number 5IP0) (Zhao et al. 2016). The $PhaP_{Ahy}$ was used as template to predict the three-dimensional structures of the *A. brasilense* Sp7 phasins by the I-TASSER and SWISS-MODEL servers (Fig. 2 and Additional file 3). The results showed a good structural similarity for $PhaP1_{Abs}$ to $PhaP4_{Abs}$ models (QMEAN ranging from −1.03 to −3.60).

Due to the similarity between $PhaP1_{Abs}$ and $PhaP5_{Reu}$ (*R. eutropha* PhaP5) (55.8%) and based on the data that we obtained it was decided to focus on the analyses of the function of $PhaP1_{Abs}$ on PHB granule morphology and PHB accumulation.

PhaP1 does not affect growth of *A. brasilense*

Growth curves of *A. brasilense* strains were carried out using minimal medium containing malic acid and ammonium chloride at C:N ratios of 30:1, 60:1 and 90:1 (Fig. 3). At all evaluated C:N ratios, the exponential growth phase was reached at 15 h of culturing, whereas the stationary phase occurred at 21 h. As was expected, the strains of study grew better when a C:N ratio of 30:1 was used. By comparing the growth curves of the mutant (*A. brasilense* Δ*phaP1*) and complemented (*A. brasilense* $PhaP1^{+++}$) strains with respect to the wild type (*A. brasilense* Sp7) strain was shown that $PhaP1_{Abs}$ is not important for the growth of *A. brasilense*.

Deletion of *phaP1* gene affects the morphology of the PHB granules

Wild type, mutant and complemented strains were cultivated for 15 h in minimal medium at C:N ratios of 30:1 and 90:1. Ultra-thin sections of the strains were analyzed by TEM (Fig. 4). At a C:N ratio of 30:1, several PHB granules were observed in the wild type strain. These granules are distributed throughout the cytoplasm (Fig. 4a). On the contrary, the mutant strain produced few PHB granules that appear to be larger and are located either at the center or at the pole of the cell (Fig. 4b). By restoring the $PhaP1_{Abs}$ function in the complemented strain, the number and appearance of the PHB granules was restored (Fig. 4c). This suggests that at a C:N ratio of 30:1, $PhaP1_{Abs}$ is involved in the control of the number and size of the PHB granules. However, when the bacteria were grown at a C:N ratio of 90:1, no differences in the size or distribution of the PHB granules could be observed (Fig. 4d–f). These results could suggest the participation of other PhaP proteins that contribute in the maintenance of the architecture of the PHB granules at the evaluated conditions.

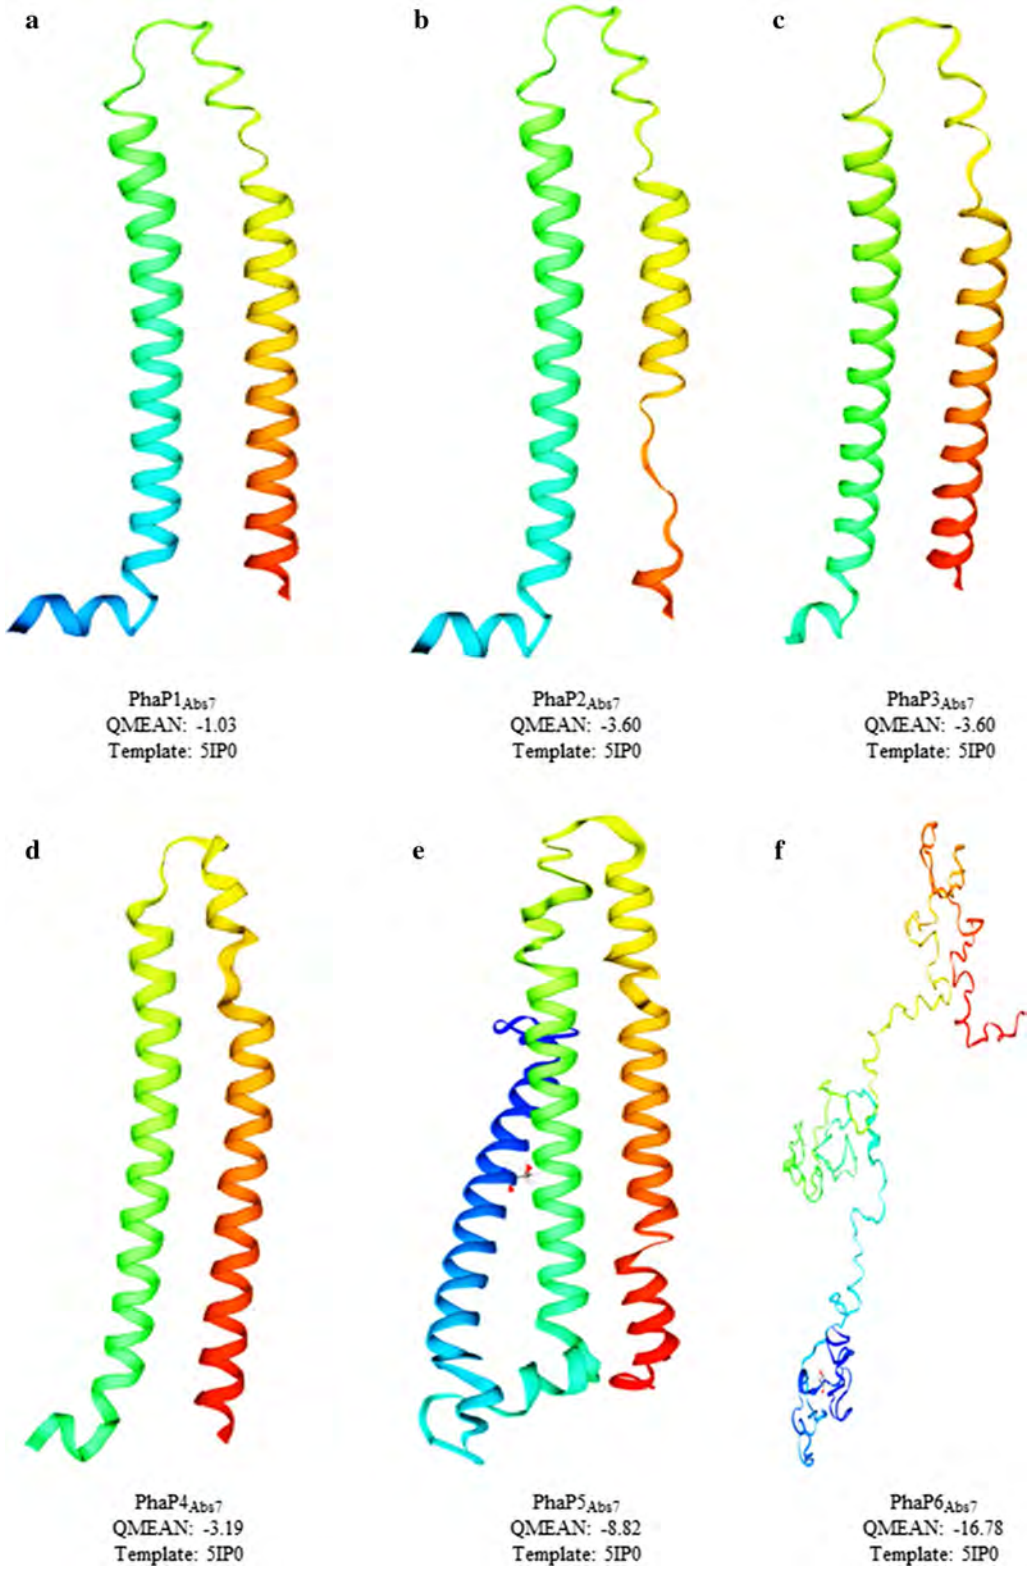

Fig. 2 Predicted three-dimensional structures of *A. brasilense* Sp7 phasins. Structures were predicted using the I-TASSER and SWISS-MODEL servers. The crystal structure of PhaP from *A. hydrophila* (PDB number 5IP0) was used as template. For each *A. brasilense* Sp7 phasin, the QMEAN value was calculated and the Ramachandran plots were obtained (see Additional file 3). **a** $PhaP1_{Abs}$, **b** $PhaP2_{Abs}$, **c** $PhaP3_{Abs}$, **d** $PhaP4_{Abs}$, **e** $PhaP5_{Abs}$ and **f** $PhaP6_{Abs}$

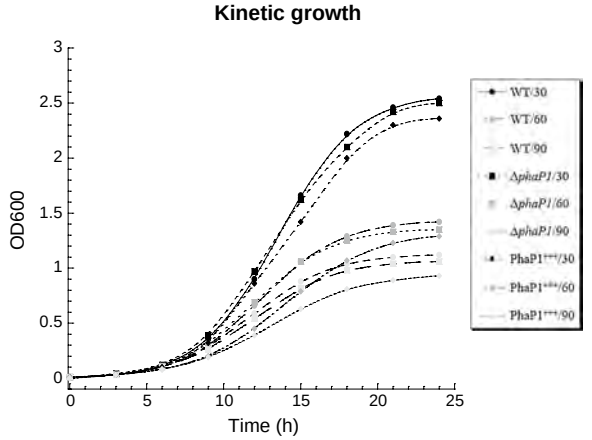

Fig. 3 Growth kinetic behavior of *A. brasilense* strains. *A. brasilense* strains were inoculated in flasks containing minimal medium supplemented with malic acid and ammonium chloride, at C:N ratios of 30:1, 60:1 and 90:1, to an OD600 of 0.01. Samples were taken every 3 h for 24 h and measured spectrophotometrically at an OD600. Growth of *A. brasilense* Sp7 (WT) (circles), *A. brasilense* Δ*phaP1* (Δ*phaP1*) (squares) and *A. brasilense* PhaP1^{+++} (PhaP1^{+++}) (diamonds). Dark spots indicate a C:N ratio of 30:1, gray spots for a C:N ratio of 60:1 and light gray spots denotes a C:N ratio of 90:1

The deletion of the *phaP1* gene affects early (24 h) PHB accumulation depending on the C:N ratio used

PHB accumulation was quantified to evaluate the possible involvement of PhaP1$_{Abs}$ on biopolymer metabolism. Malic acid and ammonium chloride were used at C:N ratios of 30:1, 60:1 and 90:1 in cultures subjected to low or null oxygen transfer (as described in materials and methods). General comparison of the growth conditions evaluated for PHB accumulation (C:N ratio with low or null-oxygen transfer) is observed that the oxygen transfer limits PHB accumulation by approximately 50% (Fig. 5).

Moreover, by analyzing the PHB accumulation at a C:N ratio of 30:1 in cultures with null-oxygen transfer (Fig. 5a) it can be observed that the PHB is accumulated at 24 h of growth and subsequently degraded in wild type and mutant strain. However, it is observed that the mutant strain accumulates 17% PHB/DCW with respect to 9.5% PHB/DCW that was accumulated by the wild type strain. In addition, the PHB produced by the mutant is easily degraded to similar levels as wild type strain. This suggests that PhaP1$_{Abs}$ somehow regulates the early stage of PHB accumulation. Moreover, the restoration of PhaP1$_{Abs}$ function in the complemented strain results in an increased PHB content to reach 17.5% PHB/DCW, it is about 90% more PHB with respect to the PHB accumulated by wild type strain. It should be noted that there was no signal observed for PHB degradation, since the PHB content decreased with time in the wild type and mutant strains but it was increased in the complemented strain. We also quantified the PHB accumulation in *A. brasilense* strains cultured at a C:N ratio of 30:1 but subjected to low-oxygen transfer (Fig. 5b). Both, wild type and mutant strains reported a similar behavior in PHB accumulation. In these strains, PHB content reach the maximum level at 24 h (~5% PHB/DCW) and it was subsequently decreased to minimum levels (~1% PHB/DCW) at the end of bacterial culturing time (96 h). Taken together data obtained is suggested that PhaP1$_{Abs}$ could be involved in the control of PHB synthesis or utilization at a C:N ratio of 30:1 in cultures subjected to null-oxygen transfer when early PHB synthesis occurs (24 h) (Fig. 5a). It should be noted that under low-oxygen transfer this does not occur (Fig. 5b).

To analyze whether the behavior observed is constant at other C:N ratios, it was decided to quantify PHB accumulation by increasing the C:N ratio to 60:1 and 90:1 under low or null-oxygen transfer (Fig. 5c–f). The data obtained at a C:N ratio of 60:1 in cultures with null-oxygen transfer showed a similar behavior by wild type, mutant and complemented strains from 72 to 96 h. However, at 24 h it appears that PHB synthesis in the mutant and complemented strains is delayed but at 48 h, they accumulated more PHB than the wild type strain (Fig. 5c). The observed phenotype may be due to the presence of another phasin protein that support PHB accumulation when a C:N ratio of 60:1 is combined with null-oxygen transfer. The above mentioned does not occur when PHB is measured in cultures subjected to low-oxygen transfer as can be observed in Fig. 5d.

Furthermore, when the PHB was quantified in cultures grown at a C:N ratio of 90:1 was observed that PHB is rapidly synthesized by the mutant strain when it is grown in cultures subjected to a null-oxygen transfer. At 24 h, the mutant strain accumulates approximately 50% PHB/DCW, whereas the wild type strain accumulates 35% PHB/DCW (Fig. 5e). It should be noted that the excess of PHB accumulated by the mutant strain is degraded after 48 h and remains constant up to 96 h of culture. Whereas, the PHB produced by the wild type strain increases over time. The complemented strain does not recover the wild type phenotype in PHB accumulation (Fig. 5e). Moreover, when cultures were grown at a C:N ratio of 90:1 and subjected to a low-oxygen transfer (Fig. 5f), it was found that, between 24 and 48 h of culture, the mutant strain increases the PHB content from 50 to 60% with respect to the wild type strain. PHB is accumulated rapidly by the mutant strain in contrast to a slow accumulation of PHB by the wild type.

INFORME DE LABORES 2019

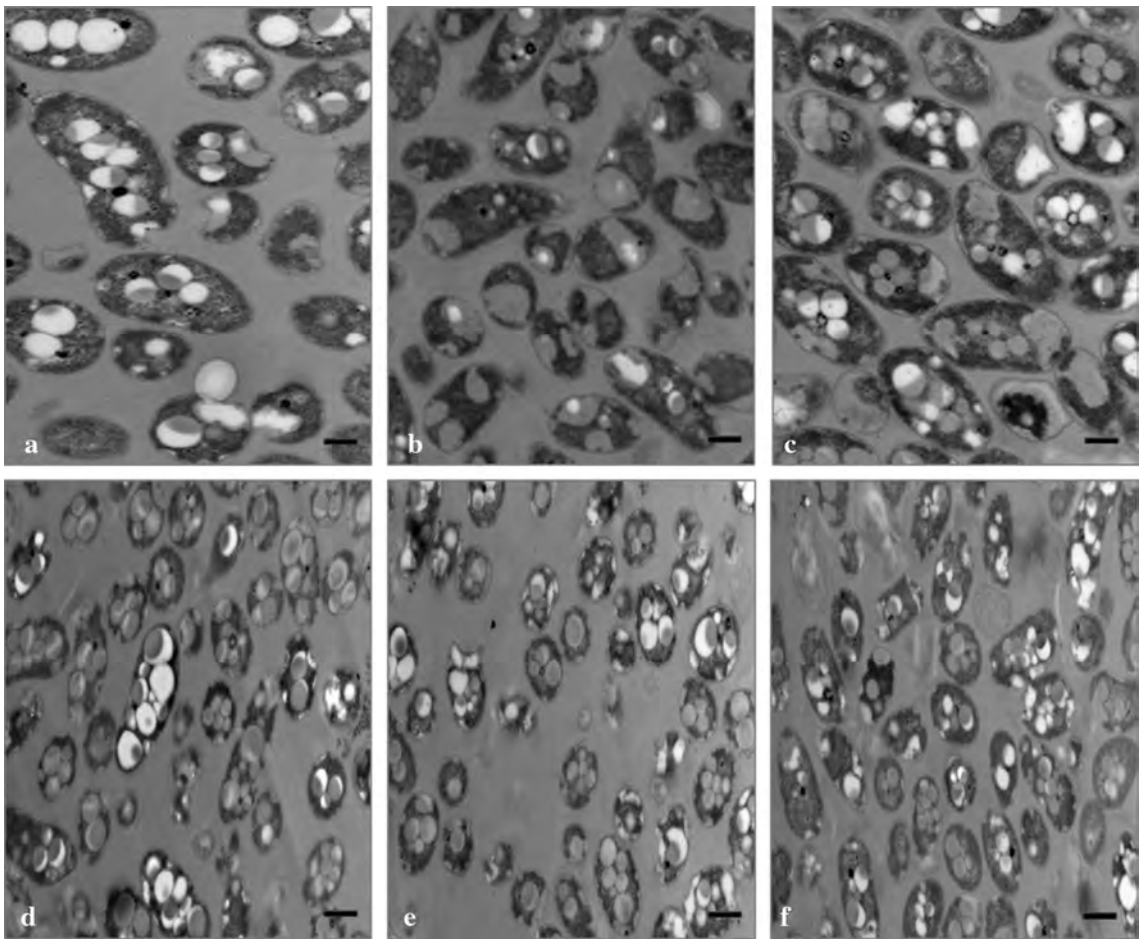

Fig. 4 Transmission electron microscopy of ultra-thin sections of *A. brasilense*. Strains were grown on minimal medium containing malic acid and ammonium chloride at C:N ratios of 30:1 (**a**–**c**) and 90:1 (**e**–**g**). Strains were incubated at 32 °C and 110 rpm for 24 h. PHB granules of wild type (*A. brasilense* Sp7) (**a** and **e**), mutant (*A. brasilense* Δ*phaP1*) (**b** and **f**) and complemented (*A. brasilense* PhaP1^{+++}) (**c** and **g**) strains are shown as intracellular granules. Label Scale bar = 1 µm

Differential transcription of putative phasin genes under three different C:N ratios

TEM images obtained from ultra-thin sections of *A. brasilense* strains grown at a C:N ratio of 90:1 showed no differences in the size and number of PHB granules by both, mutant and complemented strains, compared to the wild type strain (Fig. 4d–f). Additionally, the data obtained from the PHB quantification at C:N ratios of 60:1 and 90:1 showed an unclear phenotype. This suggests the possible involvement of other phasin proteins for the PHB accumulation and the maintenance of the structure of the PHB granules. To address this possibility, the transcripts of the *phaP* genes of wild type and mutant strains were evaluated by RT-PCR (Fig. 6). The results show that, *phaP1* and *phaP2* are the main genes transcribed in the wild type strain when cultures are grown at a C:N ratio of 30:1 (Fig. 6a). However, in the mutant, the *phaP2* transcript was the most prominent of all phasins and the *phaP3* transcript was partially increased (Fig. 6a). Nevertheless, it is still possible that the *phaP2* product could compensate for the lack of $PhaP1_{Abs}$ in the granule structure as well as the PHB content in the mutant strain. Transcripts of the *phaP4* and *phaP6* were not observed either in wild type and mutant strains and the transcript of *phaP5* was slightly detected at a C:N ratio of 30:1 (Fig. 6a). However, when *A. brasilense* was grown at a C:N ratio of 90:1 (Fig. 6b), *phaP3* transcript increased to levels similar to *phaP2* in the wild type strain. A similar behavior was observed for the mutant strain (Fig. 6b). It should be mentioned that the transcript of the *phaP4* gene was not observed in both, wild type and mutant strains, whereas the *phaP5* and *phaP6* transcripts were present at low levels (Fig. 6b). Our results suggest that the C:N ratio has important implications on phasin genes transcription in this bacterium.

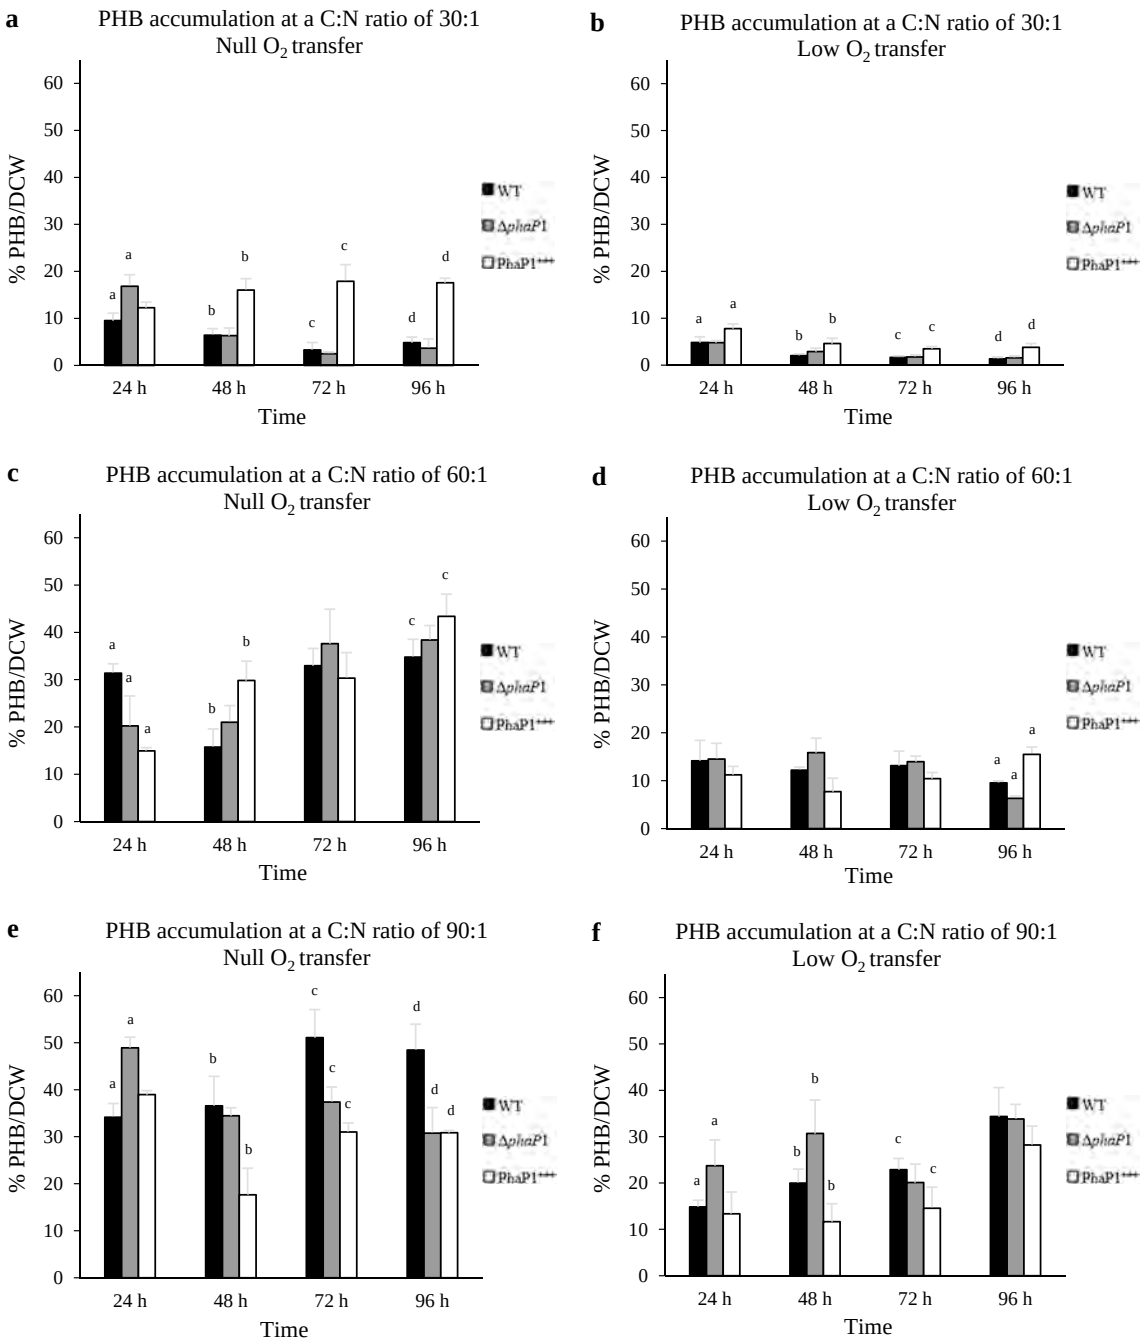

Fig. 5 PHB/DCW content in *A. brasilense* strains. For PHB quantitation, flasks containing minimal medium supplemented with malic acid and ammonium chloride at C:N ratios of 30:1 (**a** and **b**), 60:1 (**c** and **d**), and 90:1 (**e** and **f**) were inoculated with the *A. brasilense* strains in flasks subjected to null (**a**, **c** and **e**) or low (**b**, **d** and **f**) oxygen transfer. Samples of cultures of *A. brasilense* were taken every 24 h for 96 h. Cells were harvested and dried, then PHB was extracted and quantified. PHB produced by *A. brasilense* Sp7 (WT), *A. brasilense* Δ*phaP1* (Δ*phaP1*) and *A. brasilense* PhaP1+++ (PhaP1^{+++}) are shown. Data are presented as mean ± standard deviation of three independent experiments. Letters in each graphic denote significant differences ($p > 0.05$) according to a one-way ANOVA test

Discussion

The function of $PhaP1_{Abs}$ on PHB synthesis and PHB granule structure in *A. brasilense* was analyzed. Phasin proteins have been mainly implicated in PHB granule stabilization which occurs due to their amphiphilic properties (Pötter and Steinbüchel 2005) that avoid the

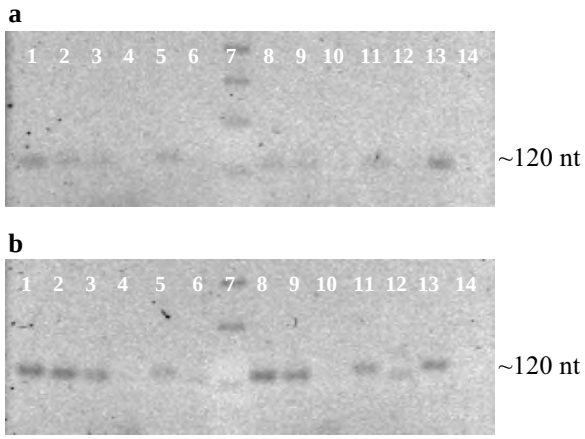

Fig. 6 Analysis of the transcription of *A. brasilense* Sp7 phasin genes. RT-PCR assays of the internal region of putative phasin genes were conducted using cDNA of wild type (*A. brasilense* Sp7) and mutant (*A. brasilense* Δ*phaP1*) strains. RNA was extracted from cultures grown on minimal medium containing malic acid and ammonium chloride at C:N ratios of 30:1 and 90:1. Transcripts were visualized on a 3% agarose gel electrophoresis. **a** Transcription analyses of putative phasin genes of wild type and mutant strains grown at a C:N ratio of 30:1. coalescence of the PHB granules (Wieczorek et al. 1995; Pfeiffer et al. 2011). Every PHB-producing microorganism has at least one phasin, however there are reports of bacteria with several phasin proteins such as *R. eutropha* with seven PhaP proteins (Wieczorek et al. 1995; Pötter et al. 2004; Pfeiffer and Jendrossek 2011, 2012). Despite the existence of multiple homologues in some bacterial species and the fact that most of them can be bound to the PHB granule, only one or two are covering the PHB granules (Pötter et al. 2004; Yoshida et al. 2013). In this study, bioinformatic analyses of the *A. brasilense* Sp7 genome revealed six putative phasin genes, referred as *phaP1* to *phaP6*. The amino acid sequences of *A. brasilense* phasins are not highly conserved however similar results have been reported for phasins of *R. eutropha* (Pötter et al. 2004; Pfeiffer and Jendrossek 2012), *H. seropedicae* (Alves et al. 2016), *Bradyrhizobium japonicum* (Yoshida et al. 2013) and *Haloferax mediterranei* (Cai et al. 2012) among others. The predicted secondary structures of $PhaP1_{Abs}$ to $PhaP5_{Abs}$ reveals a high percentage of α-helix content as has been reported for this type of proteins (Mezzina and Pettinari 2016; Zhao et al. 2016).

The deletion of the main phasin that covers the PHB granules results in a single enlarged granule rather than five to ten granules that are observed in the wild type strains (Steinbüchel et al. 1995; Jurasek and Marchessault 2002; Cai et al. 2012). To analyze the role of the $PhaP1_{Abs}$ in the PHB granule morphology, the *phaP1* gene was deleted. TEM images of the carbonosomes from the mutant strain showed fewer PHB granules that were larger than those observed in the wild type strain. This strongly suggests that $PhaP1_{Abs}$ controls to a certain extent the number and size of the PHB granules.

Among other functions attributable to phasins are the regulation of synthesis and degradation of PHB (York et al. 2001; Handrick et al. 2004a, b; Cai et al. 2012) and the distribution of the PHB granules during cell division (Galán et al. 2011; Pfeiffer and Jendrossek 2011; Wahl et al. 2012; Bresan and Jendrossek 2017). To analyze the possible involvement of $PhaP1_{Abs}$ on PHB synthesis and degradation in *A. brasilense* Sp7, a *phaP1* mutant strain was constructed and PHB accumulation was determined. For that, minimal medium supplemented with malic acid and ammonium chloride at different C:N ratios in addition to either low or null-oxygen transfer conditions was used. The results showed that $PhaP1_{Abs}$ controls early PHB synthesis at a C:N ratio of 30:1 when the oxygen transfer is null. The overexpression of $PhaP1_{Abs}$ in the complemented strain resulted in the increase of PHB over time, suggesting a possible increment in the PHB synthesis or a decrement in the PHB utilization. However, when the accumulation of PHB in *A. brasilense* was quantified in cultures grown in minimal medium at C:N ratios of 60:1 and 90:1 and subjected to low or null-oxygen transfer, no clear effect caused by the lack or overexpression of $PhaP1_{Abs}$ was observed. This suggest a possible participation of other phasin proteins to maintain PHB accumulation.

By analyzing the behavior of phasins in *R. eutropha*, it was found that the *phaP1* mutant strain accumulates approximately 40% PHB/DCW less than the wild type strain (Pötter et al. 2005). However, the deletion of *phaP2*, *phaP3* or *phaP4* did not affect PHB accumulation (Pötter et al. 2005). In *H. seropedicae* SmR1, the deletion of *phaP1* reduced PHB accumulation by 50% PHB/DCW but the *pha*P2 deleted strain produced 30% PHB/DCW more than the wild type strain when grown on glucose as a carbon source, suggesting that $PhaP2_{Hse}$ (*Herbaspirillum seropedicae* PhaP2) compensates for the lack of $PhaP1_{Hse}$ (Alves et al. 2016). Similar results

have been obtained for *Methylobacterium extorquens* AM1 (Korotkova et al. 2002). The deletion of *phaP1* and *phaP2* in *H. seropedicae* and *phaP1* to *phaP4* in *R. eutropha* H16 abolished PHB accumulation (Pötter et al. 2005; Alves et al. 2016). These results, in addition to the changes observed in polymer accumulation allow to infer a possible interaction between phasin proteins and the PHB polymerase, which has been corroborated for *R. eutropha* (York et al. 2001), *Aeromonas caviae* (Fukui et al. 2001; Ushimaru et al. 2014) *A. hydrophila* (Tian et al. 2005), and, in this work, is suggested for *A. brasilense* Sp7, however the mechanism by which the interactions take place has not been elucidated.

Furthermore, a strong interaction between $PhaP5_{Reu}$ and the PHB depolymerase or the regulator protein (PhaR) has been proven (Pötter et al. 2005; Pfeiffer and Jendrossek 2011). Studies of $PhaP2_{Reu}$ and $PhaP4_{Reu}$ on PHB degradation conclude that both phasins, limit PHB degradation by interacting with the depolymerases PhaZ2, PhaZ3 and PhaZ7. Moreover, the expression of $PhaP1_{Reu}$ reduced the PHB content in *E. coli* when expressing the *phaCAB* operon of *R. eutropha* (Eggers and Steinbüchel 2014).

In conclusion, in this study we demonstrated that early PHB synthesis and the morphology of the PHB granules are influenced by $PhaP1_{Abs}$ when *A. brasilense* Sp7 is grown in a medium with a C:N ratio of 30:1. Nevertheless, when C:N ratios of 60:1 and 90:1 were used, PHB synthesis and the morphology of the PHB granules seem to be influenced by the coordinated action of several phasin proteins.

ABSTRACT

Message-specific translational regulation mechanisms shape the biogenesis of multimeric oxidative phosphorylation (OXPHOS) enzyme in mitochondria from the yeast *Saccharomyces cerevisiae*. These mechanisms, driven mainly by the action of mRNA-specific translational activators, help to coordinate synthesis of OXPHOS catalytic subunits by the mitoribosomes with both the import of their nucleus-encoded partners and their assembly to form the holocomplexes. However, little is known regarding the role that the mitoribosome itself may play in mRNA-specific translational regulation. Here, we show that the mitoribosome small subunit protein Cox24/mS38, known to be necessary for mitoribosome-specific intersubunit bridge formation and 15S rRNA H44 stabilization, is required for efficient mitoribogenesis. Consequently, mS38 is necessary to sustain the overall mitochondrial protein synthesis rate, despite an adaptive ∼2-fold increase in mitoribosome abundance in *mS38*-deleted cells. Additionally, the absence of mS38 preferentially disturbs translation initiation of *COX1*, *COX2,* and *COX3* mRNAs, without affecting the levels of mRNA-specific translational activators. We propose that mS38 confers the mitochondrial ribosome an intrinsic capacity of translational regulation, probably acquired during evolution from bacterial ribosomes to facilitate the translation of mitochondrial mRNAs, which lack typical anti-Shine-Dalgarno sequences.

INTRODUCTION

A major challenge in biology is to understand how protein expression is regulated to attend cellular needs. One of the orchestrating layers of regulation involves the translation machinery itself, where protein synthesis is tightly regulated to prevent wasting cellular resources (1). The mitochondrion, a eukaryotic organelle that possesses its own protein synthesis apparatus, has also evolved several mechanisms of translational control, some of which were identified and best studied in the yeast *Saccharomyces cerevisiae* (2). However, the possible role the mitochondrial ribosome plays in these mechanisms and whether it exerts an additional layer of intrinsic regulation remains largely unexplored.

The yeast mitochondrial genome (mtDNA) encodes eight proteins, two ribosomal RNAs (rRNAs) and a set of tRNAs. Seven hydrophobic proteins are components of the multimeric oxidative phosphorylation (OXPHOS) system enzymes, and the eighth is a soluble mitoribosomal protein of the small subunit (mtSSU). Regarding the OXPHOS system, one subunit (Cyt*b*) from the *bc1*-complex or complex III (CIII), three (Cox1, 2 and 3) from the cytochrome *c* oxidase (COX) or complex IV (CIV), and three (Atp6, 8 and 9) from the ATP synthase are encoded in the mtDNA. The remaining subunits of the OXPHOS system complexes, the mitoribosome proteins, and the factors required to assemble these macrostructures are all encoded by the nuclear genome, synthesized in cytoplasmic ribosomes and imported into mitochondria. Therefore, efficient protein synthesis and complex assembly within this organelle require careful coordination to synchronize mitochondrial and cytosolic translation programs (3).

Translation of mitochondrial mRNAs occurs in mitoribosomes, whose composition and structure are adapted to translate mitochondrial mRNAs that lack a typical anti-Shine-Dalgarno element, and to synthesize highly hydrophobic membrane proteins (4). The understanding of

these adaptations and their evolution from yeast to humans was recently illuminated by high-resolution cryo-EM reconstructions of the yeast, porcine and human mitoribosomes (5–8). These structures confirmed that some proteins present in bacterial ribosomes have been lost, proteins with homologs in bacteria have substantial extensions, and the mitoribosome has acquired many additional proteins. The assembly lines of the yeast (9) and human mitoribosomes (10) are also starting to emerge and provide insight into the essentiality of mitoribosome proteins for mitoribosome assembly and function.

The yeast mitoribosome small subunit (mtSSU) contains an almost complete set of proteins with homologs in bacteria, with the single exception of bS20 (8). It additionally contains 14 mitochondria-specific proteins, 7 of which have homologs in the mammalian mitoribosome (8). A protein in the latter group is Cox24, the yeast homolog of MRPS38, recently renamed as mS38 (8). Yeast Cox24 was reported to participate in *COX1* mRNA splicing and also translation, as *cox24*-deleted strains carrying intronless mtDNA have attenuated Cox1 synthesis (11). However, the mechanism/s by which Cox24 could influence or regulate *COX1* mRNA-specific translation remained unexplored. Now that Cox24 has been recognized as the mtSSU mS38 protein, the intrigue regarding how it can modulate mRNA-specific translation has only increased.

In the present study, we have used strains carrying intronless mtDNA to analyze the role of mS38 in mitoribosome assembly and function, and its requirement for mRNA-specific translation. We have demonstrated that mitoribosomes lacking mS38 are capable of synthesizing all proteins, although at a strongly attenuated overall mitochondrial translation rate. Importantly, we show that mS38 is preferentially required for translation initiation of not only *COX1* but also *COX2* and *COX3* mRNAs. The mechanism does not directly involve mRNA-specific translational activators, but it involves functional interactions of mS38 with the 5′UTRs of *COX1*, *COX2* and *COX3* mRNAs. Mitoribosome loading onto these mRNAs can occur in the absence of mS38, but their translation is inhibited. Our results suggest that mS38 was acquired by the mitoribosome before or concurrently with the remodeling of the mRNA channel to facilitate the translation of mitochondrial transcripts. The influence of mS38 on the flexibility of elements forming the mRNA channel and the interaction of mS38 with the *COX1–2-3* mRNAs would be required for the efficient translation of these mRNAs. In this way, our data support the concept of mitoribosome-mediated translational regulation.

MATERIALS AND METHODS

Yeast strains and media

All *S. cerevisiae* strains used are listed in supplemental Table S1. The composition of the standard culture medium used is defined in the Supplemental material.

Antibodies

Several attempts to obtain antibodies against an mS38 peptide were unsuccessful. However, a working antibody against purified recombinant mS38 was obtained using the services of GenScript. The antibody, however, produced multiple crossreacting bands in immunoblotting assays (Supplementary Figure S3A). Therefore, a GST-tagged version of mS38 was generated. A list of all antibodies used in this study is presented in supplemental Table S2.

Characterization of the mitochondrial respiratory chain and oxidative phosphorylation system

Endogenous cell respiration was assayed in whole cells in the presence of galactose using a Clark-type polarographic oxygen electrode from Hansatech Instruments (Norfolk, UK) at 30°C as described (12).

Mitochondria were prepared from the different strains as described (13) and used for spectrophotometric assays performed at 24°C to measure KCN-sensitive COX activity and antimycin A-sensitive NADH cytochrome *c* reductase, as described (12).

The abundance of OXPHOS complexes in mitochondrial extracts obtained in the presence of 1% lauryl-maltoside was analyzed by Blue Native polyacrylamide gel electrophoresis (BN-PAGE) using a linear 3–12% acrylamide gradient gel (14).

In vivo mitochondrial protein synthesis

Mitochondrial gene products were labeled with [^{35}S]-methionine (7 mCi/mmol, Perkin Elmer) in whole cells at room temperature in the presence of 0.2 mg/ml cycloheximide to inhibit cytoplasmic protein synthesis (12). In most experiments, we used 10 μCi [^{35}S]-methionine for a final methionine concentration of 17.2 nM. In some time-course experiments, we used a mixture of labeled (2.5 μCi; 4.3 nM) + cold methionine (12.9 nM). When indicated, mitochondrial translation was inhibited by addition of 0.08 mg/ml puromycin and 40 mM cold methionine and samples were chased for the indicated times. Equivalent amounts of total cellular proteins were separated by SDS-PAGE on a 17.5% polyacrylamide gel, transferred to a nitrocellulose membrane and exposed to X-ray film.

Sucrose gradients

The sedimentation properties in sucrose gradients of mS38, translational activators and mitoribosomal proteins from total mitochondrial extracts were analyzed essentially as previously described (13,15) and are further described in the supplemental experimental procedures.

Analysis of mitochondrial polysomes

Yeast cells were grown in medium supplemented with 4 mg/ml chloramphenicol (CAP) for 3 h and in fresh medium for 1 h before proceeding with mitochondrial isolation as described (16–18). Mitochondria were further purified using a step sucrose gradient as described (19). Mitochondrial extracts were prepared in the presence of 0.8% sodium deoxycholate (NaDOC), 10 mM Tris–HCl pH. 7.5, 100 mM NH_4Cl, 20 mM $MgCl_2$ and 200 U of RNaseOUT (Thermo Fisher) and loaded onto 10 ml 10–30% sucrose gradients.

Downloaded from https://academic.oup.com/nar/article/47/11/5746/5436776 by UNAM Instituto de Investigaciones Biomédicas user on 20 October 2020

INFORME DE LABORES 2019

The gradients were centrifuged in an SW41 Ti rotor (Beckman) at 32 700 rpm during 2.5 h at 4°C. Subsequently, the gradients were fractionated using a BR-188 Density Gradient Fractionation System (Brandel). Aliquots of each of 28 fractions were used for immunoblotting analysis of mitoribosomal markers. The rest was used for RNA extraction, to analyze the presence of the 15S and 21S rRNAs, and *COX1 and COB* mRNAs by cDNA synthesis followed by RT-PCR amplification.

RNA analysis

Methods for RNA isolation and quantitative real-time polymerase chain reaction (RT-PCR) are described in the supplemental experimental procedures.

Statistical analysis

All of the experiments were done at least in triplicate. The data are presented as the means ± S.D. of absolute values or percentages of control. The values for the several parameters studied, obtained for WT and Δ*mS38* mutant strains, were compared by Student's *t*-test. $P < 0.05$ was considered significant.

RESULTS AND DISCUSSION

mS38 is a mitoribosome SSU protein specifically required for the efficient synthesis of mtDNA encoded COX subunits

Yeast Cox24 was initially reported to act in *COX1* mRNA splicing and translation (11), and subsequently to be the mitoribosome-specific mtSSU protein mS38 (8). How a mtSSU structural subunit participates in mRNA-specific translation is intriguing. To ascertain the mechanism involved, we utilized for all our experiments a Δ*mS38* strain carrying intronless mtDNA (I^0), to avoid the described effects on *COX1* mRNA splicing, and started by assessing its ability to support mitochondrial mRNA translation and cellular respiration.

As previously reported (11), the Δm*S38* I^0 strain was found to grow poorly in respiratory YPEG media (Figure 1A). Furthermore, endogenous cell respiration was 45% of WT (Figure 1B). The respiratory defect can be partially attributed to a decrease in the activity of CIII since NADH-cytochrome *c* reductase activity (NCCR) was 70% of WT (Figure 1B). However, the major contributor to the respiratory defect appears to be COX, whose activity was severely decreased to 20% of WT (Figure 1B), in agreement with the markedly low levels of assembled CIV (Figure 1C) and COX subunits (Figure 1D), detected in Δ*mS38* I^0 mitochondria. The levels of several COX assembly factors were not affected by the *mS38* mutation (Figure 1D). This is particularly relevant for Mss51, a *COX1* mRNA translation activator and Cox1 chaperone (16,20) since the *mS38* gene on chromosome XII of *S. cerevisiae* genome is 'head to head' with *MSS51* and, as they share regulatory elements (21), the *mS38* deletion could have affected *MSS51* expression.

To confirm that the OXPHOS biogenesis defect in the Δ*mS38* strain stems from a defect in mtDNA gene expression, we performed *in vivo* mitochondrial translation experiments by following the rate of incorporation of [^{35}S]-methionine into the different translation products at increasing pulse times. Our results showed that Δ*mS38* cells could synthesize mitochondrial proteins albeit not efficiently (Figure 1E and Supplementary Figure S1). In the experiment presented in Figure 1E, the labeling reaction was supplemented with cold methionine to slow down and better estimate the rate of [^{35}S]-methionine incorporation into newly synthesized polypeptides. As previously reported, the Δ*mS38* mutation most specifically affected synthesis of Cox1 (11), but also of Cox2 and Cox3 (Figure 1E and Supplementary Figure S1). The incorporation of [^{35}S]-methionine into Cox1 in the mutant was ∼20% of WT, even at the later time points (Figure 1E and Supplementary Figure S1). For Cox2 and Cox3, labeling was ∼30–70% of WT after 1h of pulse-labeling (Figure 1E). For cytochrome *b* and Var1, although the rate of synthesis in the Δ*mS38* mutant was initially lower than in the WT, in the longer pulses these proteins reached WT labeling saturation (Figure 1E and Supplementary Figure S1).

The poor labeling of COX subunits in the Δ*mS38* mutant strain could be due to an effect of the *mS38* mutation on the rate of protein synthesis or turnover. However, the fact that incorporation of [^{35}S]-methionine into Cox1, Cox2 and Cox3 is undetectable after short pulses (Figure 1E, 2.5 min) and that the residual proteins synthesized after 1 h pulse are stable in chase experiments (Supplementary Figure S2A) argues against fast turnover. Likewise, the protein synthesis defect in Δ*mS38* cells is not due to a discrepancy in mRNA levels, as Δ*mS38* I^0 mitochondria had wild-type levels of *COX2* and *COB* mRNAs, and even enhanced levels of *COX1* mRNA (Figure 1F).

mS38 is required for translation initiation of *COX1*, *COX2* and *COX3* mRNAs

The general decrease in mitochondrial protein synthesis rate in the absence of mS38 could be attributed to a change in mtSSU structure near the decoding center and the mRNA exit channel, as well as to the absent intersubunit bridges that involve mS38 (see below). However, translation of a subset of mRNAs, *COX1*, *COX2* and at a lower extent *COX3*, is deeply affected. These mRNAs might undergo specific interactions with the mS38-containing mtSSU that are missing or attenuated in *ΔmS38* mitochondria.

To test the direct involvement of mS38 in the translation of *COX1*, *COX2* and *COX3* mRNAs, we used strains carrying a mitochondrion-encoded reporter gene (20) in either WT or Δ*mS38*. The strains are deleted for the nuclear *ARG8* gene, and the reporter is a recoded version of *ARG8,* termed *ARG8^m,* that encodes a matrix-localized biosynthetic enzyme, which allows us to look directly at mitochondrial translation by scoring the growth of yeast in the absence of arginine. In the strain YC162, the *COX1* coding sequence was completely replaced by *ARG8^m* (*cox1*Δ::*ARG8^m*). Similarly, *ARG8^m* gene replaced the *COX2* coding sequence in the strain RGV139 (*cox2*Δ::*ARG8^m*), the *COX3* coding sequence in the RGV140 strain (*cox3*Δ::*ARG8^m*), and as a control, the *COB* coding sequence in the RGV137 strain (*cob*Δ::*ARG8^m*) (Figure 2A). In these strains, *ARG8* mRNA translation is dependent on the 5′- and 3'- un-

INFORME DE LABORES 2019

translated regions (UTRs) of *COX1*, *COX2*, *COX3* and *COB* respectively (20). When carrying a WT allele of *mS38,* Arg8^{m} is synthesized in all strains and supports arginine-independent growth (Figure 2B). However, the Δ*mS38* mutation affected capacity of the strains to grow in the absence of exogenous arginine (Figure 2B) due to the general translation defect observed in the Δ*mS38* strain (Figure 1E). The deleterious effect was particularly prominent in the Δ*cox1* and Δ*cox2* strains, less prominent in the Δ*cox3* strain, and markedly less severe in the Δ*cob* control strain (Figure 2B). The growth results correlate well with the steady-state levels of Arg8^{m} detected in each of these strains (Figure 2C). These results indicated that whereas mitochondrial translation in mS38-less mitoribosomes is generally compromised, they are preferentially impaired in translation initiation of *COX1*, *COX2* and *COX3* RNAs.

The mS38-dependent Cox1 synthesis defect is not the result of Cox1 translational regulation

Synthesis of Cox1 is coupled to its assembly into COX by a translational negative feedback loop in which Mss51 plays an essential role (16,20). Mss51 acts on the *COX1* mRNA 5′-UTR to promote translation initiation and forms a complex with newly synthesized Cox1 that is stabilized by two specific chaperones, Cox14 and Coa3. Interactions with these chaperones trap Mss51 in a ∼450 kDa Cox1 pre-assembly complex until Cox1 is matured or interacts with its assembly partners (15,20,22–24). When this occurs, Mss51 is released from its interaction with the Cox1 polypeptide, forms a ∼120 kDa recycling complex with the Hsp70 chaperone (Ssc1) and becomes available to promote new rounds of *COX1* mRNA translation (15). To further test whether the decrease in Cox1 synthesis that we observed in the *mS38* mutant is due to a primary defect in translation and not the result of Cox1 synthesis downregulation, we followed two strategies to bypass feedback regulation of *COX1* mRNA translation. First, we previously reported that additional copies of wild-type *MSS51* or a single copy of the mutant allele *mss51*^{F199I} increases Cox1 synthesis in COX assembly mutants in which Cox1 synthesis is downregulated (12,16). As shown in Figure 2D, these strategies did not alleviate the Cox1 synthesis defect observed in the Δ*mS38* strain. Second, we introduced a Δ*cox14* mutation in the Δ*mS38* strain. In most COX assembly mutants, the absence of Cox14 destabilizes the complex of sequestered Mss51 with newly synthesized Cox1 and renders Mss51 available for translation, thus bypassing the regulatory feedback mechanism (16). As shown in Figure 2E, the absence of Cox14 suppressed the Cox1 synthesis downregulation in the control COX mutant strain Δ*shy1* but not in the Δ*mS38* strain. *SHY1* codes for the SURF1 homolog of yeast, a known conserved COX assembly factor (12). The additional Δ*cox14* mutation was not found deleterious for the residual Cox1 synthesis capacity retained by the Δ*mS38* strain (Figure 2E), as previously reported (11). Instead, using pulse-chase assays, we found that as in the Δ*cox14* strain, newly synthesized Cox1 is also very susceptible to degradation in the double mutant strain (Supplementary Figure S2A).

We subsequently followed the sedimentation pattern of Mss51 in sucrose gradients in Δ*cox14,* ΔmS38 and the double Δ*cox14*Δ*mS38 strain.* In WT mitochondria, most Mss51 sediments in the ∼450 kDa Cox1-preassembly complexes, whereas in Δ*cox14* mitochondria it sediments in the 120 kDa Mss51 recycling complex ((15) and Figure 2F). In the absence of mS38, only traces of Mss51 sediment in the ∼450 kDa complex, and the additional absence of Cox14 exerts an epistatic effect (Figure 2F). Furthermore, mS38 and Mss51 do not interact genetically, as overexpression of each protein does not compensate for the absence of the other in terms of protein synthesis (Figure 2D) and respiratory growth (Figure 2G).

We concluded that the Cox1 synthesis defect in the Δ*mS38* strain does not result from negative-feedback translation regulation, but from a *COX1* mRNA translation impairment affecting initiation according to the Arg8^{m} reporter experiments presented earlier, that can be extended to *COX2* and to a lesser extent also to *COX3* mRNAs.

Specific attenuation of the synthesis or assembly of mtDNA-encoded subunits has been reported in strains carrying point mutations in some mtLSU proteins, although the mechanisms involved differ from those underlying the Δ*mS38* phenotype. Temperature-sensitive point mutations in the mtLSU protein bL34 (such as the highly conserved R95 residue to W) result in specific alterations in the synthesis of Cox1 and Cox3, but normal Cox2 synthesis (25). The conserved bL34-R95 residue is in close contact with the 21S rRNA. bL34 also interacts with uL23 and uL24, two components of the polypeptide exit tunnel that was modified from bacteria to become adapted for the passage of hydrophobic polypeptides (5). It has been proposed that the bL34 mutations could slightly modify the exit tunnel cavity and then challenge or block the path for the most hydrophobic polypeptides such as Cox1 and Cox3 (25). Differently, strains expressing variants of mL38, a component of the mtLSU central protuberance, carrying point mutations in its phosphatidylethanolamine-binding protein (PEBP)-like domain (*mL38*^{Y275}) undergo normal synthesis of all proteins, even enhanced for Cox1, but have impaired COX assembly (26). The mL38-ts mutation might affect the functional integrity of Coa3, Cox14 and Mss51, three Cox1-binding proteins essential for Cox1 elongation, membrane insertion and stability (26,27).

The phenotype of Δ*mS38* is also reminiscent of that of Δ*mss116.* Mss116 is a DEAD-box helicase that plays distinct roles in *COX1* mRNA splicing, mtLSU biogenesis, and mitochondrial *COX* mRNA-specific translation, predominantly affecting Cox1 synthesis (28). The absence of Mss116 renders unstable the pentatricopeptide repeat protein Pet309, a *COX1* mRNA-specific translational activator, thus explaining the Cox1 synthesis defect. Cox14, Coa3, Mss51 and Mss116 were found stable in Δ*mS38* mitochondria (Figure 1D).

Therefore, mS38 is a mtSSU protein that could directly influence the selection of mitochondrial mRNAs for translation. A potential mechanism could involve mitoribosome heterogeneity, with mitoribosome pools containing or not mS38. However, this possibility is tempered by the fact that over-expression of mS38 in wild-type cells did not affect the synthesis rate of Cox1–3 or any other protein (Supplementary Figure S2B), as it would be expected for a mitoribosomal protein present in all mitoribosomes. Furthermore,

INFORME DE LABORES 2019

the cryo-EM structural reconstruction of the yeast mitoribosome did not display any heterogeneity involving mitoribosomal proteins (8).

Mitoribosomes are assembled and more abundant in mS38-depleted mitochondria

Recently, mS38 has been identified as a mtSSU subunit by cryo-EM analysis (8). However, the fact that the Δ*mS38* strain can perform mitochondrial translation, despite at a low rate, implies that mitoribosomes are assembled and somehow functional in the absence of mS38.

To further explore the role mS38 plays in mitoribosome biogenesis and function, we generated a polyclonal antibody against purified recombinant mS38 (Supplementary Figure S3A) that allowed us to determine that in wild-type mitochondria, all endogenous mS38 co-sediments with mtSSU markers (Figure 3A). Similarly, a near fully functional GST-tagged version of mS38 (Supplementary Figure S3B–D) co-sediments with the mtSSU and monosome fractions (Figure 3B) when using extracts prepared in the presence of Mg^{2+}. However, when mtSSU and mtLSU are separated by addition of EDTA, a portion of mS38-GST accumulates in a non-assembled pool (Figure 3C), suggesting that under these extraction conditions the large GST tag could destabilize the association of mS38 with the mtSSU. Association of mS38-GST with the mtSSU was further tested by treatment with high concentrations of RNase to disrupt ribosomal integrity. The RNAse treatment resulted in the accumulation of all mS38 in the smaller complex (Figure 3C), further confirming that mS38 is an integral component of the mtSSU.

To probe for a possible mitoribosome assembly defect, mitochondrial proteins were extracted from isolated WT mitochondria using 0.8% digitonin and 25 mM KCl and analyzed by sucrose gradient sedimentation. The sedimentation of the 74S monosome, the 54S mtLSU, and the 37S mtSSU were similar in the WT and Δ*mS38* strains in extracts prepared either in the presence of 0.5 mM $MgCl_2$ to preserve the intactness of the monosome or in the presence of 5 mM EDTA to promote subunit dissociation (Figure 3B and C). To obtain a comprehensive picture of potential differences in the composition of assembled mitoribosomal subunits, sucrose gradient fractions from Figure 3C, corresponding to the mtSSU were methanol/chloroform precipitated and analyzed by mass spectrometry (supplemental Table S3). Proteins mS38, mS47 and mS48 were not detected in any of the samples. The rest of the mtSSU proteins were detected in fractions from both WT and Δ*mS38* mitochondrial extracts, which indicates that the absence of mS38 does not prevent incorporation of the remaining proteins into the mtSSU.

To compare the accumulation of mitoribosome protein markers in WT and Δ*mS38* extracts, we ran in parallel, in a single gel, samples from the relevant sucrose gradient fractions (Figure 3D). We determined that the levels of mtSSU and mtLSU proteins were increased in the corresponding fractions and in the fractions where the monosome peaks. In agreement, the steady-state levels of mitoribosome proteins indicated that the concentrations of two mtSSU and five mtLSU proteins tested were enhanced in *ΔmS38* cells compared to the WT control (Figure 3E). Similarly, the steady-state levels of 15S and 21S rRNAs were also found ∼1.5–2-fold increased in Δ*mS38* mitochondria (Figure 1F). We concluded that the steady-state levels of mS38-less mitoribosomes are enhanced, probably to attempt compensating for their inefficient functional performance.

Mitoribosome loading onto *COX1* mRNA can occur in the absence of mS38

A failure of translational activators to bind their specific RNA is expected to prevent the proper mRNA loading onto the mitoribosome (29). To assess whether the absence of mS38 limits the mitoribosome-*COX1* mRNA association, we used highly purified mitochondria from WT and Δ*mS38* I^0 strains, both carrying a null allele of the unspecific mitochondrial nuclease *nuc1*, to avoid RNA degradation during sample processing, as reported (29). Yeast cells were grown in chloramphenicol (CAP) for 3 h and in fresh medium for 1 h prior to mitochondrial isolation (Figure 4A). The CAP treatment allows accumulation of cytoplasmically-synthesized proteins required for mitoribosome assembly and mitochondrial gene expression, which results in a robust increase in the proportion of mito-polysomes and of mitochondrial protein synthesis (16,17,28). Mitochondrial extracts were prepared in the presence of 0.8% NaDOC, 10 mM Tris pH 7.5, 100 mM NH_4Cl, 20 mM $MgCl_2$ and 200 U of RNaseOUT, and fractionated in sucrose gradients. Aliquots of each fraction were used for immunoblot analysis of mitoribosomal markers. The rest was used for RNA extraction and the presence of the 21S and 15S rRNAs, and the *COX1 and COB* mRNAs analyzed by cDNA synthesis followed by quantitative RT-PCR amplification (Figure 4A). Polysomes were detected in the two strains analyzed (Figure 4B). However, they were dramatically decreased in Δ*mS38* mitochondria compared to WT. In our experimental conditions, in both strains, all *COX1* and *COB* mRNAs were found cosedimenting with mitoribosomal particles and not in free pools (Figure 4B). In WT mitochondria, the proportion of *COX1* and *COB* mRNAs detected in the mtSSU was lower than in the monosome and polysome fractions (Figure 4B). On the contrary, in Δ*mS38* mitochondria, the proportion of *COB* and *COX1* mRNAs was higher in the mtSSU and monosome, and attenuated in the polysome fractions, indicating a general role of mS38 in translation. The proportion of *COX1* mRNA on Δ*mS38* polysome fractions was particularly attenuated (Figure 4B), which explains why only traces of newly synthesized Cox1 are detected in mitochondrial protein synthesis experiments (Figure 1E).

Using similar experiments, we previously reported that mitoribosome loading onto *COX1* mRNA could occur in the absence of Pet309 or Mss116 (28). However, the *COX1* mRNA was not detected in polysomes, thus supporting the requirement of Pet309 and Mss116 for *COX1* mRNA translation initiation (28). Similarly, the results presented here indicate the mS38 is not required for the loading of *COX1* mRNA on the mtSSU and the monosome, but rather for its translation.

The mRNA molecules in the cell often assume a secondary and a tertiary structure that might be tight for some

genes, and loose for others. For translation to proceed, such structure must first allow ribosome binding and then needs to be threaded through the ribosome, thus providing an opportunity to regulate the translation efficiency of mRNAs (30,31). The 5′-UTRs of *S. cerevisiae* mitochondrial mRNAs are highly variable in length, from 54 nt for *COX2* to 954 nt for *COB*. Their structures have not been determined *in vivo*, where RNA-specific binding proteins are expected to modify them. However, models determined *in silico* by applying free energy rules using the *mfold* web server algorithms have shown that the secondary structures of all naked 5′-UTRs are complex (28). According to these structures, the *COX1* and *COB* 5′-UTRs contain convoluted stem–loops and *COX2* has the shorter and perhaps the simplest 5′-UTR. Although a single short stable hairpin can inhibit ribosome loading at the 5′-end of an mRNA (31), these models suggest that there is more than differences in 5′-UTR arrangements behind the disfavored *COX1–3* mRNAs translation observed in the absence of mS38.

INFORME DE LABORES 2019

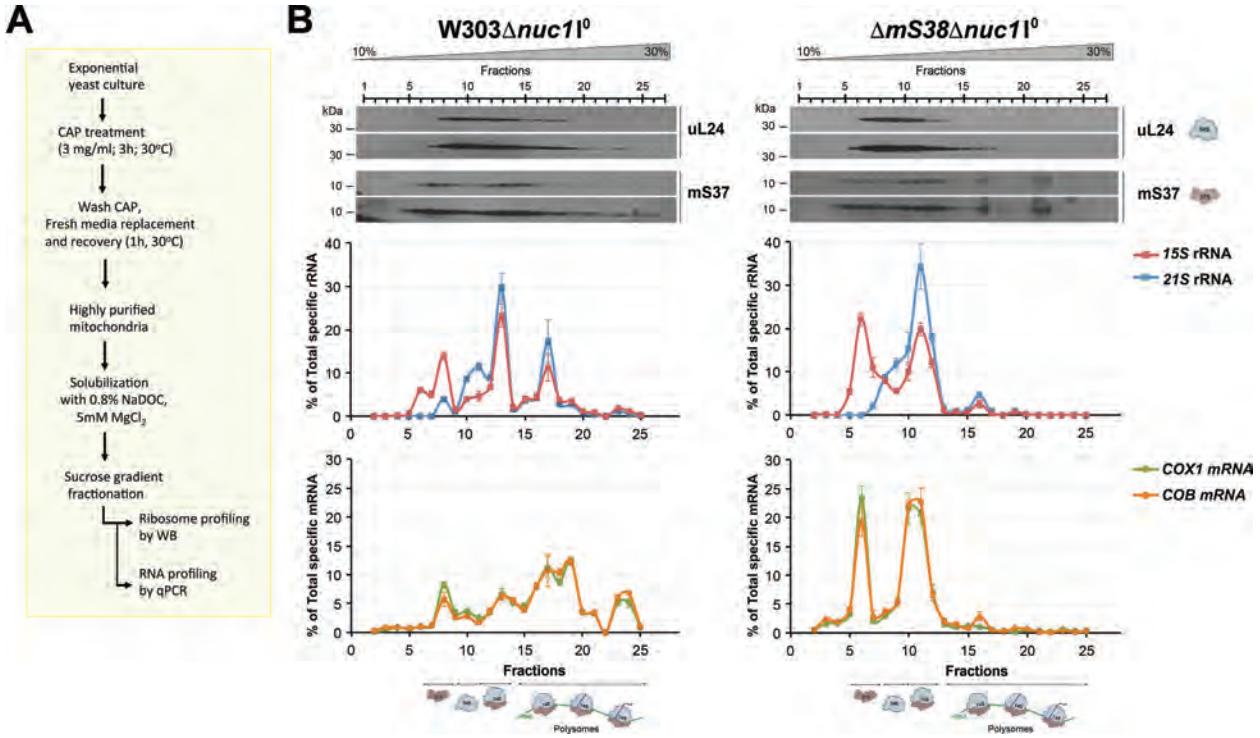

Figure 4. In the absence of mS38, *COX1* mRNA is loaded onto the mitoribosomes but is poorly detected in polysomes. (**A**) Scheme depicting the experimental protocol for mito-polysome profiling. (**B**) Sucrose gradient sedimentation analyses of mitoribosomal subunits, monosomes, and polysomes in extracts obtained from mitochondria isolated from the indicated strains. One representative image of three independent experiments is shown. The graphs in the lower panels represent the relative amount of the indicated rRNAs and mRNAs in the gradient fractions, estimated by RT-qPCR. The bars represent the average ± SD of three independent repetitions.

The preferential inability of mS38-less mitoribosomes to synthesize Cox1 is independent of the *COX1* mRNA-specific translational activators

Next, we investigated whether mS38 genetically or physically interacts with the *COX1* mRNA translational activators, Mss51, Mss116, Pet309, Mam33 and Pet54, which could facilitate the recruitment of the *COX1* mRNA to the mtSSU.

As mentioned above, the five proteins are required for intron splicing on the *COX1* transcript, a function that has also been proposed for mS38 (11), and have been shown to act on the *COX1* mRNA 5′-UTR to promote translation (16,20,28,32). Moreover, Pet54 is a multifunctional protein that acts primarily as a translational activator of *COX3* mRNA and plays a role in Cox1 synthesis possibly by rendering Mss51 competent as a *COX1* mRNA translational activator (33).

We started by testing whether overexpression of each translation activator suppresses the Δ*mS38* phenotype. Extra copies of *MSS51* (Figure 2D-G and Supplementary Figure S5C), *MSS116* (data not shown), *MAM33* (Supplementary Figure S5C) or *PET54* (Supplementary Figure S4F-G) failed to restore the respiratory growth or protein synthesis defects observed in the Δ*mS38* strain. Furthermore, the steady-state levels of endogenous Mss51 and Mss116 (Figure 1D) and functional tagged Pet54, Pet309 and Mam33 (Figure 5A, Supplementary Figure S4A and B and Supplementary Figure S5A and B), were not affected by the presence or absence of mS38. Additionally, no additive effect on the rate of Cox1 synthesis was observed in a double null mutant strain *Δpet54ΔmS38* compared to the single mutant *ΔmS38* (Supplementary Figure S4E).

Subsequently, we examined the association of the translational activators with mitoribosomes using sucrose gradient sedimentation analyses. A small fraction of Mss51 was found to co-sediment with the mtSSU in mitochondrial extracts prepared in the presence of EDTA from WT or from Δ*mS38* reconstituted with a GST-tagged version of mS38 (Figure 5B). The absence of mS38 abolished the co-sedimentation of Mss51 with 37S mitoribosomal particles (Figure 5B). This observation could suggest an mS38-mediated interaction of Mss51 with these particles. Alternatively, the Mss51-mitoribosome interaction is most probably mediated through newly synthesized Cox1 and then abolished in Δ*mS38* mitochondria in which Cox1 synthesis is strongly attenuated. To solidify this concept we performed similar experiments using strains carrying a Δ*cox11* mutation, since we have previously shown that the interaction of Mss51 with the mitoribosome is particularly prominent in strains deficient in Cox1 maturation or assembly, such as Δ*cox11,* in which Cox1 synthesis is stalled (15). Consistent with our hypothesis, that Mss51 could interact with the ribosome through newly synthesized Cox1, we observed that Mss51 co-sedimented with the 37S mitoribosome in Δ*cox11ΔmS38* mitochondrial extracts (Figure 5B). Also, a functional FLAG-tagged version of Pet54 (Supplementary Figure S4A and B) was found to co-sediment with 37S

INFORME DE LABORES 2019

(Figure 5C and D) and 74S mitoribosomal particles (Figure 5D), although its sedimentation properties were not altered in the absence of mS38 (Figure 5C). Immunoprecipitation studies using a strain expressing *PET54-FLAG* (Figure 5E and F) further confirmed that the interaction of Pet54 with mitoribosomes is independent of mS38. Lastly, no sedimentation with the mitoribosomes was observed for a Flag-tagged functional version of Mam33 (data not shown).

As an additional relevant observation, we noted a different sedimentation pattern in sucrose gradients for Mss51 extracted from strains expressing wild-type mS38 or mS38-GST. The interaction of mS38-GST with the mitoribosome is labile, and a portion is removed from the mitoribosome particle in the presence of EDTA (Figures 3C and 5B), suggesting that the fusion protein may not be fully functional. In fact, although mS38-GST fully supports respiratory growth (Supplementary Figure S3B) and largely restores overall mitochondrial protein synthesis, the synthesis of Cox1 (and at a lesser extent also Cox2 and Cox3) is not fully restored (Supplementary Figure S3D and 7D). For this reason, a portion of Mss51 is trapped in the Mss51 recycling complex (Figure 5B). Importantly, the results obtained with the mS38-GST strain further support the predominant requirement of mS38 for the synthesis of COX subunits.

Overall, from the results presented in this section, we conclude that the preferential inability of mS38-less mitoribosomes to synthesize Cox1 is independent of the *COX1* mRNA-specific translational activators. The case reported here differs from other instances in which interplay between translational activators and mitoribosome subunits, has been reported. Such was the case of mutations in bS6 (former Mrp17) reported to compensate for a C-terminal truncation of Pet122, a *COX3* mRNA-specific translational activator (34).

The absence of mS38 modifies the decoding center in the mtSSU

In the mtSSU, mS38 interacts with the 15S rRNA helix 44 ((8) Figure 6A-B). This helix is an element present in all ribosomes that forms several inter-subunit bridges, which regulate the relative movement of the subunits, and is part of the decoding center. In bacteria, the lower part of the helix is rigid and anchored by bS20, whereas the middle part forms major intersubunit bridges, and the upper part is flexible being involved in tRNA translocation (35). These H44-involving bridges are also present in the yeast mitoribosome, which contains nine mitochondria-specific bridges, one of which involves mS38 (8). Specifically, mS38 aa residues 101–102, 105–106 and 109–110 connect with 21S rRNA helices H70 (nt 1832–1834), H71 (nt 1859–1860), H62 (nt 1643–1644) and H67 (nt 1739–1741 and 1874–1877), respectively. It has been proposed that the extensive intersubunit bridges may restrain the movement of the yeast mitoribosomal subunits (8). The lack of mS38 in yeast is then predicted to affect subunit association. Additionally, the upper part of H44 is largely more flexible in mitochondrial compared to bacterial ribosomes and its movement is mainly constrained by the presence of mS38. As a consequence, in mS38 absence, H44 is likely to be unrestricted, and decoding could be affected, due to loss of H44 base pairing.

To determine how the absence of mS38 affects H44 near the decoding center we exploited the fact that aminoglycoside antibiotics such as paromomycin bind to the 15S rRNA in the aminoacyl-tRNA site (A-site) to cause misreading of the genetic code and inhibit translocation. Studies in bacteria comparing the 30S subunit with and without paromomycin (36) confirmed an earlier model (37) in which bases 1492 and 1493 of the 16S rRNA are in a position to monitor the codon:anticodon fit via hydrogen bonding to the codon:anticodon duplex. Paromomycin alters the structure of the 16S rRNA to mimic conditions of a perfect codon:anticodon fit, so that incorrect aminoacyl-tRNAs may be selected. In yeast mitochondria, resistance to paromomycin (Par^R) arises from a single base change in the 15S rRNA H44 region ((39), Figure 6B). This mutation causes a base pair mismatch, which is likely to increase the flexibility of the decoding center. When the Δ*mS38* mutation was introduced into a Par^R mtDNA background strain, it did not affect respiratory growth of the resulting strain in regular media (Figure 6C) or its mitochondrial protein synthesis capacity (Figure 6D, E and Supplementary Figure S6) compared to the Par^S background. However, the double mutation conferred greater resistance to exogenous paromomycin than the Par^R mutation alone (Figure 6C). Notably, the lack of mS38 is associated with strong thermosensitivity. At 37°C, whereas WT mitochondrial translation was unaffected, the synthesis of Cox1, Cox2 and Cox3 was barely detected in Δ*mS38* Par^S or Par^R backgrounds (Figure 6E), and therefore resistance to exogenous paromomycin was eliminated (Figure 6C). An increase in temperature could also affect the decoding region structure, as reported for *Escherichia coli* ribosomes (38).

Together, these results indicate that the absence of mS38 modifies the decoding center in the mtSSU.

The mS38 N-terminus is sufficient to support SSU assembly and normal synthesis of all proteins other than COX subunits

Saccharomyces cerevisiae mS38 is a 111-aa protein that contains a predicted 15-aa N-terminal mitochondrial targeting sequence (MTS, shadowed in yellow in Figure 7A). The C-terminal aa 81–111 form an arginine-lysine-rich domain (shadowed in red in Figure 7A) conserved from yeast to human. As seen in the cryo-EM structure (8), from the C-terminus, this domain forms a helix that runs parallel to the 15S rRNA H44 at the subunit interface and contains the residues involved in intersubunit bridge formation ((8) and Figure 6B). mS38 then bends, probably restricting the movement of the upper part of H44 that forms the decoding center, and subsequently forces the mS38 N-terminus to protrude into the 15S rRNA (8). The structure of the N-terminal portion of the protein (aa 15–80), which is highly divergent (Figure 7A), was not resolved by cryo-EM. The most probable model of the structure of the full mature protein (aa 16–111), obtained using Quark (Supplementary Figure S8), is shown in Figure 7B. Quark is a computer algorithm for *ab initio* protein structure prediction and protein peptide folding, which aims to construct the correct protein 3D model from amino acid sequence only (39).

(**A**) Localization of the mRNA path in the mtSSU, the proteins located at the entrance and exit channels, as well as mS38, the 15S rRNA helix 44 and the decoding center in the yeast mitoribosome structure (PDB 5MRC) (8). (**B**) Close-up of the mS38-h44 region in the mtSSU structure. The location of the paromomycin-resistance mutation (Par^R) and key amino acids in mS38 are indicated. (**C**) Serial dilutions growth test of the indicated strains in complete fermentable (YPD) or non-fermentable (YPEG) solid media. The effects of paromomycin supplementation and incubation at 37°C were also tested. Pictures were taken after two days of growth or the time indicated. (D, E) *In vivo* mitochondrial protein synthesis of the indicated strains performed as in Figure 2D. In (**D**), the intronless WT (W303 I^0) and Δ*mS38* strains with mtDNA carrying the paromomycin-resistant mutation (Par^R) were incubated or not overnight (ON) in the presence of 4 mg/ml of paromomycin (Par) and pulsed with ^{35}S-methionine for 10 or 30 min. In (**E**), the strains with mtDNA carrying paromomycin-sensitive or resistant 15S rRNA sequences were incubated at 30°C in the presence or absence of 4 mg/ml paromomycin for 2 hrs or 37°C and pulsed for 10 minutes with ^{35}S-methionine in the same conditions.

Once acquired by the mitoribosome, mS38 probably co-evolved with H44 and the downstream 3'-15S rRNA sequences that mark the mRNA exit path. As an example, the mS38 C-terminus is longer in human than in yeast (Figure 7A). Coevolution was tested by assessing heterologous complementation of the *S. cerevisiae* Δ*mS38* strain with *mS38* from human (also known as AURKAIP1) and several yeast and plant species (Supplementary Figure S7A-C). Human mS38 was unable to substitute for the *S. cerevisiae* protein even when the *S. cerevisiae* mS38 N-terminus was co-expressed (Supplementary Figure S7C). Among fungi, mS38 from *Kluyveromyces lactis* and *Yarrowia lipolytica* complemented the *S. cerevisiae* Δ*mS38* strain. Among plants, mS38 from *Arabidopsis thaliana* did it only partially, and that of *Oriza sativa* did not (Supplementary Figure S7A). These results highlight the structural diversity of mitoribosomes across evolution.

In an attempt to dissect the roles of the mS38 N- and C- termini, each half of the protein was expressed in the Δ*mS38* strain. Expression of either mS38 N-domain (aa 1–81) or mS38 C-domain (aa 1–15+81–111), both containing the 15-aa N-terminal mitochondrial targeting sequence, largely restored the respiratory growth defect of the Δ*mS38* strain (Figure 7C) by repairing its general mitochondrial protein synthesis deficiency (Figure 7D). However, translation of *COX1*, *COX2* and *COX3* mRNAs remained slightly inefficient in the $mS38^{1–81}$ strain and more attenuated, particularly *COX1* mRNA translation, in the

INFORME DE LABORES 2019

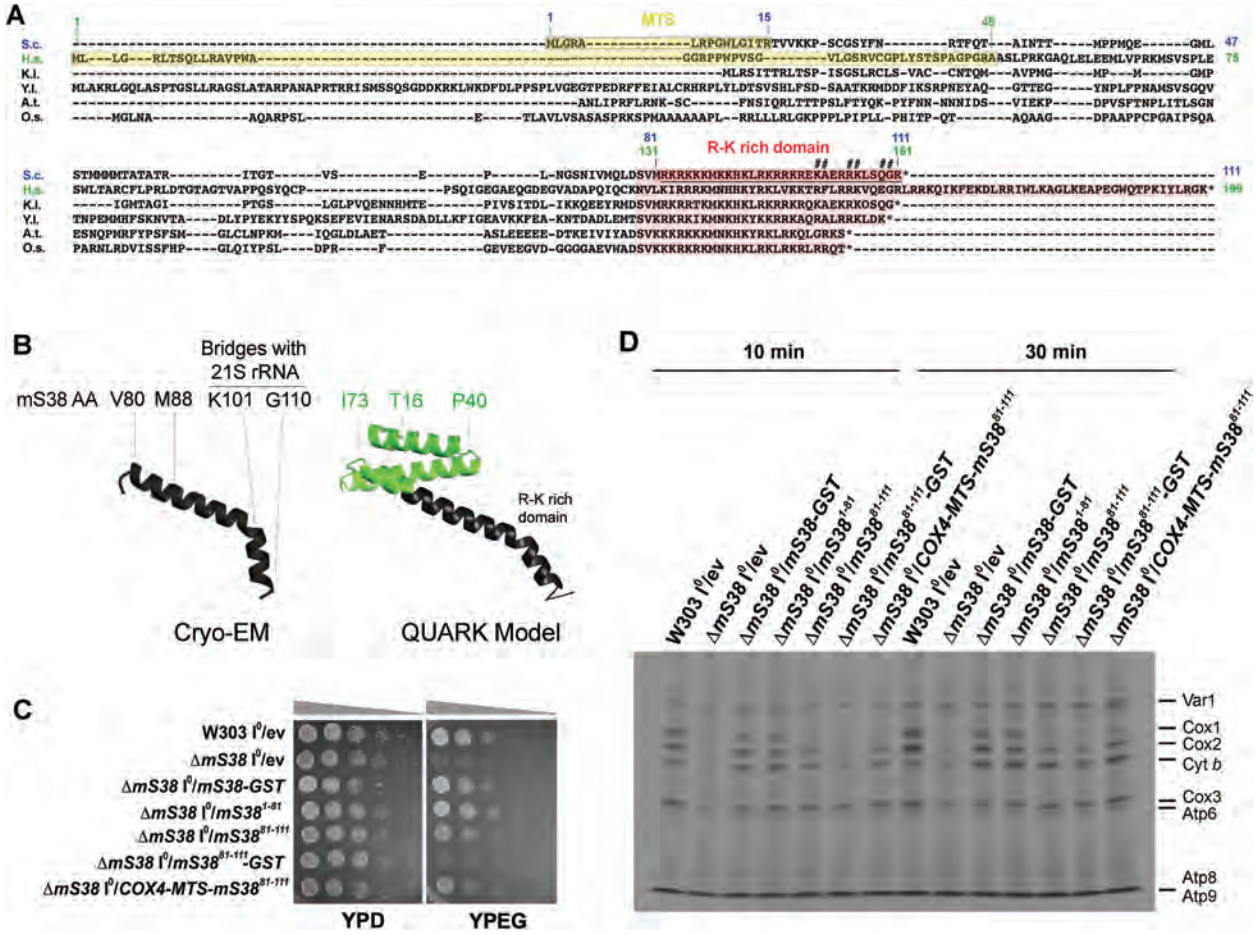

Figure 7. The N- and C-terminal portions of mS38 perform different roles in ribosome assembly and mRNA-specific translation. See also Supplementary Figures S7 and S8. (**A**) Alignment of mS38 sequences from *Saccharomyces cerevisiae (S.c.), Homo sapiens (H.s.),* other yeasts (*Kluyveromyces lactis*—K.l- and *Yarrowia lipolytica*—Y.l.) and plants (*Arabidopsis thaliana*—A.t., *Oriza sativa*—O.s.). The mitochondrial targeting sequence (MTS) in *S.c* and *H.s.* are marked in yellow. The arginine-lysine (R-G)-rich domain present in the C-terminus of all proteins is labeled in red. Numbers in blue indicate amino acids (aa) in the *S. cerevisiae* protein and numbers in green, amino acids in the human protein. The underlined region in *S. cerevisiae* mS38 is the region that was resolved in the cryo-EM structural reconstruction by (8). The # symbol indicates residues in *S. cerevisiae* mS38 involved in the formation of intersubunit bridge mB3 with elements of the 21S rRNA (8). Bridge mB3 is exclusive of mitochondrial ribosomes but conserved from yeast to mammals. (**B**) Structure of *S. cerevisiae* mS38 as obtained by cryo-EM including amino acids 80–111 (8) and a model of the whole mature protein (aa 16–111) obtained using Quark, a computer algorithm for *ab initio* protein structure prediction (39). Key amino acid residues are indicated. (**C**) Serial dilutions growth test of the indicated strains in complete media containing fermentable (YPD) or non-fermentable (YPEG) carbon sources. Pictures were taken after two days of growth at 30°C. (**D**) *In vivo* mitochondrial protein synthesis using the indicated strains and performed as in Figure 2D following ^{35}S-methionine pulses of the indicated increasing times.

mS38$^{81–111}$ strain (Figure 7D). Similar results were obtained using a strain in which mS38$^{81–111}$ contained the first 15 aa in mS38, predicted to form its mitochondrial targeting sequence (MTS), or when a COX4 MTS was used instead (Figure 7D). In the mS38$^{1–81}$ strain, the stability of newly synthesized polypeptides was as in the wild-type (Supplementary Figure S7D), which suggested that the potential presence of large amounts of aberrant proteins resulting from compromised translational fidelity unable to engage in OXPHOS complex assembly could be disregarded.

Together, the data presented in this section indicates that the N- and C-terminal portions of mS38 are each sufficient to functionally stabilize the mitoribosome and facilitate the translation of most mRNAs, including *COX2* and *COX3*. However, the N-terminal portion of mS38, which according to the structure would be expected to contact mtSSU elements that could influence the transit of mRNA throughout the channel, near the exit site, is particularly important for the translation of *COX1* mRNA.

CONCLUSION

A requisite property of all ribosomes is their ability to translate genetic information into polypeptides in an accurate and rapid manner. The SSU elements that ensure translation fidelity in bacteria are conserved in mitochondrial and eukaryotic ribosomes, although some adaptations have occurred. In the mitoribosome, these adaptations include the remodeling of the rRNA H44 and surrounding proteins. The mitochondrion-specific SSU protein mS38 was acquired to stabilize the upper part of H44 where the decoding center is located and to establish the critical mitoribosome-specific intersubunit bridge mB4 with the mt-LSU rRNA

INFORME DE LABORES 2019

H71. In this work, we report that *S. cerevisiae* mS38 plays an additional fundamental role in the selection of mRNAs that will be translated.

Our data show that although the absence of mS38 in *S. cerevisiae* attenuates mitochondrial protein synthesis globally, it particularly prevents efficient initiation of *COX1, COX2,* and *COX3* mRNA translation.

The analysis of eukaryotic and bacterial ribosomes across species might provide clues regarding mS38 function. Although mS38 is a mitoribosome-specific protein, it has been noticed by Desai and colleagues (8) that the location and structure of mS38 C-terminus resembles eL41, which is more strongly associated with the eukaryotic SSU 40S subunit than with the LSU 60S subunit and forms a eukaryotic-specific intersubunit bridge (eB14) that stabilizes the monosome (8). Therefore, eL41 and mS38 could be the products of convergent evolution. eL41 is not essential, but its absence reduces the binding efficiency of 60S subunits to translation pre-initiation complexes and also decreases peptidyltransferase activity while enhancing translocation efficiency (40). However, no effect of eL41 on selective mRNA translation has been so far reported.

In bacteria, resolution of the structure of the *Mycobacterium smegmatis* 70S ribosome has revealed the existence of a previously unknown protein, bS22, absent in the *E. coli* ribosome, which folds in a manner and occupies a location beneath the mRNA channel similar to mS38, thus indicating a common evolutionary origin (41). Like mitochondrial mS38, mycobacterial bS22 is rich in arginines and lysines, interacts with the rRNA H44 and probably contributes to its stabilization during translocation of tRNAs. Moreover, it has been proposed that contacts of bS22 with H45 might modify the mRNA channel near its exit site immediately upstream of the anti-Shine-Dalgarno sequence (41). Canonical translation initiation in bacteria requires mRNAs with a 5′-UTR and Shine Dalgarno sequence for ribosome assembly and start codon selection. However, the transcriptome of most bacteria contains 1–2% of leaderless mRNAs, and alternative translation mechanisms have been invoked (42). Remarkably, a quarter of the mycobacterial transcriptome is expressed as leaderless and lack both a 5′-UTR and Shine-Dalgarno sequence (43), raising the intriguing possibility that mycobacterial-specific ribosome proteins such as bS22 could facilitate leaderless translation initiation in mycobacteria (42).

Mammalian mitochondrial mRNAs are also leaderless and, although *S. cerevisiae* mitochondrial mRNAs have long 5′-UTR leaders, they lack Shine-Dalgarno sequences, and require transcript-specific translational activators to initiate translation (2). It is tempting to speculate that the acquisition of mS38 by mitochondrial ribosomes co-evolved with the loss of Shine-Dalgarno sequences in the mRNAs. However, it has been recently shown that in mammalian mitochondria, start codon selection could occur by mitoribosome-specific mRNA engagement and subsequent threading of the mRNA into the mRNA channel for start codon-anticodon interactions, which would be stabilized by a domain insertion that is present in the mammalian mitochondrial initiation factor 2 (44). Focusing on *S. cerevisiae*, although the 15S rRNA of yeast mitochondria lacks the Shine-Dalgarno sequence (45), it has been shown to have in its 3' end a 10-nucleotide sequence complementary to different extents with sequences in the 5′ leaders of the messages for *COX1* (10 nt), *COX2* (7 nt), *COX3* (7 nt) and *ATP6* (8 nt) (45). However, yeast mitoribosome structural studies have shown that the 3′ end of the 15S rRNA is not constrained to a position at the mRNA channel exit but extends into the mtSSU body where it is surrounded by mitoribosomal proteins (8). Different from bacteria, a wide V-shaped canyon flanked by mitoribosomal proteins forms at the mRNA channel exit, above which mRNA-specific translational activators may functionally interact (8). The presence of mRNA occupying this canyon during translation initiation would explain ribosome-profiling data, which have shown that the yeast mitoribosome protects longer mRNA stretches during active translation than cytosolic ribosomes (∼38 versus 28 nucleotides) (3). The absence of mS38 in the deletion strain might change the flexibility of the elements forming the mRNA exit channel. Such a modification could affect the transit of specific mRNAs (e.g. *COX1*, *COX2* and *COX3*), perhaps giving them a chance to interact with the 3′ end of the 15S rRNA unproductively or merely misfold, thus jamming the channel.

In conclusion, we propose that mS38 is a core component of the mitoribosomal SSU that may exert regulatory effects by interacting with specific mRNAs and by interfacing with structural elements in the mRNA exit channel to facilitate their correct translation initiation. This hypothesis is reminiscent of the 'ribosome filter' model according to which specific riboproteins would allow the ribosome to interface with specific subsets of mRNAs to regulate their translation (46).

ABSTRACT

Double-stranded breaks (DSBs) in plant organelles are repaired via genomic rearrangements characterized by microhomologous repeats. These microhomologous signatures predict the existence of an unidentified enzymatic machinery capable of repairing of DSBs via microhomology-mediated end-joining (MMEJ) in plant organelles. Here, we show that organellar DNA polymerases from *Arabidopsis thaliana* (AtPolIA and AtPolIB) perform MMEJ using microhomologous sequences as short as six nucleotides. AtPolIs execute MMEJ by virtue of two specialized amino acid insertions located in their thumb subdomains. Single-stranded binding proteins (SSBs) unique to plants, AtWhirly2 and organellar single-stranded binding proteins (AtOSBs), hinder MMEJ, whereas canonical mitochondrial SSBs (AtmtSSB1 and AtmtSSB2) do not interfere with MMEJ. Our data predict that organellar DNA rearrangements by MMEJ are a consequence of a competition for the 3′-OH of a DSBs. If AtWhirlies or AtOSBs gain access to the single-stranded DNA (ssDNA) region of a DSB, the reaction will shift towards high-fidelity routes like homologous recombination. Conversely MMEJ would be favored if AtPolIs or AtmtSSBs interact with the DSB. AtPolIs are not phylogenetically related to metazoan mitochondrial DNA polymerases, and the ability of AtPolIs to execute MMEJ may explain the abundance of DNA rearrangements in plant organelles in comparison to animal mitochondria.

INTRODUCTION

Plant organellar genomes encode for macromolecular assemblies indispensable for oxidative phosphorylation and photosynthesis (1–3). Thus, faithful organellar replication and regulated transcription are necessary for cell survival. Contrary to the representation of a circular structure as the predominant form of mitochondrial DNA, plant mitochondrial genomes are heterogeneous linear molecules with a strong tendency to produce rearrangements (4–7). The notion that plastid DNA exists as a circular molecule is challenged by findings of linear molecules in maize seedlings and in *Medicago truncatula* (4,8,9). Although the mechanisms that mediate plant organellar DNA replication are unknown, DNA rearrangements in plant organelles are common and are attributed to the repair of double-strand breaks (DSBs) (6,10–14).

Repair of DSBs occurs by two main pathways: homologous recombination (HR) and non-homologous end joining (NHEJ) (Reviewed in (15)). HR is an error-free pathway in which identical DNA segments are used as templates. In contrast, NHEJ is an error-prone pathway. NHEJ is divided into two sub-pathways: Ku-dependent classical non-homologous end joining (c-NHEJ) and alternative end joining (alt-EJ). A subset of DNA breaks repaired by alt-EJ employs a mechanism that requires minimal base pairing of microhomologous sequences, dubbed microhomology-mediated end joining (MMEJ) (16–18).

MMEJ was discovered as a sub-pathway derived from the Archaeo-Prokaryotic (AP)-NHEJ. Within this sub-pathway bacterial DNAPs promote synapsis of DSBs using short microhomologous sequences, these annealed sequences assemble the 3′-OH primers and are extended by virtue of strand-displacement synthesis by specialized DNAPs

(19,20). Eukaryotic DNA polymerases θ (HsPolθ), β, λ and μ, also perform MMEJ using short microhomologous sequences. As in bacterial MMEJ, the proposed DSB repair mechanism involves annealing of microhomologous sequences in *trans* to create a template DNA synapse and nucleotide extension (21–24). Crystal structures of DNAPs during MMEJ illustrate that they promote the stabilization of microhomologous sequences via unique structural elements that mediate synapse formation (19,25,26).

The plant mitochondrial genome frequently recombines via homologous recombination of large size (>500 bp) or intermediate size repeats (50–500 bp). Break-Induced Replication (BIR) and Single-Strand Annealing (SSA) are postulated to drive illegitimate recombination events at intermediate size repeats (6,27,28). However, plant organellar genomes also undergo rearrangements attributed to illegitimate recombination at intermediate size repeats (>50 base pairs) (6,11,12,27,29–33). These rearrangements are associated with MMEJ, microhomology-mediated break-induced replication (MMBIR) and microhomology-mediated recombination (12,28–30). DSBs in Arabidopsis´ chloroplasts, generated by ciprofloxacin or by a homing endonuclease, are repaired using microhomologous sequences that rank between 4 and 18 nts (29,31,32). The nature of the sequences at the junctions of the DNA rearrangements indicates that DSBs are repaired by a route that involves annealing of microhomologous sequences. The length of these microhomologies resembles the length of microhomologous segments in metazoan DNA repaired by MMEJ (17) or MMBIR (34).

Flowering plants harbor two organellar family-A DNA polymerases, known as plant and protist DNA polymerases (POPs) that are not phylogenetically related to yeast or metazoan mitochondrial DNA polymerase γ and are the sole DNAPs in plant organelles (35–39). Both AtPolIs display lower nucleotide insertion fidelity that metazoan mitochondrial DNAPs, elongate RNA primers synthesized by the organellar DNA primase-helicase and harbor strand-displacement and 5′-deoxyribose phosphate lyase activities (29,40–43). From the DNAPs able to execute MMEJ, HsPolθ is the only one that belongs to the family-A of DNAPs. This enzyme harbors a polymerization domain linked to a helicase domain and seminal work demonstrated that both domains participate in MMEJ (44,45). Structure-function studies of HsPolθ indicate that a specific insertion in its polymerization domain is responsible for MMEJ (21) The ortholog of HsPolθ in plants (24), TEBICHI, is involved in T-DNA random integration by MMEJ (46,47). Although TEBICHI participates in nuclear MMEJ, a mechanism for MMEJ has not been identified in plant organelles.

AtPolIs and HsPolθ bypass DNA lesions via unique amino acid insertions in their polymerization domain (25,40). Because of this convergence, and the necessity of a unique amino acid insertion in HsPolθ to execute MMEJ (21,48), we wanted to determine whether AtPolIs could execute MMEJ. To our surprise, AtPolIs are able to efficiently mediate synapsis formation on microhomologies as short as 6-bp. We found that members of the single-stranded binding proteins unique to plants, Whirly-2 and Organellar Single-stranded DNA Binding proteins (OSBs), inhibit MMEJ by competing with the single-stranded overhang. In contrast, mtSSBs do not interfere with MMEJ formation. Our results indicate the MMEJ in plant organelles is mediated by the available concentration of single-stranded binding proteins and AtPolIs.

MATERIALS AND METHODS

Cloning of recombinant Single-Stranded DNA-Binding proteins

The coding regions corresponding to processed AtOSB2 (AT4G20010), AtOSB3 (AT5G44785), AtWhirly2 (AT1G71260), AtmtSBB1 (AT4G11060.1), AtmtSSB2 (AT3G18580.1) were PCR amplified from cDNA. The PCR products were digested and cloned into a modified pET19b or pET28b vectors. Positive clones were verified by DNA sequencing.

Expression and purification of recombinant proteins

In this study, we use recombinant AtPolIs that lack their first 257 amino acids. Those residues correspond to a dual targeting sequence (DTS) and a disordered region. Removal of those amino acids increases protein yield during heterologous purification without affecting exonucleolytic degradation or DNA polymerization (40) Thus, recombinantly expressed AtPolIs contain intact 3′-5′ exonuclease and polymerization domains, as metazoan DNAP γ and the Klenow fragment of bacterial DNAPs. The 3′-5′ exonuclease deficient variants of AtPolIs substitute two invariant carboxylates in exonuclease motif I of AtPolIA (D294 and D296) and AtPolIB (D287 and D289) to alanine. Exonuclease deficient AtPolIB (AtPolIB exo$^-$) was used as template to construct deletions in the unique insertions present in AtPolIs. The AtPolIB variant with a deletion in insertion 1 (AtPolIB-Δins1) eliminates residues 581 to 619, AtPolIB-Δins2 eliminates residues 648 to 712, and AtPolIB-Δins2 eliminates residues 845–869. All mutant polymerases are readily purified using three chromatographic steps (40) (Supplementary Figure S1).

AtmtSSB2 was purified following published protocols (49). Recombinant AtmtSSBs, AtOSB2, AtOSB3, and AtWhirly2 were expressed using an *Escherichia coli* BL21 PKJE7 strain. Cell cultures were grown until they reached an OD_{600} of 0.6 and were induced with 0.5 mM IPTG (isopropyl-1-thio-β-D-galactopyranoside) at 16°C during 18 h. Cells were recollected by centrifugation at 4°C and resuspended in 30 ml lysis buffer (25 mM HEPES pH 8, 600 mM NaCl, 10 mM imidazole, 10% glycerol and 1 mM PMSF). The lysate was supplemented with lysozyme 0.5 mg/ml and sonicated on ice. The clear lysate was filtrated and loaded onto a Ni-NTA column. The column was washed with lysis buffer containing 30 mM imidazole. Proteins were eluted using lysis buffer supplemented with 500 mM imidazole and dialyzed in buffer A (25 mM HEPES pH 8, 50 mM NaCl, 2 mM EDTA, 30% glycerol and 5 mM DTT). SSBs were loaded into a Hi-Trap heparin column, and further purified using a 0.1 M to 1 M NaCl gradient. Pure fractions were stored into a buffer B (25 mM HEPES pH 8.0, 100 mM NaCl, 2 mM EDTA, 50% glycerol and 5 mM DTT) at −20°C.

INFORME DE LABORES 2019

Substrates

5′-End oligonucleotide labeling was performed with T4 polynucleotide kinase using [γ-^{32}P] ATP and purified with Nucleotide Removal Kit following manufacture's protocol. Oligonucleotides used for the MMEJ assay are described in Supplementary Table S1.

Microhomology-mediated end joining (MMEJ) assays

MMEJ assays were performed at 37°C using 20 nM 5′-end radiolabeled pssDNA, in a buffer containing 10 mM Tris–HCl pH 7.5, 50 mM NaCl, 1.5 mM DTT, 10% glycerol and 0.1 mg/ml BSA. The mix was incubated with 100 nM AtPolIs for 15 min and then supplemented with 500 μM of dNTPs and 10, 6 or 2 mM $MgCl_2$ for 30 min. The reactions were terminated using a stop buffer (95% formamide, 10 mM EDTA, 0.1% bromophenol blue and 0.1% xylene cyanol). The reactions were loaded on a 17% polyacrylamide denaturing gel and analyzed by phosphorimaging. In the MMEJ assay with singled-stranded DNA binding proteins, the same labeled pssDNA substrates were at 5 nM and AtSSBs were present at the concentrations described in the figure legends.

Electrophoretic-mobility shift assay (EMSA)

To investigate the binding of plant SSB to ssDNA we use a radioactively labeled poly-T of 70 nts oligonucleotide. Reactions were incubated in buffer containing 10 mM Tris–HCl pH 7.5, 50 mM NaCl, 1.5 mM DTT, 10% glycerol, 0.1 mg/ml BSA, 10 mM $MgCl_2$, using varying concentrations of SSBs. The reactions were run on 4% polyacrylamide nondenaturing gel at 4°C and visualized by phosphorimaging.

Fluorescence anisotropy binding assay

Dissociation constant (K_d) were measured using a fluorescein-labeled ssDNA of 45 nts ($ssDNA_{(45)}$) or a Cy3-labeled pssDNA-10 in 10 mM Tris–HCl pH 7.5, 50 mM NaCl, 0.05 mg/ml BSA,10% glycerol and 10 mM $MgCl_2$. Increased concentration of purified proteins (AtmtSSB1, AtOSB2 and AtWhy2) were individually evaluated. The reactions were incubated at 25°C in darkness during 20 min. Changes in anisotropy were quantified on an Infinite M1000 Microplate Reader (Tecan®) using excitation and emission wavelength (λ) of 470 and 525 nm, respectively. The data were analyzed using GraphPad Prism 6 according to the specific binding with Hill slope model following this equation: $Y = B_{max}*X^h/(K_d{}^h + X^h)$, where B_{max} indicates the maximum number of binding sites, K_d refers to ligand concentration that binds to half the receptor sites at equilibrium and h is the Hill slope.

Fluorescence resonance energy transfer (FRET) assay

For evaluation of DNA synapsis formation, oligonucleotides labeled with different fluorescence probes (Cy3 and Cy5) were annealed as described in the figure legends. Titration experiments were performed using equimolar concentration of labeled DNA (50 nM) with increasing concentrations of AtPolIs. Variations in fluorescence intensity upon incubation of AtPolIs were measured in an Infinite M1000 microplate reader using wavelengths (λ) of 530 nm for excitation and 675 nm for emission. Reactions were incubated in 10 mM Tris–HCl pH 7.5, 50 mM NaCl, 1.5 mM DTT, 10% glycerol, 0.1 mg/ml BSA and varying concentrations of AtPolIs. The reactions were incubated for 20 min in darkness at 25°C by triplicate. The data were normalized and analyzed in GraphPad Prism 6.

Gel filtration analysis

The elution profiles of plant SSBs in solution were evaluated using gel filtration. The proteins were injected into a Superdex 75 10/300 column equilibrated with 20 mM HEPES pH 8.0, 200 mM NaCl, 10% glycerol, 2 mM EDTA and 1 mM DTT. Elution peaks were analyzed using molecular weight markers.

Homology model

The homology model of AtPolIB was carried out using the homology modeling platform of the Swiss-Model Workspace (50) using as templates the Klenow fragments from the crystal structures of *Thermus aquaticus*, *Geobacillus stearothermophilus* and *Geobacillus kaustophilus*. From those homology models, we selected the one generated with the crystal structure of *G. kaustophilus* DNAP I in complex with dsDNA (PDB: 4DSE), because this model positions insertions 1 and 3 in an optimal position to interact with dsDNA.

SEC-MALS analysis

The SEC-MALS analysis was performed on a DAWN HELEOS multi-angle light scattering detector, with eighteen angles detectors and a 658.9 nm laser beam, (Wyatt Technology, Santa Barbara, CA, USA) and an Optilab T-rEX refractometer (Wyatt Technology) in-line with two coupled Superdex 200 Increase 10/300 GL size exclusion chromatography analytical columns. Experiments were performed using an isocratic pump (Agilent) with a flow of 0.5 ml/min at room temperature (25°C). Data collection was performed with ASTRA 6.1 software (Wyatt Technology). For the experiments, 300 μl at 1.3 mg/ml protein were loaded on the columns with running buffer of 25 mM HEPES pH 8, 10% glycerol, 300 mM NaCl and 2 mM EDTA. Calibration was performed with high-molecular weight markers from GE Healthcare (thyroglobulin, 669 000 Da; ferritin, 440 000 Da; aldolase, 158 000 Da; conalbumin, 75 000 Da; and ovoalbumin, 43 000 Da).

Strand-displacement assays

A 65mer DNA template (5′-CCT TGG CAC TAG CGC ACG ATG CCG CTA AGA ACC TCA GGG CCA GTT AGG TGG GCA GGT GGG CTG CG-3′) was annealed with a 5′-end radioactively labeled 24mer primer (5′-CGC AGC CCA CCT GCC CAC CTA ACT-3′) and a DNA blocking oligonucleotide (5′-GA GGT TCT TAG CGG CAT CGT GCG CTA GTG CCA AGG-3′) to create a gap of 6 nucleotides. Reactions were run at 37°C mixing 10 mM

Downloaded from https://academic.oup.com/nar/article/47/6/3028/5304310 by UNAM user on 20 October 2020

Tris–HCl pH 7.5, 50 mM NaCl, 0.2 mg ml^{-1} BSA, 1.5 mM DTT, 2 mM $MgCl_2$, 10% glycerol, 10 nM DNA substrate, 20 nM DNA polymerases and initiated adding 200 μM of dNTPs.

MicroScale Thermophoresis (MST)

MST analysis of the interactions between AtPolIB exo$^-$ and plant SSB's was carried out as follows. AtPolIB was purified with a 10× histidine tag at the N terminal and labeled using NanoTemper's Monolith His-Tag Labeling Kit RED-Tris-NTA at 100 nM. SSB's were purified and their His-tag was removed by addition of precision protease and gel filtration. SSBs were titrated against labeled AtPolIB in 16 serial dilutions from initial concentrations of 150, 200 and 250 μM for AtmtSSB1, AtOSB2 and AtWhy2, respectively. Reactions were incubated for 10 min at 25°C in PBS buffer + 0.05% Tween™ 20. The measurements were performed using a NanoTemper Monolith NT.115 pico instrument. Analyses were conducted at 10% LED power and 50% MST power on standard capillaries.

RESULTS

AtPolIs execute MMEJ on partially resected DSBs

Pioneering work by Herrin and Brisson´s laboratories revealed that DSBs in chloroplast are repaired using illegitimate recombination mechanisms attributed to MMEJ (12,29–31,33). The predicted melting points for several of those microhomologies is <37°C (51) (Figure 1A), suggesting that protein factors may be involved in stabilizing the annealing of microhomologous sequences that are repaired by MMEJ during DSBs. Plant organelles in *A. thaliana* harbor only two DNA polymerases, AtPolIA and AtPolB that have as a distinctive feature the presence of three insertions in their polymerization domain.

Given that HsPolθ performs TLS and MMEJ by a specific amino acid insertion and that unique amino acid insertions are responsible for TLS activity in AtPolIs, we hypothesize that AtPolIs may perform MMEJ via unique amino acid insertions (21,40). To investigate the putative MMEJ capabilities of AtPolIs, we used recombinant AtPolIA and AtPolIB harboring amino acid deletions of their first 257 amino acids. Those amino acids correspond to a predicted disordered protein region and their removal increases the yield of recombinant active protein (40). Thus, recombinant AtPolIs harbor both 3′-5′ exonuclease and polymerization domain activities (Figure 1B). The initial substrate used to test MMEJ, consisted of a partially resected DSB (pssDNA) with a 5′-CCCCGGGG-3′overhang sequence of 8 nts (pssDNA-8) with a predicted Tm for the microhomologous region of 22.5°C (Figure 1C). This substrate was formerly used to asses MMEJ formation by HsPolθ (21,48).

Synapse formation, followed by polymerization on the single-stranded portion of the template and strand-displacement would generate a MMEJ product of 56 nts (Figure 1C). MMEJ reactions were initially executed using 10 mM of $MgCl_2$ and 2 mM of $MnCl_2$, as those are optimal metal concentrations during primer extension on a canonical primer-template (data not shown) and high nucleotide concentrations (500 μM). Reaction products of 56 and 57 nts product were synthetized by exonuclease proficient AtPolIs, in the presence of Mg^{2+} (Figure 1D, lanes 2–5), whereas products of 56–58 nts were synthetized in reactions incubated with Mn^{2+} (Figure 1D, lanes 6–9). The presence of Mg^{2+} promotes the addition of an extra base, whereas incubation with Mn^{2+} promotes the addition of two extra bases, possibly due to terminal transferase activity. Thus, reactions incubated with pssDNA-8 generate MMEJ products in the presence of AtPolIs harboring an active exonuclease domain or exonuclease deficient DNAPs (Figure 1D). AtPolIs incubated with Mn^{2+} exhibit an increase in their 3′-5′ exonuclease activity. The exonuclease activity of AtPolIs is halted after digestion of 16 nts, at the boundary of the double-stranded DNA template (Figure 1D, lanes 2–9). Disruption of the exonuclease activity by site-directed mutagenesis in AtPolIs increases MMEJ activity, resulting in the appearance of a MMEJ product of 58 nts (Figure 1C, lanes 11–18).

In order to asses if AtPolIs could execute MMEJ at physiological nucleotide concentrations, we used a pssDNA-8 substrate that templates for 20 consecutive thymines or adenines, after the assembly of the MMEJ substrate. In this experiment, we used nucleotide concentrations that rank from 0.0037 to 245.76 μM (Figure 2A). At low micromolar dATP or dTTP concentrations (Figure 2A and B, lanes 2–5 and 12–15) a single MMEJ product of 56 nts is observed. At higher nucleotide concentrations, a band of 57 nts is shown in reactions incubated with dTTP and a band of 58 nts is observed in reactions incubated with dATP (Figure 2A and B, lanes 7–10 and 17–20). AtPolIB exhibits a nearly 20-fold higher K_M for dNTP during nucleotide incorporation on a canonical primer-template substrate with respect to AtPolIA (43). Thus, the observation that AtPolIA and AtPolIB exhibit similar MMEJ efficiency during all the assayed dNTP concentrations suggests that during MMEJ annealing the mechanism that dictates the affinity of the incoming nucleotide differs from the one during primer-template incorporation.

In order to determine the minimal microhomologous length in which AtPolls are able to execute MMEJ, we performed MMEJ reactions using substrates than contained microhomologies from 0 to 12 nts. We initially used similar reaction conditions to those previously reported for HsPolθ, but with the addition of 50 mM NaCl (21). Full nucleotide incorporations on these pssDNA substrates are designed to generate products from 54 to 98 nts, and only a pssDNA substrate containing a microhomology of 12 nts (pssDNA-12) exhibits a T_m higher than 37°C (Figure 2A).

The Klenow Fragment of *E. coli* DNA polymerase I (KF-DNAP I) control generates faint products of approximately 56 and 98 nts in reactions incubated with pssDNA-8 and pssDNA-12 and not with any other pssDNA substrates, indicating that transient alignment of the microhomologous sequence does not form a stable substrate for DNAPs (Figure 2B, lanes 18–21). This result contrasts with a previous report in which KF-DNAP I generates low molecular weight MMEJ products on a pssDNA containing a microhomology of 4nts (pssDNA-4) (21). Thus, exonuclease deficient KF-DNAP I is unable to efficiently use pssDNAs as substrates, including a pssDNA-12 substrate. In contrast, wild-type (AtPolIB exo$^+$) and exonuclease deficient

INFORME DE LABORES 2019

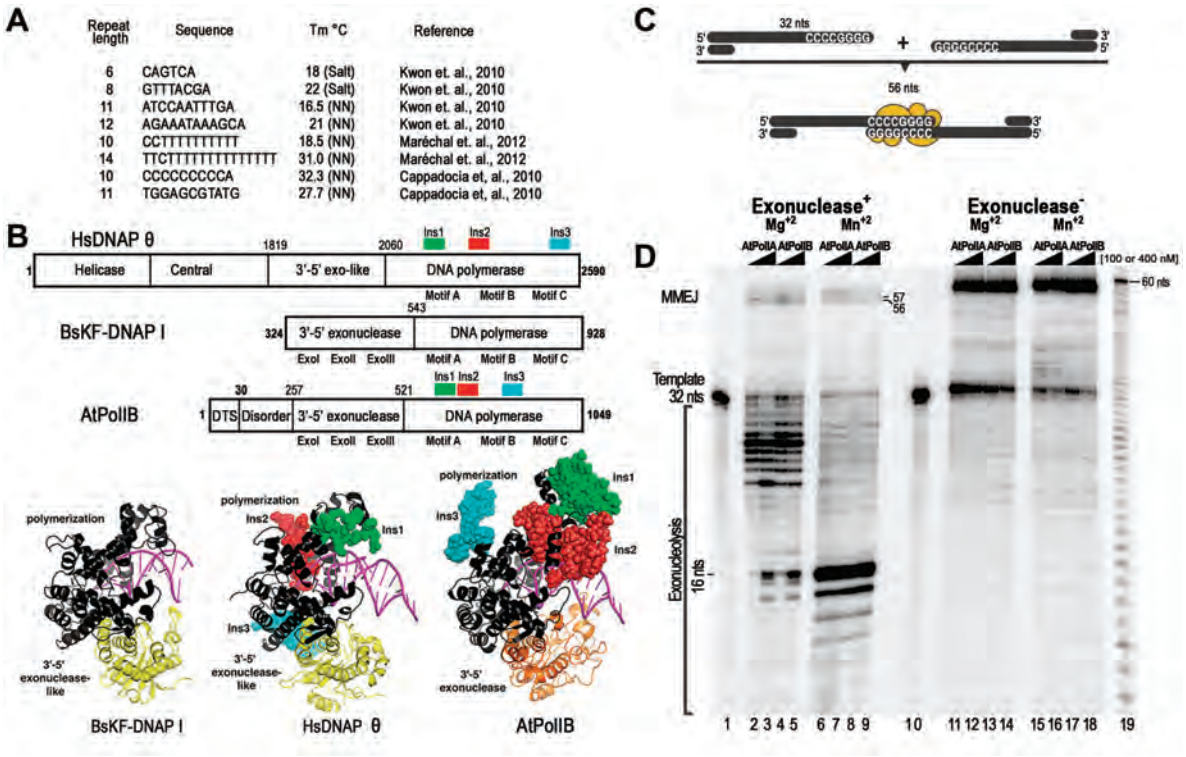

Figure 1. AtPolIs mediate MMEJ *in vitro*. (**A**) Representative microhomologous sequences present in chloroplast DNA from *A. thaliana* upon DSB repair (30–32). The calculated melting temperature (T_m) for single-stranded regions shorter than 8 nts were calculated using the salt-adjusted method (salt) and regions longer than 8 nts were calculated using the Nearest Neighbor (NN) method (51). (**B**) Structural comparison between a homology model of AtPolIs with the crystal structures of HsPolθ (25) (PDB: 4x0Q) and the Klenow fragment of *Bacillus* DNAP I (68) (PDB: 3BDP). The polymerization domains are colored in black, the active 3′-5′ exonuclease domain of AtPolIB in orange and the inactive 3′-5′ exonuclease domains of HsPolθ and *Bacillus* DNAP I in yellow. The unique amino acid insertions in HsPolθ and AtPolIB in comparison to bacterial DNAPs I are depicted in a ball-stick representation. In all DNAPs the dsDNA (magenta) is poised for nucleotide incorporation. (**C**) Proposed arrangement of a micromologous sequence of 8 nts showing DNA synapse formation and extension upon dNTPs incorporation by MMEJ. (**D**) Denaturing polyacrylamide gel showing MMEJ reactions catalyzed by wild-type and exonuclease deficient AtPolIs present at concentration of 100 or 400 nM. In the presence of Mg^{2+} or Mn^{2+}. AtPolIs extend the pss-DNA(8) substrate to MMEJ products of 56, 57 and 58 nts. The migration of the MMEJ products of 56, 57 and 58 nts and the pss-DNA(8) substrate are indicated.

AtPolIB (AtPolIB exo$^-$) efficiently use substrates with microhomologous sequences of 8 nts (pssDNA-8) to perform MMEJ (Figure 2B, lanes 1 to 16). A MMEJ product is not observed in reactions incubated with pssDNA-6, pssDNA-4, pssDNA-2, and pssDNA-0 substrates (Figure 2B, lanes 11, 12 and 13). The predicted Tms of the microhomologous regions in pssDNA-6 and pssDNA-8 are <37°C, suggesting that spontaneous template annealing is unfavorable and that MMEJ is mediated by AtPolIB. As the editing activity of AtPolIs hampers MMEJ, we subsequently utilized exonuclease deficient variants of AtPolIs to investigate their MMEJ properties.

AtPolIs exhibited limited terminal deoxynucleotidyl transferase activity

In the presence of high nucleotide concentrations, AtPolIs generate MMEJ products with additional non-templated nucleotides residues at the 3′ end (Figure 2A, lanes 6–10 and 16–20). Bacterial family-A DNAPs, like Taq DNA polymerase (Taq DNAP), present limited non-templated nucleotide or terminal transferase activity. In this reaction, one or two nucleotides, preferentially dATP, are added to a 3′-OH primer (52). In contrast, HsPolθ and terminal deoxynucleotidyl transferases exhibit a robust terminal transferase activity and are able to add several nucleotides the 3′-OH primer (48,53). To test the efficiency of the predicted terminal transferase activity by AtPolIs, we used three different substrates: a homopolymeric ssDNA poly-dT, a double-stranded blunt-ended DNA substrate, and a MMEJ substrate (Figure 3). AtPolIB exo$^-$ fails to incorporate any nucleotide having as a substrate a poly-dT oligonucleotide in the presence of individual nucleotides or in the presence of all nucleotides (Figure 3A). In contrast, AtPolIB exo$^-$ exhibits limited terminal transferase activity catalyzing the addition of one or two nucleotides on a double-stranded blunt-ended DNA substrate (Figure 3B). This activity is reminiscent of the limited terminal transferase exhibited by Taq DNAP. In the presence of Mg^{2+} as cofactor AtPolIB exo$^-$ efficiently incorporates two non-templated dAMP molecules (Figure 3B, lane 2), whereas all other nucleotides are incorporated only once (Figure 3B). AtPolIB exo$^-$ also shows limited terminate transferase activity when $MgCl_2$ is used as a cofactor (data not shown). In a MMEJ substrate, AtPolIB exo$^-$ synthesizes products that rank from 56 to 58 nts. This product corresponds to the annealing of the pssDNA-8 substrates plus the addition of two extra nucleotides. Using individual nucleotides, we

INFORME DE LABORES 2019

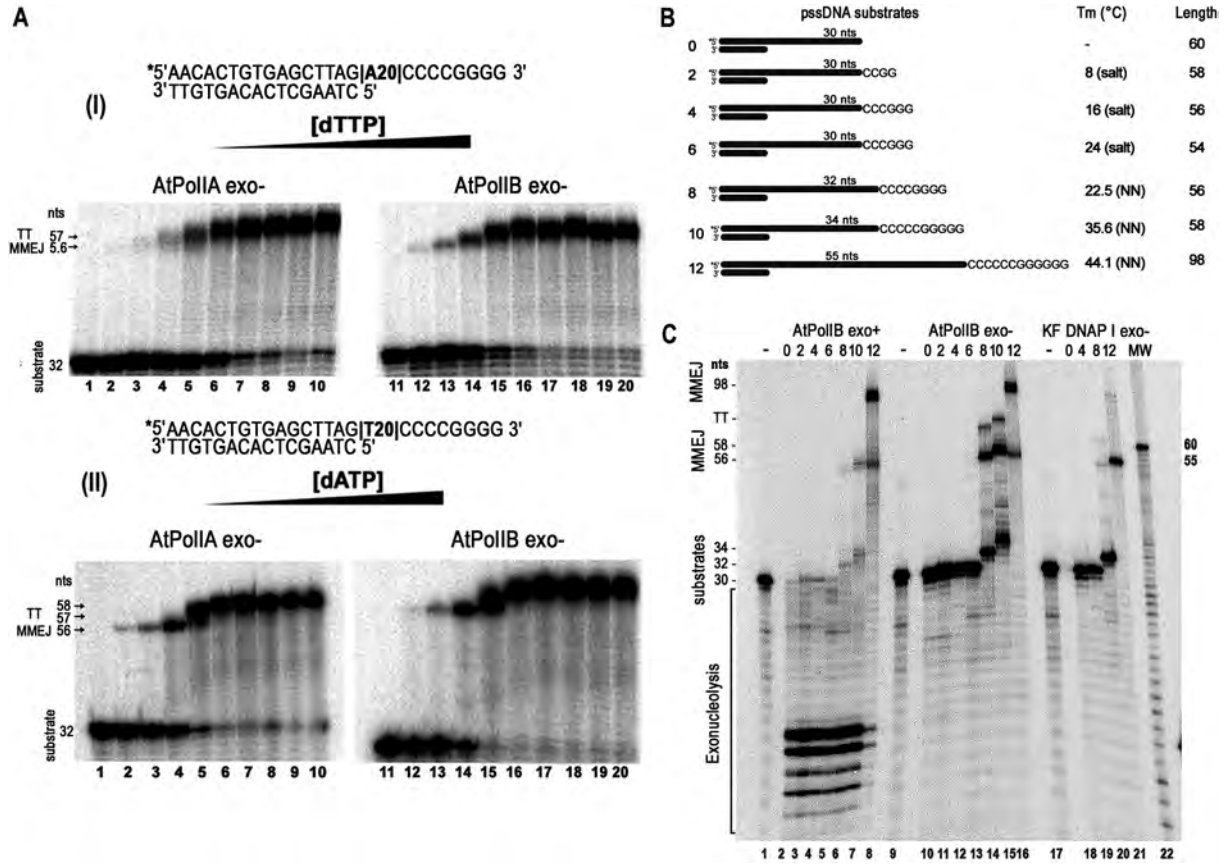

Figure 2. AtPolIs performs MMEJ using microhomology sequence longer than 8 nts at high $MgCl_2$ concentrations. (**A**) Exonuclease deficient AtPolIs execute MMEJ on a pss-DNA(8) substrate at physiological dNTP concentrations. Reactions incubated in the absence of dNTPs (lanes1 and 11) show the migration o the labeled substrate. MMEJ reactions were incubated using increasing dTTP (panel I) or dATP (panel II) from 0.0037 to 245.76 μM using four-fold increments (lanes 2–10 and 12–20). At low micromolar dNTP concentrations (lanes 2–5 and 12–15) a MMEJ product of 56 nts is observed. In contrast, a band of 57 nts is observed in reactions incubated with dTTP using high nucleotide concentrations and a band of 58 nts is observed in reactions incubated with high concentrations of dATP. (**B**) Schematic representation of the pssDNAs substrates used for MMEJ assays. Asterisks indicate the position of the 5′-radioactive label. The microhomology lengths (from 0 to 12 nts), the calculated Tm for DNA synapsis formation and the expected lengths of the MMEJ product are indicated at the right. (**C**) Denaturing sequencing gel showing MMEJ reactions by wild-type (lanes 2–8) and exonuclease deficient (lanes 10–16) AtPolIBs in comparison to reactions incubated with the exonuclease deficient Klenow Fragment of DNAP I (lanes 18–21). Al reactions contained 10 mM $MgCl_2$ as a cofactor. A control labeled substrate corresponding to pss-DNA(8) is present in lanes 1, 9 and 17. MMEJ products are observed in reactions incubated with AtPolIBs on substrates with microhomologies longer than eight nucleotides (lanes 6, 7, 8, 14, 15, 16). These products correspond to bands of 56, 58 and 98 nts respectively. In contrast, Klenow Fragment is unable to efficiently use MMEJ substrates and only low amounts of products are formed with pssDNAs of 8 and 12 nts (lanes 20 and 21). TT denotes products generated by a predicted terminal transferase activity.

observed an efficient nucleotide incorporation only when dCTP is present in the reaction (Figure 3C, lane 4). The pssDNA-8 substrate poises a template guanosine as the first template base after the annealing of the microhomologous CCCCGGGG sequence. The incorporation of two dCMPs on this substrate may be related to the low fidelity during nucleotide incorporation by AtPolIB (43) or to a transient misalignment of the 3′-OH (Figure 3C).

In order to discern if the observed MMEJ products could be due to a template-dependent extension in *cis* (snap-back replication), we used a single-stranded pssDNA-8 substrate in the presence of individual nucleotides. In this experiment, the single-stranded oligonucleotide is predicted to assemble a primer-template by the annealing of four cytidines and four guanosines in *cis* (Figure 3D). This snap-back assembly is predicted to position a template guanosine for dCMP incorporation. In the presence of dCTP both AtPolIs incorporate multiple dCMPs (Figure 3D, lanes 5 and 11) possible due to a misalignment of the primer-strand. The presence of products derived from the incorporation of multiple cytidines on a single-stranded template contrast with the incorporation of two dCMPs in a pssDNA-8 substrate predicted to form a synapse (Figure 3C, lane 5). In the sole presence of dGTP, AtPolIs efficiently incorporate a dGMP molecule, possibly due to an alignment of only three cytidines with three guanosines that generate that a cytidine poised for dGTP incorporation (Figure 3C, lanes 6 and 12).

AtPolIs use substrates with microhomologies longer than 6 nts

DSBs are repaired using microhomologous sequences as short as four nts in chloroplasts (30,32), suggesting that the machinery responsible of MMEJ should efficiently anneal pssDNA with short microhomologous regions. To investigate if AtPolIB exo$^-$ could perform MMEJ on these sub-

INFORME DE LABORES 2019

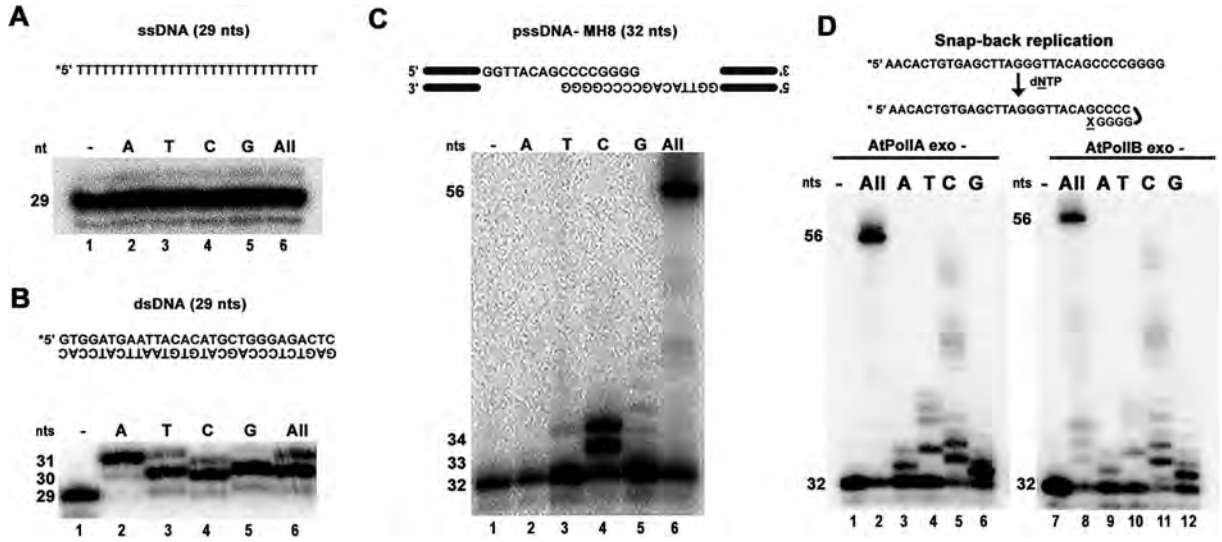

Figure 3. AtPolIB exhibits limited terminal transferase activity on double-stranded substrates. (**A**) Denaturing gel showing the lack of terminal transferase activity on a poly-dT ssDNA template incubated in the presence of individual nucleotides. (**B**) Denaturing acrylamide gel showing AtPolIB exo- nucleotide incorporation on a ds-DNA substrate in the presence of individual nucleotides. (**C**) AtPolIB performs MMEJ using DNA templates in *trans*. Denaturing gel showing MMEJ reactions incubated in the presence of individual nucleotides on pss-DNA(8) substrate. (**D**) AtPolIB performs limited snap-back replication. Denaturing gel showing reactions incubated in the presence of individual nucleotides on a MH-8 substrate with AtPolIA exo- (lanes 1–6) and AtPolIB exo – (lanes 7–12).

strates, we studied the effect of three different concentrations of $MgCl_2$ (10, 6 and 2 mM) on MMEJ. As previously shown, reactions incubated with 10 mM $MgCl_2$ produced a faint MMEJ-product on a pssDNA-6 substrate and efficiently uses a pssDNA-8 substrate (Figure 4A, lanes 22, 24). However, in reactions incubated with 2 and 6 mM $MgCl_2$, AtPolB exo$^-$ is able to use templates with microhomologous sequences of 6 nts (Figure 4A, lanes 6, 14).

We further investigated synapse formation by AtPolIs exo$^-$ using two substrates labeled with different fluorophores poised for fluorescence resonance energy transfer (FRET). Two pssDNA-8 substrates labeled with Cy3 or Cy5 dyes were incubated with AtPolIs in the absence of dNTPs. The efficiency of FRET increases in a proportional manner to the amount of AtPolIA exo$^-$ or AtPolIB exo$^-$ present in the reaction, indicating that AtPolIs drive DNA synapse formation of the fluorescent Cy3–Cy5 donor–acceptor pair (Figure 4B).

MMEJ by different DNAPs predict the formation of a synapse that is stabilized by two DNA polymerases in *trans* (19,21,25,26). To evaluate the possibility that AtPolIB assemblies in *trans* forming a dimer, we use size-exclusion chromatography (SEC)-coupled multiangle light scattering (MALS) on AtPolIBexo$^-$ incubated in the presence and absence of a DNA substrate (Figure 4C). These analyses found an average molecular weight for AtPolIB exo$^-$ of 180 kDa that corresponds to a molecular mass of two AtPolIB monomers (93 kDa). AtPolIB incubated with DNA increases its molecular mass to 235 kDa, a molecular mass that corresponds to two AtPolIB monomers interacting with two DNA molecules (27 kDa). Thus, the SEC-MALS analysis are consistent with synapse formation driven by a dimer assembly of AtPolIB and a pssDNA substrate.

MMEJ by AtPolIB is mediated by insertions 1 and 3

AtPolIs are family-A DNA polymerases that contain three unique insertions in their polymerization domain (35,37,40) (Figure 1B). In order to investigate if MMEJ would depend on these insertions, we used mutant polymerases harboring individual deletions. Deletion mutants eliminate 38, 64, and 24 amino acids corresponding to insertions 1, 2 and 3 respectively (Figure 5A). Insertions 1 and 2 are located at the thumb subdomain and structural modeling suggests that they are poised to interact with the primer-template, whereas insertion 3 is located at the fingers subdomain in a position that is predicted to be distant from DNA (40) (Figure 5A). Mutant polymerases harboring deletions in those insertions are active on a canonical primer-template, suggesting that these mutant polymerases do not have severe alterations in their structure (40). The ability of AtPolIB exo$^-$ deletion variants to execute synapse formation was assessed by FRET on a pssDNA-8 substrate in the absence of dNTPs (Figure 1B). As previously shown, AtPolIB exo$^-$ produces a concentration-dependent increase in fluorescence. However, AtPolIB exo$^-$ harboring deletions in insertions 1 and 3 (AtPolIB-Δins1 or AtPolIB-Δins3) failed to produce a concentration-dependent change in fluorescence (Figure 5B). In contrast, a mutant AtPolIB exo$^-$ harboring a deletion in insertion 2 (AtPolIB-Δins2) showed a FRET response that is dependent on protein concentration, albeit with less efficiency compared to an unmodified AtPolIB exo$^-$ (Figure 5B). Thus, the FRET experiments suggest that AtPolIB variants harboring deletions in insertions 1 and 3 are inefficient in MMEJ (Figure 5B). To corroborate this result, we performed MMEJ reactions on a pssDNA-8 substrate. As expected, a product band of 58 nts was observed in reactions incubated with AtPolIB exo$^-$ and AtPolIB-Δins2. In contrast, no product was synthesized in

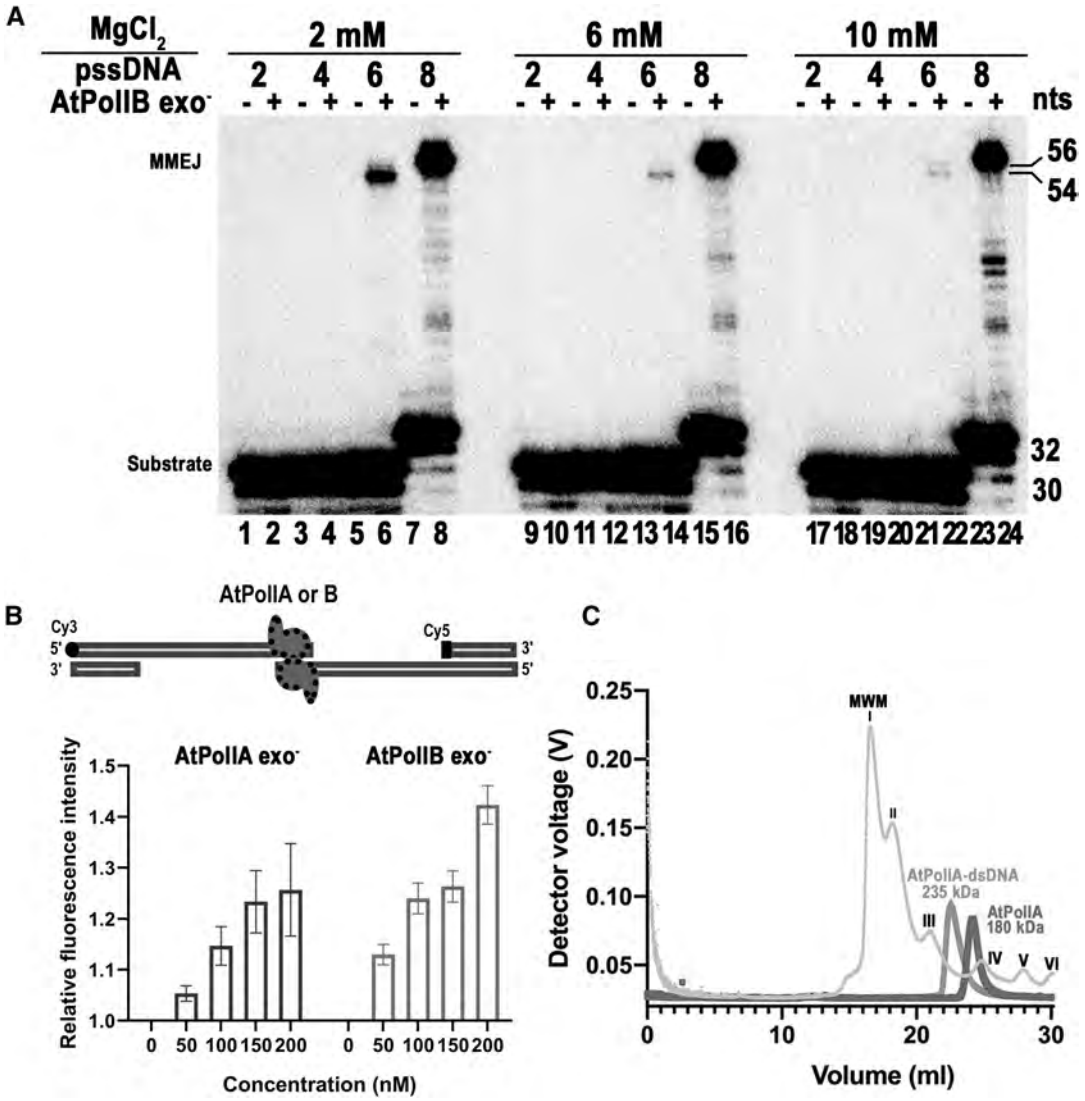

Figure 4. AtPolIs performs MMEJ in short homologous sequences at physiological MgCl2 concentrations and template synapse formation by AtPolIs. (**A**) MMEJ assays using three $MgCl_2$ concentrations (2, 6 and 10 mM) in psDNA templates with microhomologies ranking from 2 to 8 nts. MMEJ reactions were incubated in the absence of $MgCl_2$ (odd numbers) and with the indicated $MgCl_2$ concentration (even numbers). A defined MMEJ product band of 54 nts is observed in reactions incubated with 2 mM $MgCl_2$ on a pssDNA-6 substrate (lanes 6) whereas this product is hardly observed in reactions incubated with 6 and 10 mM $MgCl_2$ (lanes 14 and 22). Reactions incubated with pssDNA-2 and pssDNA-4 do not generate a MMEJ product at any metal concentration. (**B**) Changes in the intensity of fluorescence indicative of the formation of a Cy3–Cy5 intermediate upon incubation of AtPolIs. The relative fluorescence increases in relation to the amount of added of exonuclease deficient AtPolIA and AtPolIB. Experiments were performed in triplicate and the graph shows the mean and the standard deviation. (**C**) SEC-MALS analysis of the oligomerization state of AtPolIB exo- in the absence and presence of DNA substrate. The chromatogram shows the readings of the light scattering for the molecular mass standards and AtPolIB exo- incubated in the presence and absence of DNA. The molecular mass of the standards is indicated by roman numbers: I) blue dextran (2 000 000 Da), II) thyroglobulin (669 000 Da), III) ferritin (440 000 Da), IV) aldolase (158 000 Da), V) conalbumin (75 000 Da), and ovoalbumin (43 000 Da).

samples incubated with AtPolIB exo$^-$ mutants harboring a deletion in insertions 1 and 3 (Figure 5C). Therefore, only an AtPolIB exo$^-$ mutant harboring a deletion in insertions 2 is able to execute MMEJ, although their products are different from the wild-type AtPolIB.

To further corroborate the role of insertions 1 and 3 in MMEJ, we constructed a shortened version of deletion 1 (δ599–610) and point mutations to alanine of individual lysine and arginine residues in this loop. We also constructed a point mutant in residue K866 located in loop 3. An MMEJ reaction using those mutant polymerases, show that a shorted version of loop 1 decreases MMEJ formation by ∼90% and individual K590A and K593A mutations also decrease the amount of MMEJ product to 20 and 50% of the consumed substrate (Figure 5D, lanes 5, 6, 7). Interestingly an alanine mutant of residue K866 also decreases MMEJ formation by MMEJ by nearly 40% (Figure 5D, lane 13).

AtPolIB-Δins2 primarily generates a product of approximately 42 nts that correlates with the necessity to displace the 5′-end of the primer stand corresponding to the opposite template (Figures 5C and 3C). AtPolIs har-

INFORME DE LABORES 2019

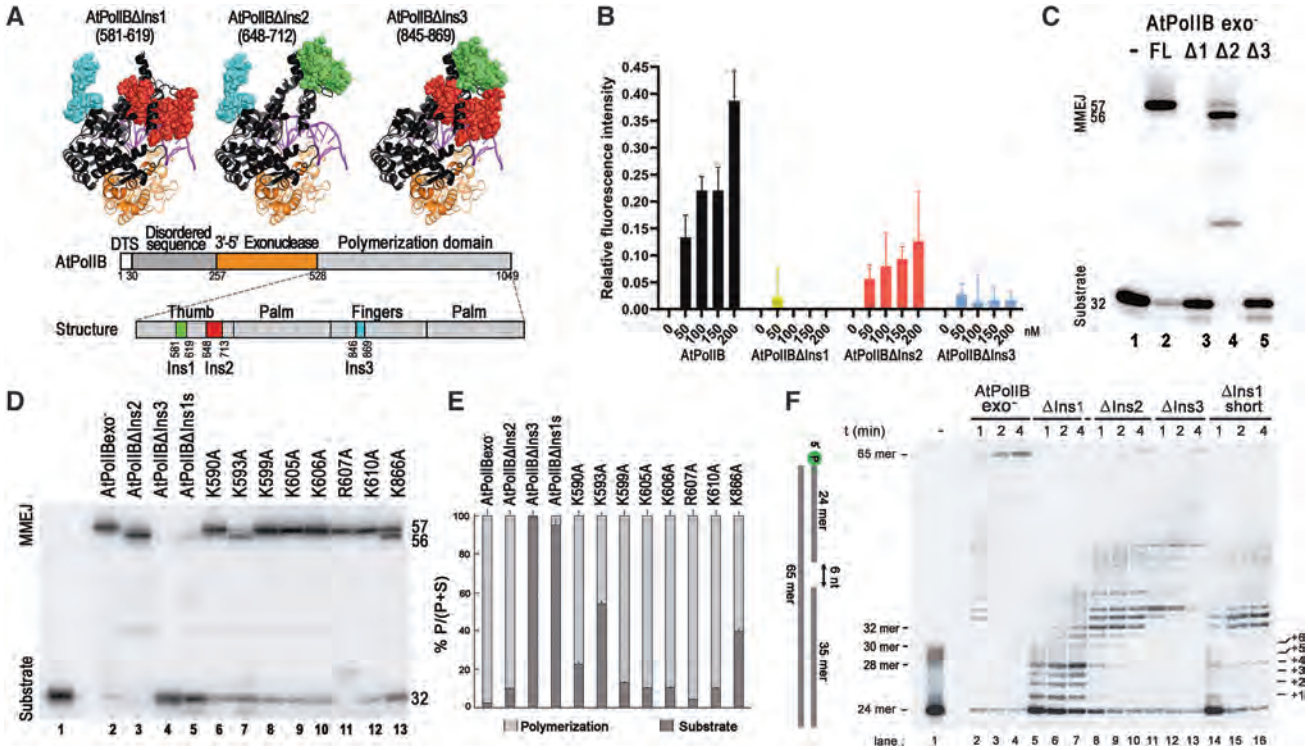

Figure 5. MMEJ by AtPolIs is mediated by unique amino acid insertions in their polymerization domain. (**A**) Homology model showing the predicted localization of the unique insertions in the polymerization domain of AtPolIB. Insertions 1 and 2 are located at the thumb subdomain (green and red colored, respectively), whereas insertion 3 (cyan colored) is located at the palm subdomain. A representative structure of mutant polymerases showing individual deletions is present. (**B**) FRET assay using exonuclease deficient AtPolIB and exonuclease deficient deletion mutants. AtPolIB and AtPolIB-Δins2 generate a concentration-dependent change in the relative fluorescence, whereas incubation with AtPolIB-ΔIns1 and AtPolIB-ΔIns3 do not have an effect on the relative fluorescence. Data show the mean of three independent experiments. (**C**) MMEJ reaction assays using AtPolIB deletion mutants on a pssDNA-8 substrate. A MMEJ product is observed upon incubation with full-length (FL) AtPolIB (lane2), in contrast AtPolIB-ΔIns1 and ΔIns3 mutants (Δ1 and Δ3) are severely deficient in MMEJ product formation (lanes 3 and 5), AtPolIB-ΔIns2 forms the expected MMEJ product reaction products of 56 and of lower molecular weight products (lane 4) that correlate with the observed strand-displacement deficiency of this mutant (lane 4). (**D** and **E**) MMEJ reactions by point and deletion mutants in loops 1 and 3. A short deletion of 11 amino acids (599–610) in loop 1 abolishes MMEJ formation (lane 5). Point mutants K590 and K593A in loop 1 decrease MMEJ formation by 20 and 50% respectively, whereas a point mutant. K886A (loop 3) decrease MMEJ formation by 35%. MMEJ formation is quantified as the percentage of MMEJ product (P) in relation to the total amount of product and substrate (P+S). The graphical representation shows the mean of three independent experiments. (**F**) Denaturing polyacrylamide gel showing a time course reaction (from 1 to 4 minutes) by AtPolIB exo- and deletion mutants on a gapped-substrate. The six-nucleotides gapped DNA substrates, the length of the primer (24-mer), the expected maximal extension (30-mer) before strand-displacement and the full-length strand-displacement (65-mer) are indicated in the left side of the figure.

bor strong strand-displacement capabilities (40,42), mutant AtPolIs harboring a deletion in loop 1 abolish strand-displacement on a 1-nt gap, whereas mutant AtPolIB-Δins2 and AtPolIB-Δins3 severely decrease this property (42). In order to investigate if the appearance of the band of 42 nts synthesized by AtPolIB-Δins2 is related to a decrease in strand-displacement, we compare the efficiencies for strand-displacement on a 6-nt gap for all deletion mutants. Nucleotide incorporation by AtPolIB-Δins2 and AtPolIB-Δins3 is halted two and four nucleotides after the 5′-end of the blocking DNA strand (32- and 34-mer products) (Figure 5F, lanes 8 and 11). The ability of AtPolIB-Δins2 to displace two nucleotides correlates with the observed MMEJ product of approximately 42 nts (32 nts from the primer, 8 nts for extension in *trans* and 2 nts due to strand-displacement) show on a pssDNA-8 substrate (Figure 5C). The presence of the 42 nts band by AtPolIB-Δins2 supports the ability of AtPolIs to assemble a synapse in *trans* as a product mediated by snap-back replication would not be affect by the decrease in strand-displacement.

AtPolIs execute MMEJ on mismatched substrates

Analysis of microhomologous sequences found in chloroplast DNA upon DSBs contain mismatches (30,32). This suggests that in plastids MMEJ is executed by a DNAP able to extend from mismatches or that the distortions generated by a mismatch in the DNA double helix would not hamper synapse formation and its extension. We thus, investigated whether AtPolIs would use pssDNA substrates containing mismatches. We assemble six substrates using six different nucleotides annealed to the MH-8 substrate (Figure 6A and Supplementary Table S1). The first set of substrates contain three consecutive mismatches, one and two nucleotides before the 3′-OH end of the microhomologous sequence (substrate I and II, respectively). The second set of substrates (III and IV) contained one and two mismatches at their 3′-

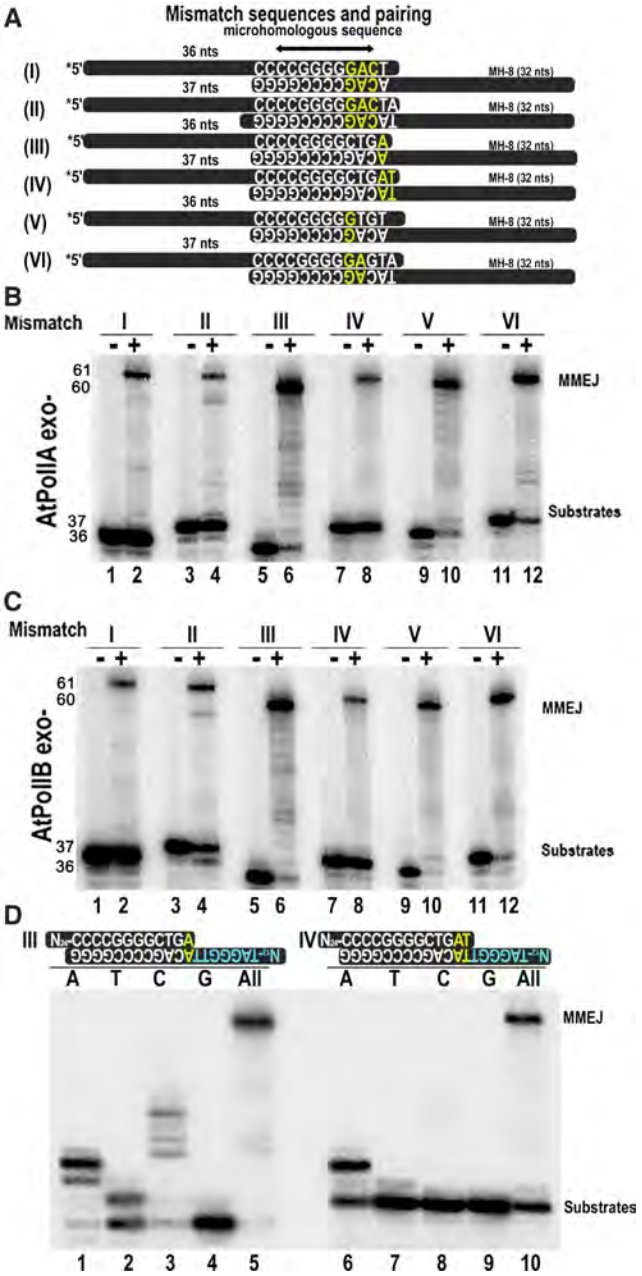

Figure 6. AtPolIA and AtPolIB execute MMEJ on mismatched substrates. (**A**) Oligonucleotide substrates containing mismatches annealed to promote MMEJ. The sequence of the microhomologous sequence of the single-stranded oligonucleotides is indicated. The mismatches are colored in red, whereas Watson-Crick pairs are colored in white. The arrangement includes mismatches located one and two nucleotides after the 3′-OH (I and II), located at the 3′-OH (III and IV), and located three and four nucleotides before the 3′-OH (V and VI). (B and C) MMEJ reactions executed by exonuclease deficient AtPolIA exo- (**B**) and AtPolIB exo$^-$ (**C**) on single-stranded substrates. The substrate without added polymerase is indicated by a negative sign (−), whereas reactions including DNA polymerase are indicated by a positive sign (+). The migration for substrates and MMEJ products are indicated. (**D**) Denaturing acrylamide gel showing the formation of MMEJ products by AtPolIB exo$^-$ on MMEJ with 3′-OH mismatches (substrates III and IV) annealed with the MH-8 oligonucleotide in the presence of individual nucleotides.

OH and the third set of substrates (V and VI) contained one and two mismatches three nucleotides before their 3′-OH (Figure 6A). To our surprise, all substrates, including a single mismatch (substrate III) and a double mismatch at the 3′-OH (substrate IV) were able to generate MMEJ products when incubated with AtPolIs exo$^-$ (Figure 6B and C). This result may relate to the fact that AtPolIs efficiently extend from a primer whose 3′-OH is confronted to an abasic site (40) and the ability of AtPolIs to extend mismatches in canonical primer-templates (43). Our data are congruent with the large repertoire of microhomologous sequences, because sequences that are not perfectly paired can be used as substrates by AtPolIs.

We decided to investigate the ability of AtPolIB exo$^-$ to incorporate individual nucleotides on substrates with one and two mismatches at their 3′-OH (substrates III and IV) (Figure 6D). On a substrate with a single nucleotide mismatch, AtPolIB exo$^-$ incorporates three dAMP nucleotides, in which two of them are expected to be template dependent and the third one due to misincorporation (Figure 6D, lane 1). AtPolIB exo$^-$ also misincoporates one adenine and several cytidines possibly due to misalignment (Figure 6D, lanes 2 and 3). On a substrate with two consecutive 3′-OH mismatches, AtPolIB exo$^-$ incorporates a dAMP molecule (Figure 6D, lane 6).

Plant specific DNA binding proteins AtmtSSBs, AtWhirlies and AtOSBs bind single-stranded DNA with different affinities

Organelles in *Arabidopsis* harbor three families of single-stranded DNA binding proteins (AtSSBs) and each family contains several members: A) The family of canonical mitochondrial DNA binding proteins (AtmtSSB) consisting of two members, B) Whirlies, which are composed of three members, and C) Organellar Single-stranded DNA Binding proteins (OSB), harboring four members (Figure 6A). AtmtSSBs contain an OB-domain follow by a C-terminal extension, AtOSBs, contain an N-terminal OB-like domain, followed by repeats (from one to four) of a PDF motif. This 50 amino acid motif is responsible for ssDNA binding. Whirlies assemble as tetramers and interact with ssDNA via the β-sheets of neighboring subunits (30,31,49,54–56) (Figure 7A).

Members of the OSB and Whirly families decrease the formation of illegitimate recombination products (31,54), whereas AtmtSSB1 promotes AtRecA strand-exchange activity (49). In order to investigate the possible role of AtSSBs in MMEJ, we directly measured their binding affinities for substrates containing ssDNAs of different lengths. In order to correctly measure their binding affinities, we first determined their oligomeric states. The elution profiles of purified AtmtSSB1, AtmtSSB2, AtOSB2, AtOSB3, and AtWhirly2 (Figure 7B, inset) on a gel filtration column revealed that all proteins assembled as tetramers in the absence of DNA (Figure 6B). In our binding studies, we used the molar concentration of the tetrameric SSBs and not the individual protomers. An EMSA on a labeled oligonucleotide of 70 nts illustrates the high binding

INFORME DE LABORES 2019

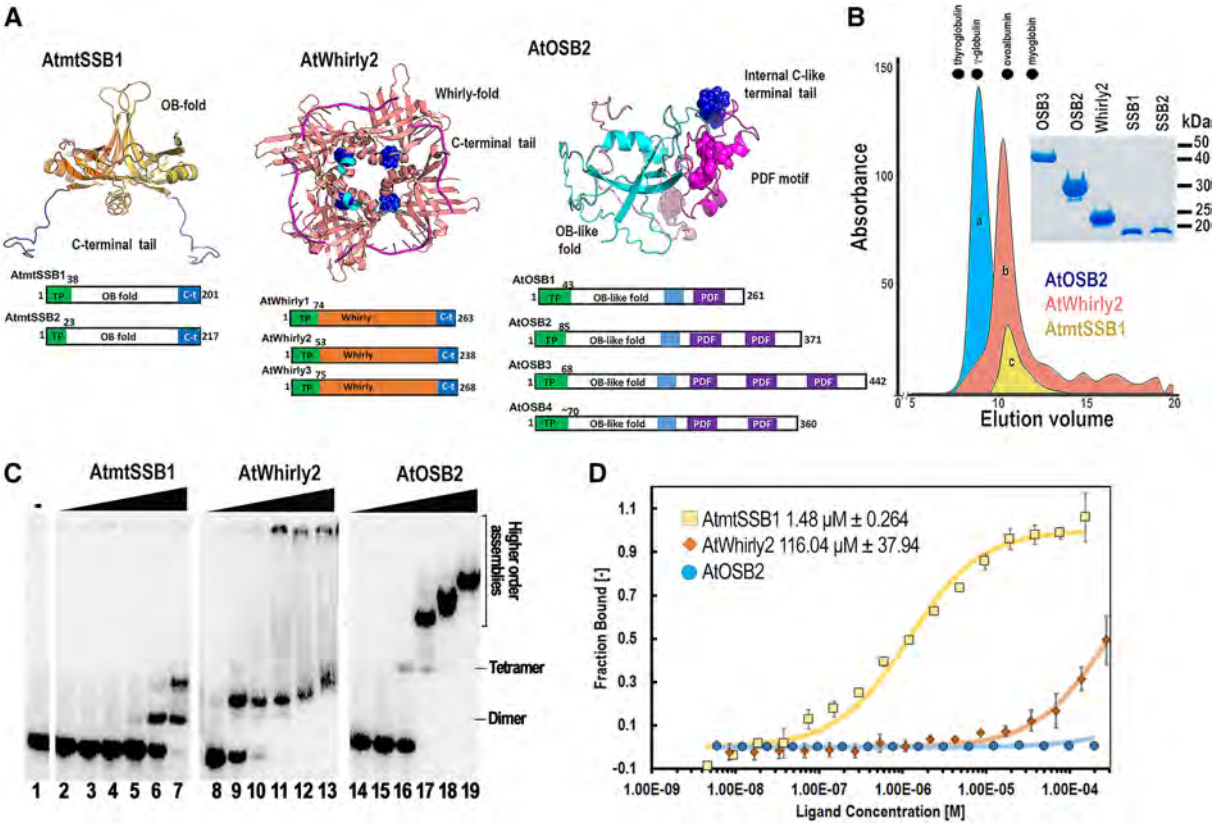

Figure 7. Arabidopsis harbors canonical and unique SSBs. (**A**) Structural organization of AtmtSSBs, AtWhirlies and AtOSBs. AtmtSSB1 and AtmtSSB2 are predicted to assemble as proteins with an oligonucleotide/oligosaccharide-binding (OB)-fold and a C-terminal disorder region, AtWhirlies (1–3) consists of a Whirly domain composed of two four-stranded β-sheets and two α–helices plus a disordered C-terminal extension (55,56), AtOSBs consist of an OB-like fold followed by one to three PDF motifs (54). The structural models of AtmtSSBs and AtOSBSs highlight the structural organization of the OB-fold domains and PDF motifs respectively. Structural modeling shows AtmtSSB1 and AtOSB1 as a dimer and monomer for clarity. The crystal structure of AtWhirly2 is shown in combination with the superimposed ssDNA co-crystallized in whirly2 from potato. The C-terminal amino acids of Whirlys are not present in their crystal structures and are proposed to be involved in protein-protein interactions. The AtWhirly2 structure illustrates the tetrameric organization and DNA binding of members this protein family. (**B**) Gel filtration profiles of purified AtmtSSB1, AtOSB2, and AtWhirly2 (inset) on a Superdex 75 column. Dots denote the elution profiles of molecular weight markers: thyroglobulin, γ globulin, ovoalbumin and myoglobin. The elution profiles of AtSSBs indicate their tetrameric assembly. (**C**) EMSA assay showing the binding of purified AtmtSSB1, AtOSB2, and AtWhirly2 to ssDNA. Reactions were incubated with increased concentration of the tetrameric SSBs (0, 1.15, 4.125, 14.87,53.5, 192.9, 694.2 nM) and 1 nM of a 5′-^{32}P-labeled 70-mer oligonucleotide. Binding reactions were resolved on an 8% non-denaturing polyacrylamide gel. (**D**) Langmuir isotherms showing the binding of AtmtSSB1 and AtWhirly2 to AtPolIB exo^{-} by MST.

affinity of AtWhirly2 for single-stranded DNA (Figure 7C, lanes 9–13). This binding is consistent with previous biochemical analyses of Whirly variants that bind ssDNA as tetramers with affinity constants of approximately 5 nM (30,55). In addition to binding as a tetramer, AtWhirly2 also forms high molecular weight complexes with ssDNA, as previously show by Cappadocia and coworkers (57). AtmtSSB1 forms two complexes that may correspond to dimeric and tetrameric assemblies in comparison to the tetrameric AtWhirly2 (Figure 7C, lanes 6 and 7). On the other hand, AtOSB2 initially binds ssDNA with a relative migration that corresponds to a tetrameric assembly, although high molecular assemblies are formed at higher protein concentrations (Figure 7C, lanes 14–19). An interesting point is the contrasting differences for ssDNA binding between plant SSBs. AtmtSSBs needs to be in a molar excess of 694-fold to shift all the 70-mer, whereas AtOSB2 and AtWhirly2 need to be in 53-fold excess (Figure 6C). Given these contrasting binding profiles, we measured the binding affinities for AtmtSSB1, AtOSB2 and AtWhirly2 on pssDNA-10 and ssDNA45-mer substrates using fluorescence anisotropy (Table 1). AtOSB2 and AtWhirly2 bind to a pssDNA-10 substrate with dissociation constants (K_d) of 8 and 22 nM respectively, whereas AtmtSSB1 was unable to bind to this substrate (Table 1). On the other hand, AtmtSSB1, AtOSB2, and AtWhirly2 bonded to a ssDNA 45-mer substrate with Kds of 62.8, 11.7 and 8.2 nM, respectively (Table 1). These values approximate the reported values for AtWhirly2 (30) and AtOSB2 (54). The EMSA and anisotropy experiments thus indicate that the binding affinity of AtmtSS1 for ssDNA substrates is weaker than the binding affinities of AtOSB2 and AtWhirly2.

AtmtSSB1, but not AtOSB2 and AtWhirly2, interact with AtPolIB with affinity constant similar to canonical replisomes

Several SSBs bind to their cognate DNA polymerases by virtue of their exposed C-terminal amino acids. In order

INFORME DE LABORES 2019

Table 1. Dissociation constants of plant organellar SSBs in pssDNA and ssDNA templates

	pssDNA-10 Oligomeric State in solution	ssDNA-45 mer Oligomeric State in solution
Protein	K_d (nM)	K_d (nM)
AtmtSSB1	—	62.8 ± 3.6 (tetramer)
AtOSB2	8.6 ± 0.46 (tetramer)	11.7 ± 2.2 (tetramer)
AtWhirly2	22.1 ± 1.3 (tetramer)	8.2 ± 0.19 (tetramer)

*Dissociation constant were determined by three independent experiments.

to investigate if AtSSBs interact with the plant organellar DNA polymerases, we evaluated a potential interaction between AtSSBs and AtPolIB exo$^-$ by MST. We found that AtPolIB exo$^-$ interacts with AtmtSSB1 with an affinity constant of 1.48 μM. This affinity constant is similar to the 1.6 μM interaction between T7 DNA polymerase and T7 SSB in the absence of thioredoxin and the 1.6 μM interaction between DNAP III and SSB from *E. coli* (58,59). In contrast, AtWhirly2 at a concentration of 250 μM (6 mg/ml) is not able to saturate a binding isotherm, suggesting that the observed interaction is non-specific or that is larger than 250 μM. AtOSB2 shows no observable binding to AtPolIB exo$^-$ (Figure 7D).

AtWhirlies and AtOSBs decrease MMEJ on long ssDNA templates

Whirlies and OSBs are proposed to compete for a partially resected DSB and prevent MMEJ in organelles (31,54). In order to obtain biochemical evidence for this hypothesis, we performed MMEJ reactions using pssDNA with microhomologies of 8 nts, but with extra single-stranded DNA sequences that ranked from 0 to 65 nts. In these reactions, we used a 50-fold molar excess of tetrameric purified SSBs (AtmtSSB1, AtmtSSB2, AtOSB2, AtOSB3, and AtWhirly2) and 5-fold AtPolIB with respect to pssDNAs (Figure 8A and B). In reactions incubated using the microhomology of 8 nts without an extra single-stranded DNA segment, pssDNA-$8_{(0)}$, the presence of SSBs did not have an effect on MMEJ formation by AtPolIB (Figure 8A, lanes 1–7). The lack of MMEJ inhibition on a pssDNA-$8_{(0)}$ correlates with the absence of binding for SSBs to this substrate (30) a (Table 1) and also indicates that the presence of SSBs does not inhibit MMEJ by AtPolIB. When 4 nts were added to the microhomologous sequence of 8 nts (pssDNA-$8_{(4)}$), AtOSB2 and AtWhirly2 completely hampered MMEJ formation (Figure 8A, lanes 12 and 14). Inhibition by AtOSB2 and AtWhirly2 on a pssDNA-$8_{(4)}$ substrate, but not by AtmtSSB1 or AtmtSSB2, correlates with the binding of AtOSB2 and AtWhirly2 to a pssDNA-10 substrate (Table 1). The presence of AtOSB3, but not AtmtSSB1 and AtmtSSB2, in substrates with single-stranded DNA regions of 43 (pssDNA-$8_{(35)}$) and 73 (pssDNA-$8_{(65)}$) nucleotides decreased product formation in pssDNA-$8_{(35)}$ and pssDNA-$8_{(65)}$ substrates (Figure 8B). The lack of inhibition for AtmtSSB1 and AtmtSSB2 on longer partially single-stranded substrates was observed even with reactions incubated with 200-fold molar excess of those proteins with respect to the ppsDNA template (Supplementary Figure S2). The binding affinity of AtmtSSB1 for a 70-mer ssDNA substrate is approximately five times weaker than the binding affinity of AtOSB2 and AtWhirly2, so the lack of MMEJ product formation by AtPolIs in reactions incubated with AtmtSSBs is not explained by a lack of binding to single-stranded DNA.

MMEJ on long substrates is favored over exonucleolysis independently of the presence of mtSSBs

MMEJ reactions incubated with substrates containing longer single-stranded DNA regions of 43 and 73 nucleotides were more efficiently used than substrates with short regions (Figure 8A and B). Canonical SSBs recruit several enzymes to DNA replication forks via their acid C-terminal extension (60,61) and AtmtSSB1 interacts with AtPolIB with similar affinities to the interactions observed in other replisomes (Figure 8D). We therefore tested whether the presence of AtmtSSBs would promote MMEJ by wild-type AtPolIs in substrates with long single-stranded DNA regions. We used substrates with increased single-stranded DNA regions of 12, 43 and 73 nucleotides while maintaining a microhomology region of 8 nts (pssDNA-$8_{(4)}$, pssDNA-$8_{(35)}$ and pssDNA-$8_{(65)}$) in the presence of increased concentrations of AtmtSSB1 and AtmtSSB2 and exonuclease proficient AtPolIB (Figure 8C–E). In a pssDNA-$8_{(4)}$ substrate, AtPolIB executed MMEJ in the presence and absence of mtSSBs with similar efficiencies and most of the substrate was degraded to 15- or a 16-mer (Figure 8C). A comparison between the amount of MMEJ product synthesized by exonuclease deficient AtPolIB and the exonuclease active form of the enzyme on the pssDNA-$8_{(4)}$ substrate shows that AtPolIB exo- converts approximately 80% of the substrate to a MMEJ product, whereas wild-type AtPolIB converts <10% of the substrate to a MMEJ product in the absence of AtmtSSB1 (Figure 8C, lanes 2 and 3). In pssDNA-$8_{(35)}$ and pssDNA-$8_{(65)}$ substrates, the exonucleolytic degradation by wild-type AtPolIB substantially decreased independent of the presence or absence of AtmtSSBs (Figure 8D and E). MMEJ reactions incubated with a pssDNA-$8_{(35)}$ substrate exhibited almost no difference when incubated with exonuclease deficient or exonuclease proficient AtPolIB (Figure 8D, lanes 2 and 3) and the addition of AtmtSSBs had no effect on MMEJ (Figure 8D, lanes 4–11). Reactions incubated with wild-type AtPolIB generate a predominant MMEJ product of 110 nts and a minimal amount of exonucleolytic products that accumulate as 15 or 16-mers (Figure 8D, lanes 3–11). A similar decrease of the exonuclease degradation products by wild-type AtPolIB is also observed in reactions incubated

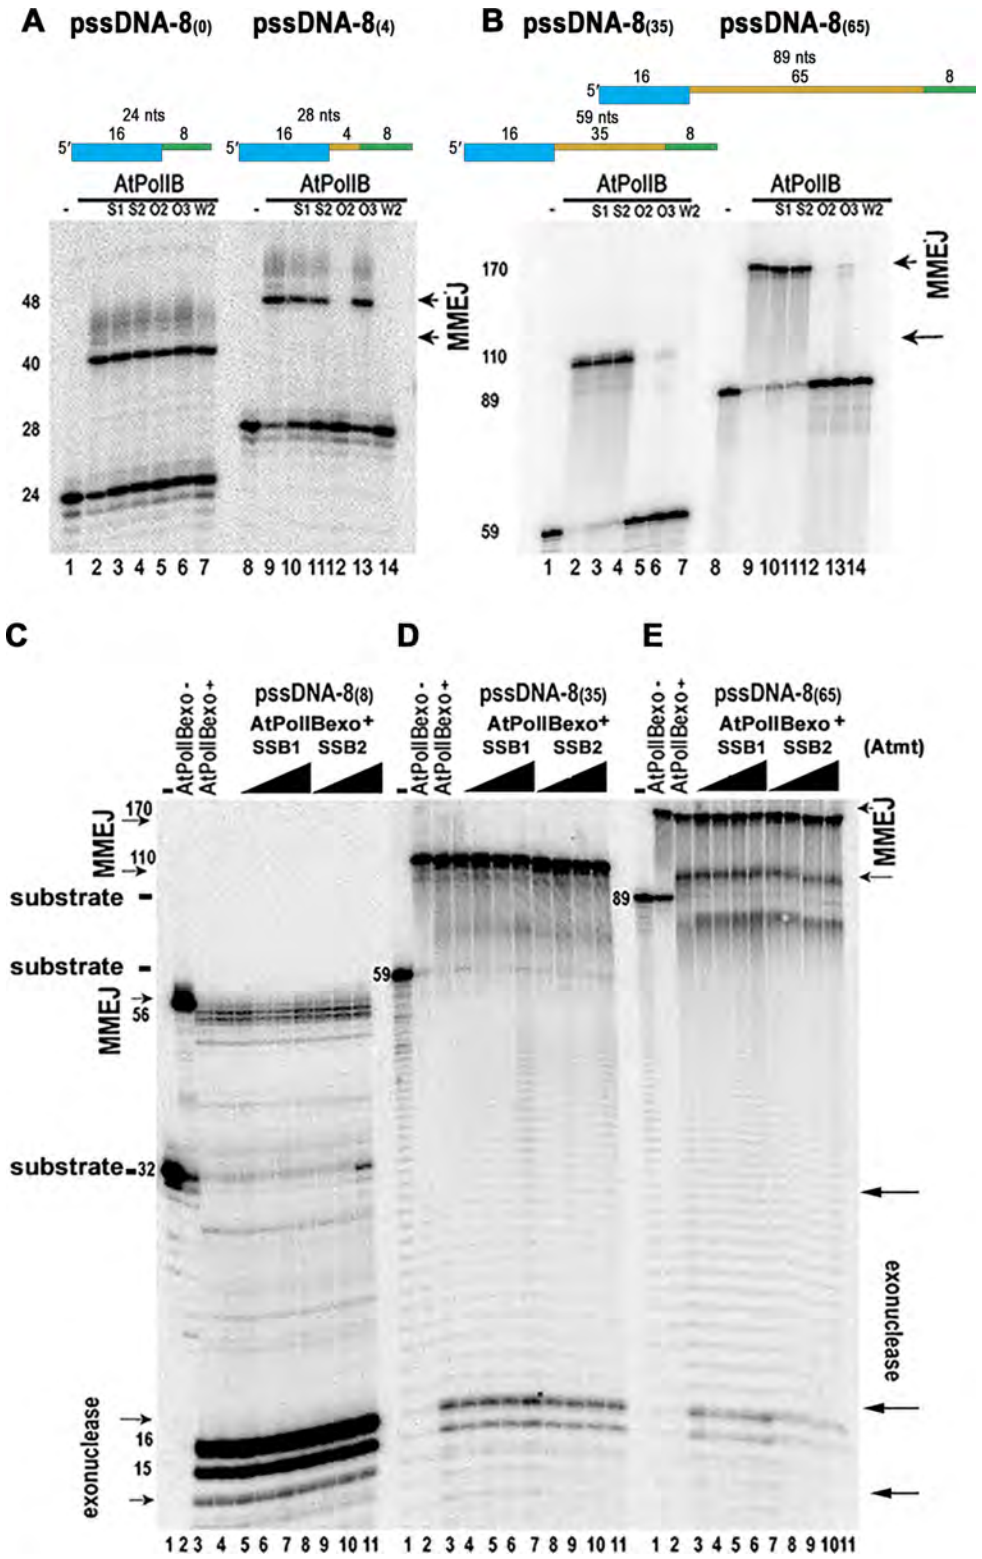

Figure 8. AtSSBs and single-stranded length of the DNA break regulate MMEJ. (**A**, **B**) Unique SSB from plant organelles hamper MMEJ on substrates with single-stranded regions longer than 8 nts. MMEJ formation by AtPolIs in the presence of plant SSBs (AtmtSSB1, S1; AtmtSSB2, S2; AtOSB2, O2; AtOSB3, O3; and AtWhirly2, W2) in MMEJ substrates with a constant microhomologous sequence of 8 nts, but varying single-stranded regions of 8 (panel A, lanes 1 to 7),12 (panel A, lanes 8–14) 43 (panel B, lanes 1–7) and 73 nts (panel B, lanes 8–14). The length of the MMEJ, single-stranded region and total oligonucleotide length of the substrates are indicated in the upper part of the panel. The length of the substrates and MMEJ products are indicated by arrows. (**C**–**E**) Wild-type AtPolIA and AtPolIB execute MMEJ with minimal exonucleolysis on substrates with single-stranded regions longer than 16 nts. (C) MMEJ reaction by AtPolIA (lanes 3–6) and AtPolIB (lanes 7–11) on a pssDNA with 8 bases of microhomologous sequence and 8 extra-bases of single-stranded DNA. The labeled substrate is indicated in lane 1 and the MMEJ product by and exonuclease deficient AtPolIB is shown in lane 2. (D and E) As in C, but with a substrate containing 35 nts or 65 nts of extra single-stranded DNA respectively.

with a pssDNA-$8_{(65)}$ substrate in the presence and absence of AtmtSSBs (Figure 8E).

DISCUSSION

Here we demonstrate that organellar DNA polymerases from the plant model *A. thaliana*, AtPolIs, efficiently perform MMEJ on partially resected DSBs longer than 6 nts, proving an explanation for DSBs repair with MMEJ signatures in plant organelles (12,29,31,32). MMEJ requires the formation of a synapse between DNA strands to join otherwise unstably paired microhomologous sequences, while creating a 3′-OH necessary for nucleotide incorporation and extension. Short microhomologous sequences could transiently pair, however these intermediates are short-lived. AtPolIs in comparison to KF DNAP I is able to stabilize these intermediates and used them as substrates. AtPolIs harbor three unique amino acid insertions in their polymerization domain (35,37) and within these insertions, insertion 1 is indispensable for MMEJ. Thus, AtPolIs and HsPolθ converged in the use of insertions for MMEJ and lesion bypass (21,40).

Mismatches are an abundant feature in DSBs repaired by MMEJ in plant organelles. For example, the Brisson group showed that 91 out of 158 induced MMEJ rearrangements in plastid DNA contain mismatches (30). Thus, the machinery responsible to execute MMEJ in plant organelles must be able to extend from mismatches. The fact that AtPolIs can efficiently anneal and extend from microhomologus sequences harboring mismatches at their 3′-OH, supports the notion that these enzymes are biochemically equipped to execute MMEJ in plant organelles. In contrast to HsPolθ, AtPolIs contain an active exonuclease domain and its modulation should be essential for MMEJ *in vivo*. In substrates that contain a short single-stranded region, *i.e.* less than 12-nts, AtPolIs exonucleolytic degradation is preferred over MMEJ. An increase in the length of the single-stranded region, however, promotes MMEJ at levels in which exonuclease deficient and wild-type AtPolIs execute MMEJ with similar efficiencies. We speculate that the presence of extra nucleotides generates a binding platform for AtPolIs that promotes synapse formation (Figure 8D and E). The ability of exonuclease proficient AtPolIs to carry out MMEJ on substrates with long single-stranded regions with the same efficiency that exonuclease deficient AtPolIs reinforces the notion of the functional relevance of these enzymes to execute MMEJ *in organello*.

Arabidopsis plants harboring T-DNA insertion mutants in *why* and *osb1* genes accumulate DSBs that are repaired via MMEJ and an increase of ectopic recombination products (30,54). As MMEJ and ectopic homologous recombination are driven by annealing of short single-stranded DNA sequences, we analyzed the effect of AtmtSSBs, At Whirly2 and AtOSBs in MMEJ by AtPolIB. Whirlies and AtOSBs are proposed to counter MMEJ and ectopic homologus recombination by binding to 3′-OH resected ends (10,30,62). This binding is predicted to hamper the annealing of the microhomologous or short-homologous sequences. We demonstrated that the presence of AtWhirly2 and AtOSBs in templates containing single-stranded regions longer than 12 nts hampers MMEJ. AtOSB3 is unable to prevent MMEJ on a pssDNA with a single-stranded region of 12 nts, but efficiently hampers MMEJ on longer substrates (Figure 8A and B). This differential correlates with the presence of an extra PDF domain, suggesting that AtOSB3 needs a larger nucleotide length for binding (10).

AtmtSSB, AtWhirly2, and AtOSBs, bind single-stranded DNA and pssDNA substrates with different affinities (10,30,31,54) (Figure 8 and Table 1). Only AtWhirly2 and AtOSBs, however, completely block MMEJ by AtPolIs. The latter suggests that the concentration of AtmtSSBs needed to block MMEJ is much higher because of its weaker affinity for ssDNA, that AtmtSSBs easily dissociate from DNA, or that AtmtSSBs physically interact with AtPolls and displaces these proteins. The weak binding for ssDNA by mtSSB is observed for other proteins from the same family that have micromolar affinities for ssDNA binding (63). A weak binding of the plant organellar OB-fold maybe related to the modular structure of AtOSBs, in which their PDF domains are responsible for binding to single-stranded DNA and their associated OB-fold domain does not contribute to ssDNA binding (54).

MMEJ inhibition by AtOSBs and Whirlies is in agreement with previous models explaining the fate of genomic DNA upon DSBs in plant organelles (10,30,62,64). Plant organelles harbor a bacterial RecA orthologue that mediates homologous recombination and a Rad52-like single-stranded annealing protein, dubbed organellar DNA-binding protein 1 (ODB1). ODB1 has been proposed to direct SSBs displacement from single-strand DNA regions and promotes loading of RecA (10,65,66). In plant organelles, U-turn-like rearrangements are mediated by microhomologies. The absence of whirlies and AtRecA in Arabidopsis increases the amount of U-turn-like rearrangements (67). Zampini and coworkers postulate that RecA promotes accurate fork restart suggesting that in the absence of whirlies the single-stranded 3′-OH of a collapsed replication fork anneals to an opposite strand generating U-turn-like rearrangement (67). Based upon our biochemical results and previous genetic analysis (6,11,27,28,32,54,65,67), we propose a model in which AtOSBs and AtWhirlies limit MMEJ by blocking the access of a single-stranded 3′-OH to AtPolIs or AtmtSSBs. AtmtSSBs binding to the 3′-OH may result in recruiting AtPolIs or the HR machinery, and MMEJ would be favored only if AtPolIs reach the end of partially resected 3′-OH (Figure 9). If the proposed block of the single-stranded 3′-OH is limited by the absence of whirlies and HR is impaired by lack of AtRecA, other DNA repair routes like MMEJ would mediate DSB repair.

Both AtPolIA and AtPolB execute MMEJ, suggesting that *in vivo* MMEJ is executed by both polymerases. This contrasts with the role of AtPolIB in preventing MMEJ rearrangements in chloroplasts proposed by Parent and coworkers (29). A plausible explanation for the increase of MMEJ rearrangements in T-DNA insertion lines inactivating AtPolIB may lie in a differential in lesion bypass abilities between AtPolIA and AtPolIB. For instance, if AtPolA possesses less efficient lesion bypass than AtPolIB, organellar DNA replication under the sole presence of AtPolIA would have a greater tendency to collapse generating double-stranded breaks. Alternatively, it is possible that At-

INFORME DE LABORES 2019

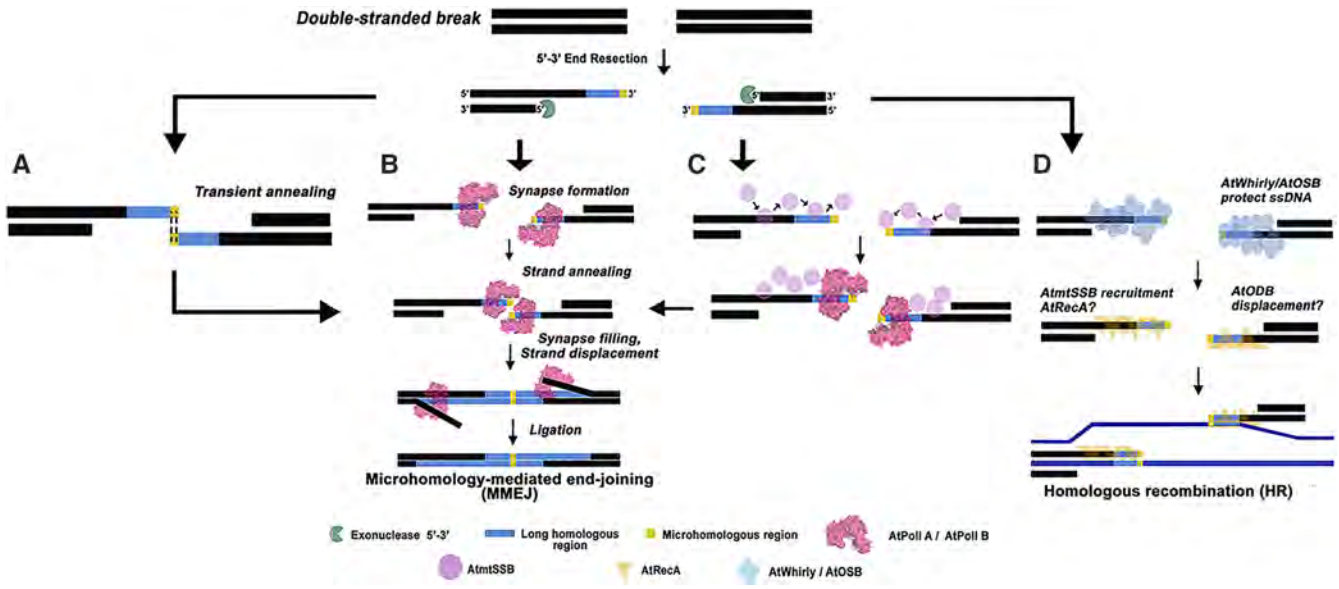

Figure 9. Proposed model for DSBs fate in plant organelles. Microhomology-mediated end-joining or Homologous Recombination is driven by the access of single-stranded binding proteins to a 3′-OH single-stranded end. Resected single-strand DNA regions with microhomologous (yellow) and long homologous (blue) sequences are produced upon DSBs. Plant SSBs and AtPolIs compete to bind the 3′-OH of a resected end. If single-stranded biding proteins AtOSBs or AtWhirlies bind to a resected end, they block the access to canonical AtmtSBB and AtPolIs. Binding of mtSSBs would promote MMEJ if sufficient AtPolIs is available to react with them. Conversely recruitment of RecA to a 3′-OH of a resected end would drive homologous recombination.

PolIB, but not AtPolIA, interacts with components of the HR machinery (29). Although the latter scenario is speculative, our data reveal that MMEJ in plant organelles is driven by a unique family of DNAPs. The presence of these polymerases, instead of metazoan DNAP γ, may account for the numerous MMEJ events in plant organelles. AtPolIs are functionally analogous to HsPolθ, in both lesion bypass and MMEJ. The functional similarities between AtPolIs and HsPolθ are and example of protein convergence in which nature has used amino acid insertions to decorate the active site of family-A DNA polymerases and execute novel DNA transactions.

Abstract

Background: Vasoinhibin, a protein derived from prolactin, regulates various vascular functions including endothelial cell survival. Of note, vasoinhibin is present in the central nervous system, where it triggers neuroendocrine and behavioral responses to stress. Moreover, vasoinhibin compromises nerve growth factor (NGF)-induced neurite outgrowth in primary sensory neurons of the peripheral nervous system. Nonetheless, information on the functions of vasoinhibin in developing neurons remains limited. The present study explored whether vasoinhibin affects the neurotrophic actions of NGF by measuring the cell differentiation and survival of PC12 pheochromocytoma cells. ***Methods:*** The effects of recombinant or lentiviral vector-transduced human vasoinhibin were tested on differentiating PC12 cells. Neurite outgrowth was quantified by measuring their length and density. The MTT assay was employed to assess cell viability, and ELISA was used to quantify DNA fragmentation as an index of apoptosis. Phosphorylated Akt and ERK1/2 were analyzed by Western blotting. ***Results:*** The addition of a human recombinant vasoinhibin, and the transduction of a lentiviral vector carrying a human vasoinhibin sequence, significantly reduced NGF-induced neurite outgrowth, cell survival, and phosphorylation of Akt and ERK1/2, and increased DNA fragmentation and caspase 3 activation in PC12 cells. ***Conclusions:*** Vasoinhibin downregulates NGF-induced differentiation and survival of PC12 cells, blocking tropomyosin receptor kinase A-triggered signaling pathways and increasing apoptosis. These results establish that vasoinhibin interaction with NGF and other neurotrophins may be critical in mediating pathways involved in neuronal survival and differentiation.

Introduction

Vasoinhibin is an endocrine and autocrine/paracrine factor that downregulates blood vessel growth and function and upregulates inflammatory responses [for reviews see 1–3]. Vasoinhibin, previously referred to as "16-kDa PRL," is a posttranslational N-terminal cleavage

product of prolactin (PRL), ranging in molecular mass between 11 and 18 kDa depending on the proteases involved in its generation, which include cathepsin D [4, 5], matrix metalloproteinases [6], and bone morphogenetic protein 1 [7]. Vasoinhibin antagonizes the angiogenesis, vasopermeability, and vasodilation induced by vascular endothelial growth factor and other vasoactive compounds [for reviews see 1–3] via a direct action on endothelial cells. Likewise, vasoinhibin stimulates inflammatory reactions in fibroblasts [8, 9].

Recent studies have revealed a diversity of roles for vasoinhibin beyond the vascular system. Nonetheless, information on the functions of vasoinhibin in the nervous system remains limited. Vasoinhibin operates in the central nervous system (CNS) and peripheral nervous system. Vasoinhibin was detected in the rat hypothalamus [10–12], specifically in the hypothalamic paraventricular and supraoptic nuclei, where it appears to function as a stimulator of vasopressin release [13] and as a functional inhibitor of vascular endothelial growth factor, whose expression is particularly high at these sites [10, 14]. Furthermore, the intracerebroventricular administration of vasoinhibin promotes behaviors associated with anxiety and depression [12], suggesting neuropeptide-like functions for vasoinhibin within the CNS. Recent studies on the peripheral nervous system have revealed direct actions of vasoinhibin on primary sensory neurons, including the inhibition of some neurotrophic actions of nerve growth factor (NGF), such as neurite outgrowth [15].

NGF is the prototypic member of the family of neurotrophins or neurotrophic factors [16] that control a variety of developmental and functional processes of the nervous system [for review see 17], including regulation of neuronal proliferation, survival, differentiation, and plasticity [18]. The signaling pathways involved in NGF-induced neuronal differentiation and survival have been extensively studied in PC12 pheochromocytoma cells [19, 20]. NGF exerts these effects through binding to two transmembrane receptors: the high-affinity tropomyosin receptor kinase A (TrkA) and the low-affinity p75. In the presence of NGF, TrkA and p75 form a cooperating receptor complex [21, 22]. TrkA receptor signaling involves initiating the phosphatidylinositol 3-kinase (PI3K)/Akt and the mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase 1/2 (ERK1/2) pathways [18]. Activation of the PI3K/Akt axis is essential for NGF-specific protection of neuronal cells from apoptosis [23] and neuronal differentiation [24], while activation of the MAPK/ERK1/2 pathway appears to be critical for the NGF-induced neuronal differentiation of PC12 cells [25].

As mentioned earlier, vasoinhibin interferes with neurite outgrowth triggered by the binding of NGF to the TrkA/p75 receptor complex in dorsal root ganglion neurons [15]. Therefore, it is important to investigate the functional interaction of vasoinhibin with NGF, as well as their putative signaling cross-talk. If the hypothesis that vasoinhibin interferes with TrkA signaling is true, vasoinhibin would suppress NGF signaling and inhibit some of its neurotrophic actions. In this study, we present evidence that a recombinant human vasoinhibin, or the transduction of a human vasoinhibin with a lentiviral vector, markedly attenuated the differentiating effect of NGF in cultured PC12 cells, as revealed by the inhibition of neurite extension. Likewise, vasoinhibin blocked the prosurvival properties of NGF in serum-deprived PC12 cells. NGF treatment resulted in the rescue of cell survival in serum-deprived PC12 cells, suggesting that vasoinhibin might partially cross-talk with the signaling pathways triggered by NGF activation of TrkA receptors. Indeed, vasoinhibin blocked the NGF-induced phosphorylation/activation of Akt and ERK1/2. Also, vasoinhibin reversed the antiapoptotic effects of NGF in serum-deprived PC12 cells. These findings reveal the inhibitory effect of vasoinhibin in the downstream action of neurotrophin signaling and provide novel insights into the functional role of vasoinhibin in the nervous system.

Materials and Methods

Cell Culture

PC12 cells (American Type Culture Collection, Manassas, VA, USA) were cultured and maintained in RPMI-1640 medium supplemented with 10% heat-inactivated horse serum, 5% heat-inactivated fetal bovine serum, 2 mM glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. Cells were routinely grown in 25 cm^2 tissue culture dishes (Corning, New York, NY, USA) at 37 °C in a humidified atmosphere containing 5% CO_2, and the medium was changed every 3 days [26]. The cell culture reagents and sera were purchased from Thermo Fisher Scientific, Waltham, MA, USA.

Cell Differentiation and Treatment

For NGF-induced differentiation into neuron-like cells, PC12 cells were cultured in serum-free RPMI-1640 medium supplemented with NGF-β (Sigma-Aldrich, St. Louis, MO, USA). In order to investigate the effects of vasoinhibin upon NGF-induced neurite outgrowth, i.e., increased cell viability and decreased apoptosis, some PC12 cell cultures were treated with a recombinant vasoinhibin containing the first 123 amino acids (aa) of the human PRL sequence and a tail of 7 histidines, generated as previously described [27]. In addition, NGF actions were also tested in PC12 cells transduced with a lentiviral vector expressing human vasoinhibin.

Generation of Vasoinhibin-Expressing PC12 Cells

Stable expression of vasoinhibin and green fluorescent protein (GFP) in PC12 cells was achieved by lentiviral transduction. To generate the lentiviral genome, the *GFP* gene from the self-inactivating pHR-SIN SEWe plasmid [28], kindly provided by PhD Brendel, Boston Children's Hospital, was substituted with a human 123-aa vasoinhibin sequence amplified by PCR from the full-length human PRL cDNA including the signal peptide from an existing construct [29]. Vasoinhibin- and GFP-expressing lentiviral vectors pseudotyped with vesicular stomatitis virus G glycoprotein were produced by transient cotransfection on HEK 293T cells, as described elsewhere [30]. Cell-free viral supernatants were concentrated and titrated by real-time PCR. To transduce the PC12 cells, 1×10^4 undifferentiated cells were seeded in 6-well plates in 1 mL of RPMI-1640 medium supplemented with 10% heat-inactivated horse serum, 5% heat-inactivated fetal bovine serum, 2 mM glutamine, 100 U/mL penicillin, and 100 µg/mL streptomycin, inoculated with 1×10^5 viral particles of the vasoinhibin- or GFP-expressing lentiviral vectors (MOI of 1), and cultured at 37 °C in a humidified atmosphere containing 5% CO_2 for 72 h.

Neurite Outgrowth Analysis

To measure neurite outgrowth, 1×10^4 wild-type PC12 cells and PC12 cells transduced with lentiviral vectors expressing either GFP or vasoinhibin were seeded in 12-well plates coated with poly-L-lysine and cultured in serum-free RPMI-1640 medium supplemented with 2 mM glutamine, 100 U/mL penicillin, and 100 µg/mL streptomycin. Cells were treated for either 1, 3, 5, or 7 days with NGF (50 ng/mL) with or without vasoinhibin (10 nM). Phase-contrast photographs were registered every day at the same time using an Olympus IX51 Inverted Microscope (Olympus, Tokyo, Japan) and a QImaging micropublisher 3.3 RTV camera (QImaging, Surrey, BC, Canada). Ten fields containing a total of at least 100 cells were randomly chosen for neurite growth assay. Cell processes longer than the cell body's diameter were counted as neurites. The length of the longest neurite was traced using ImageJ software (NIH, Bethesda, MD, USA) [31].

MTT Assay of Cell Viability

Cell viability was assessed by measuring the reduction of MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) to produce a dark-blue formazan product. Wild-type PC12 cells and PC12 cells transduced with lentiviral vectors expressing either vasoinhibin or GFP were seeded in triplicate in flat-bottom 96-well plates (Corning) at a density of 1×10^4 cells/well. Cells were cultured in RPMI-1640 medium with or without serum and exposed to NGF (50 ng/mL), vasoinhibin (10 nM), or their combination for 7 days. MTT (Sigma-Aldrich) was added to each well to a final concentration of 500 µg/mL, and incubation continued for 4 h at 37 °C. The resulting formazan product was solubilized using a detergent reagent (0.4 N HCl and 10% SDS) in the dark for 2 h at room temperature, and absorbance was measured at 570 nm. The results are expressed as percent of absorbance relative to control cells cultured with serum. Each experiment was repeated 3 times.

TUNEL and Cleaved Caspase 3 Immunofluorescence Analysis of PC12 Cell Apoptosis

PC12 cells were cultured on 18-mm glass coverslips pretreated with poly-L-lysine, and exposed 24 h later to NGF (50 ng/mL), vasoinhibin (10 nM), or a combination of both, in the presence or absence of serum. After 7 days, the cells were fixed with 4% paraformaldehyde for 1 h at room temperature and washed twice with 1× PBS. Apoptosis was detected by the TUNEL method using the In Situ Cell Death Detection Kit (Roche Diagnostics, Risch-Rotkreuz, Switzerland). Blockage of nonspecific binding sites was achieved by incubation in 1× PBS, 0.05% Triton X-100, 1% bovine serum albumin, and 5% normal goat serum during 1 h. Immunostaining was carried out overnight at 4 °C in PBS containing 1% bovine serum albumin, 0.05% Triton X-100, and polyclonal anti-cleaved caspase 3 (1:200 dilution; Millipore, Burlington, MA, USA). The samples were then washed 3 times with PBS and incubated in a PBS solution containing an anti-rabbit IgG conjugated to Alexa 546 (1:500 dilution; Invitrogen, Eugene, OR, USA). The PC12 cells were mounted with VECTASHIELD mounting medium with DAPI (Vector Laboratories, Burlingame, CA, USA). The preparations were maintained at 4 °C until observation with a Zeiss LSM 510 Confocal Microscope (Zeiss, Feldbach, Switzerland).

DNA Fragmentation Analysis of PC12 Cell Damage

PC12 cell apoptosis was also assessed using a cell death detection ELISA (enzyme-linked immunosorbent assay kit; Roche Applied Science, Penzberg, Germany) to measure the fragmentation of DNA. Wild-type PC12 cells were seeded in triplicate in 48-well plates (Corning) at a density of 1×10^5 cells/well. The cells were cultured in RPMI-1640 medium with or without serum and exposed to NGF (50 ng/mL) alone or in combination with vasoinhibin (10, 100, or 1,000 nM). After 48 h, the cells were lysed and processed according to the manufacturer's instructions.

Western Blot Analysis

For analysis of protein phosphorylation, wild-type PC12 cells and PC12 cells transduced with lentiviral vectors expressing either vasoinhibin or GFP were incubated for 10 min in serum-free RPMI-1640 medium supplemented with 50 ng/mL NGF, and analyzed for phospho-Akt, Akt, phospho-ERK1/2, and ERK1/2. The cells were lysed at 4 °C in TNTE buffer (150 mM NaCl, 1 mM EDTA, and 0.5% Triton X-100, supplemented with protease inhibitors: 2 mM leupeptin, 1.5 mM pepstatin A, 1.4 mM E-64, 4 mM bestatin, 80 µM aprotinin, and 1 mM phenylmethylsulfonyl fluoride [Sigma-Aldrich] in 50 mM Tris buffer, pH 7.4). The proteins separated by SDS-PAGE 12% gel electrophoresis were then transferred onto a nitrocellulose membrane. The membranes were blocked with 5% nonfat skimmed milk in TBST buffer (20 mM Tris-HCl, pH 7.6, 137 mM NaCl, and 0.01% Tween 20) for 1 h at room temperature, followed by incubation with primary antibodies against phosphorylated ERK, phosphorylated Akt, ERK, or Akt. After extensive washing with TBST, the membrane was reprobed with 1:3,000 horseradish peroxidase-linked anti-rabbit or anti-mouse immunoglobulin in 5% nonfat skim milk-TBST for 40 min at room temperature. Immunoblots were visualized by enhanced chemiluminescence (SuperSignal West Femto Chemiluminescent Substrate; Thermo Fisher Scientific) according to the manufacturer's protocol. All experiments were repeated at least 3 times.

Statistical Analysis

All values are expressed as means ± SEM. Statistical significance was determined by one-way ANOVA, followed by Bonferroni's multiple-comparison post hoc test, with $p < 0.05$ considered statistically significant.

Results

Vasoinhibin Inhibits NGF-Induced Neurite Outgrowth in Differentiating PC12 Cells

Neurite outgrowth represents a critical process in synapse formation during development. PC12 cells are known to differentiate into neuron-like cells in the presence of NGF [26]. We first confirmed the response to NGF in our sample PC12 cells. Treatment with 50 ng/mL NGF induced neurite outgrowth in most cells (Fig. 1a). We found that the cells were round to oval in shape without neurites in normal serum-containing medium. After treatment with 50 ng/mL NGF for 1 day, the serum-deprived PC12 cells began to develop neurites. By days 3, 5, and 7, almost all cells showed significant neurite outgrowth extension. The length of the longest neurites increased in a time-dependent manner between days 1 and 7 (Fig. 1c, white bars). The number of neurites per cell reached a plateau by day 3 (Fig. 1d, white bars).

We next investigated whether NGF-induced neurite outgrowth was affected by exogenous administration of

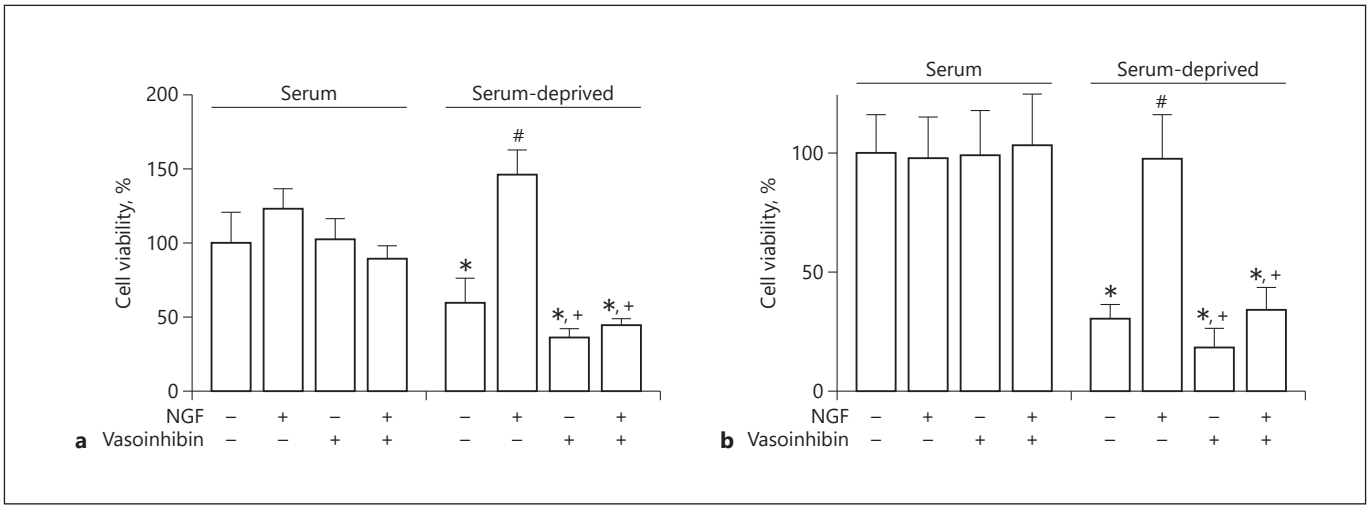

Fig. 3. Vasoinhibin decreased the prosurvival effect of nerve growth factor (NGF) in serum-deprived PC12 cells. Cell survival was analyzed by the MTT assay to quantify surviving PC12 cells. **a** Wild-type PC12 cells cultured with serum or exposed to serum starvation were challenged with NGF (50 ng/mL), vasoinhibin (10 nM), or both. **b** PC12 cells expressing green fluorescent protein (GFP) cultured with serum or exposed to serum starvation were challenged with NGF (50 ng/mL), vasoinhibin (10 nM), or both. Values shown are means ± SEM and expressed as percentage of the untreated cells cultured with serum. The experiments were repeated 3 times with similar results. * $p < 0.05$ versus corresponding serum condition; $^{\#}$ $p < 0.05$ versus untreated cells; $^{+}$ $p < 0.05$ versus NGF-treated cells.

vasoinhibin to differentiating PC12 cells. We treated serum-deprived PC12 cells with 50 ng/mL NGF and 10 nM human recombinant vasoinhibin. We found that the extent of neurite growth was significantly inhibited by the addition of vasoinhibin (Fig. 1b). The effect of vasoinhibin was mainly due to a significant reduction of the length of the neurites by days 3–7 (Fig. 1c, gray bars). The number of neurites per cell was not affected by vasoinhibin between days 1 and 5, but was significantly lower by day 7 (Fig. 1d, gray bars).

NGF-Induced Neurite Outgrowth Is Hampered in Differentiating PC12 Cells Expressing Vasoinhibin

To further investigate the effect of vasoinhibin on NGF-induced neurite outgrowth, we tested the effect of NGF on PC12 cells transduced with a lentiviral vector expressing human recombinant vasoinhibin. PC12 cells were transduced with a lentiviral vector containing a human vasoinhibin truncated at aa 123 of the human PRL sequence. In addition to wild-type PC12 cells, PC12 cells transduced with a lentiviral vector expressing GFP were used as controls. Again, treatment with 50 ng/mL NGF induced neurite outgrowth in most wild-type PC12 cells (Fig. 2a). The expression of GFP using a lentiviral vector did not alter NGF-induced neurite outgrowth (Fig. 2b). In both cell cultures, the length of the neurites increased in a time-dependent manner between days 1 and 7 (Fig. 2d, white bars).

In contrast, NGF was unable to induce neurite growth in PC12 cells transduced with a lentiviral vector expressing vasoinhibin (Fig. 2c). Both the length of the neurites and the number of neurites per cell were significantly inhibited in vasoinhibin-expressing PC12 cells (Fig. 2d, e). These results are consistent with a previous report showing that vasoinhibin inhibits neurite outgrowth of primary sensory neurons [15], and they demonstrate that our PC12 cell line responds to both types of vasoinhibin treatment.

Vasoinhibin Decreases the Prosurvival Effect of NGF in Serum-Deprived PC12 Cells

NGF is known to promote the survival of PC12 cells [26]. We first confirmed this effect investigating PC12 cell survival, as determined by the MTT assay. Serum starvation significantly decreased the cell viability of wild-type PC12 cells (Fig. 3a) and PC12 cells expressing GFP (Fig. 3b). NGF (50 ng/mL) rescued the viability of both wild-type PC12 cells (Fig. 3a) and PC12 cells expressing GFP (Fig. 3b) exposed to serum deprivation to the levels observed in cells cultured with serum. The addition of 10 nM vasoinhibin significantly suppressed the NGF-mediated neuroprotective effect on both wild-type PC12 cells

Universidad Nacional Autónoma de México
132.248.16.208 - 10/20/2020 8:49:09 AM

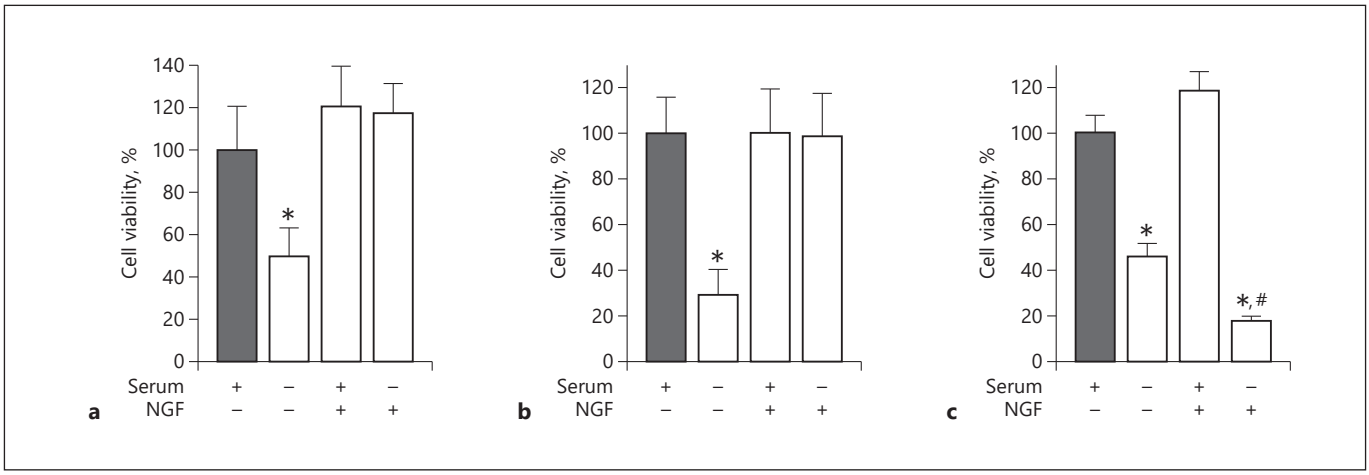

Fig. 4. The neuroprotective effect of nerve growth factor (NGF) on PC12 cells exposed to serum starvation is blocked by vasoinhibin. Cell survival was analyzed by the MTT assay to quantify surviving PC12 cells. **a** Wild-type PC12 cells, incubated with serum or exposed to serum starvation, were cultured with or without NGF (50 ng/mL). **b** PC12 cells expressing green fluorescent protein (GFP), incubated with serum or exposed to serum starvation, were cultured with or without NGF (50 ng/mL). **c** PC12 cells expressing human recombinant vasoinhibin, incubated with serum or exposed to serum starvation, were cultured with or without NGF (50 ng/mL). Values shown are means ± SEM and expressed as percentage of the untreated cells cultured with serum. The experiments were repeated 3 times with similar results. * $p < 0.05$ versus untreated cells cultured with serum; # $p < 0.05$ versus untreated cells cultured without serum.

(Fig. 3a) and PC12 cells expressing GFP (Fig. 3b). Vasoinhibin, by itself, had no effect on the cell viability of either cell type. Under serum condition, vasoinhibin was also unable to affect cell viability, either by itself or when tested with NGF.

We next quantified the protective effect of NGF in vasoinhibin-expressing PC12 cells, in comparison with wild-type and GFP-expressing PC12 cells (Fig. 4). In agreement with the effect shown by treatment with recombinant vasoinhibin, expression of vasoinhibin after lentiviral vector transduction prevented the neuroprotective effect of NGF (Fig. 4c) that was observed in wild-type PC12 cells (Fig. 4a) and in PC12 cells expressing GFP (Fig. 4b).

Vasoinhibin Reverts NGF Inhibition of Apoptosis, Caspase 3 Activation, and DNA Fragmentation in Serum-Deprived PC12 Cells

Apoptosis is the main process involved in serum deprivation-induced cell death in PC12 cells [32]. We first examined the effect of NGF on PC12 cell apoptosis by TUNEL assay, upon exposure of the cells to serum deprivation injury (Fig. 5a). Serum-deprived PC12 cells showed increased TUNEL staining, and this effect was prevented by NGF. Addition of vasoinhibin in combination with NGF completely abolished the protective effect of NGF. Cleaved caspase 3 followed the same pattern (Fig. 5b). Serum deprivation increased the number of cleaved caspase 3-positive cells, and again, this effect was prevented by NGF. Co-incubation of PC12 cells with NGF and vasoinhibin completely abolished the neuroprotective effect of NGF.

We next quantified DNA fragmentation as a third parameter of cellular apoptosis. Under conditions of serum deprivation, PC12 cells showed increased levels of DNA fragmentation as measured by ELISA (Fig. 6a). The effect of serum deprivation was prevented by incubating PC12 cells with 50 ng/mL NGF (Fig. 6a). On the other hand, 100 and 1,000 nM vasoinhibin significantly increased DNA fragmentation in PC12 cells cultured with serum (Fig. 6b). Likewise, increasing concentrations of vasoinhibin decreased the effect of NGF, as shown by the significant dose-dependent increase in DNA fragmentation in response to 100 and 1,000 nM vasoinhibin in serum-deprived PC12 cells cultured with 50 ng/mL NGF (Fig. 6c).

Vasoinhibin Prevents NGF-Induced Activation of PI3K and MAPK in Serum-Deprived PC12 Cells

PI3K and MAPK activation is necessary for NGF-induced neurite outgrowth and survival in PC12 cells [18, 33]. We examined the role of PI3K and MAPK activation

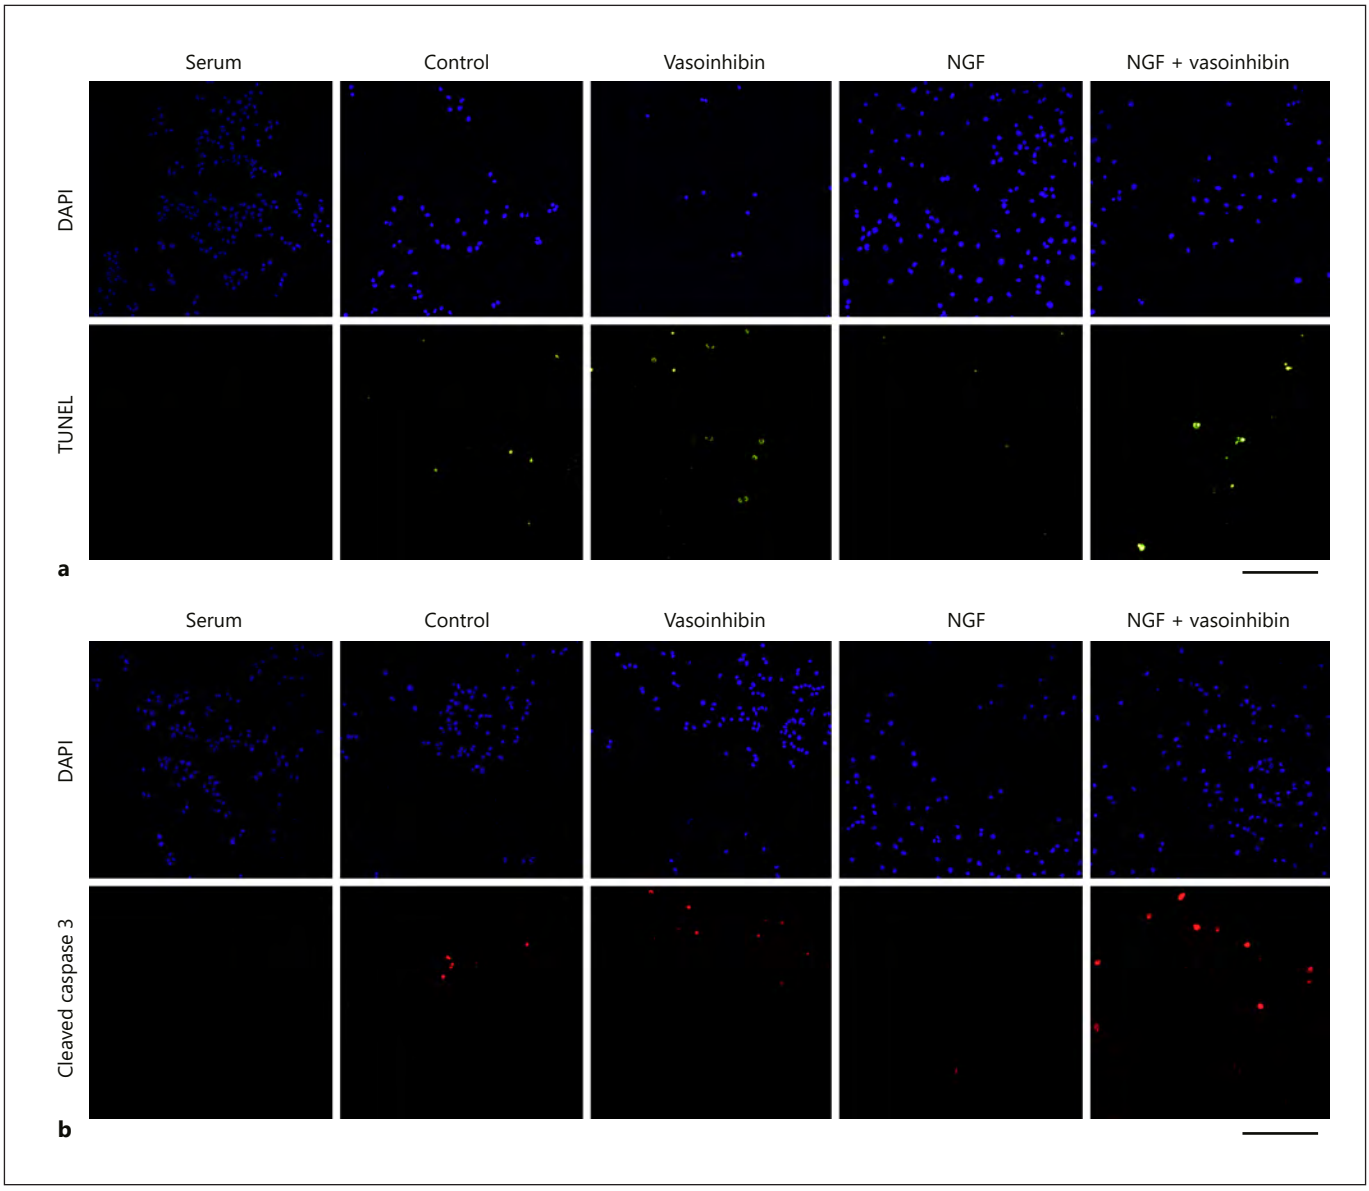

Fig. 5. Vasoinhibin prevented nerve growth factor (NGF) inhibition of apoptosis and caspase 3 activation in serum-deprived PC12 cells. Apoptosis was analyzed by TUNEL assay (**a**) and cleaved caspase 3 immunostaining (**b**) in PC12 cells. The effects of serum starvation for 24 h in the presence or absence of NGF (50 ng/mL), vasoinhibin (10 nM), or their combination are shown in representative photomicrographs of PC12 cells. **a** Green: TUNEL-positive cells. **b** Red: cleaved caspase 3 immunostaining using anti-cleaved caspase antibodies. Cells were co-stained with DAPI to demonstrate nuclear staining. Scale bars, 100 μm.

using Western blot analysis to test the ability of NGF to induce the phosphorylation of Akt and ERK1/2. The addition of NGF for 10 min enhanced Akt and ERK1/2 phosphorylation in protein extracts from wild-type and GFP-expressing PC12 cells (Fig. 7). The NGF-induced Akt and ERK1/2 phosphorylation was prevented in vasoinhibin-expressing PC12 cells.

Likewise, NGF-treated wild-type PC12 cells showed a long-term and time-dependent increase in Akt phosphorylation (Fig. 8a), which was prevented when the PC12 cells were co-treated with NGF and vasoinhibin (Fig. 8b). These results show that NGF is unable to activate the PI3K and MAPK pathways in PC12 cells in the presence of vasoinhibin.

Discussion

In this study, we explored the effects of vasoinhibin, an N-terminal fragment of PRL [1], on TrkA tyrosine kinase receptor signaling in differentiating adrenal PC12 pheochromocytoma cells. We present evidence that treatment with a recombinant human vasoinhibin, either via its administration or expressed by its transduction via a lentiviral vector, markedly attenuated the differentiation, survival, and antiapoptotic effects of NGF in cultured PC12 cells. We also explored the effects of vasoinhibin on TrkA signaling and found a dramatic attenuation of NGF-triggered PI3K/Akt and MAPK/ERK activation, two signaling cascades eventually leading to neurite outgrowth and neuronal apoptosis and fostering cell survival. Our main findings are as follows: (1) vasoinhibin suppressed neurite outgrowth induced by NGF in serum-deprived PC12 cells; (2) vasoinhibin blocked the prosurvival properties of NGF; (3) vasoinhibin reversed the antiapoptotic effects of NGF; and (4) vasoinhibin suppressed TrkA signaling induced by NGF. This study provides the first demonstration that vasoinhibin is able to interfere with NGF actions beyond the promotion of neuronal differentiation, inhibiting the neuroprotective effects of NGF on apoptosis of PC12 cells. These findings reveal the contribution of vasoinhibin to the downstream functions of this neurotrophin, and they provide novel insights into the functional role of vasoinhibin in the nervous system.

In addition to the well-known actions on the vascular system [reviewed in 1, 3], emerging information shows that vasoinhibin can modulate the function of the CNS. Vasoinhibin is present in neurons of the hypothalamic supraoptic and the paraventricular nuclei and, in their projections, conforming the neurohypophysis [10, 11], where it stimulates vasopressin release [13]. Vasoinhibin also influences stress-related behavioral responses. Acute stress reduces the rate of cleavage of PRL to vasoinhibin in the hypothalamus, while the intracerebroventricular administration of vasoinhibin triggers behaviors associated with anxiety and depression [12]. Moreover, vasoinhibin interferes with neurite outgrowth induced by the binding of NGF to the TrkA/p75 receptor complex in newborn rat dorsal root ganglia in organ culture, and in primary sensory neurons in culture [15]. These results show that vasoinhibin acts directly on primary sensory neurons to downregulate NGF-induced developmental changes. Therefore, it was important to investigate the functional interaction of vasoinhibin with NGF, as well as their putative signaling cross-talk, since in this scenario, vasoinhibin may interfere with broad TrkA signaling. If

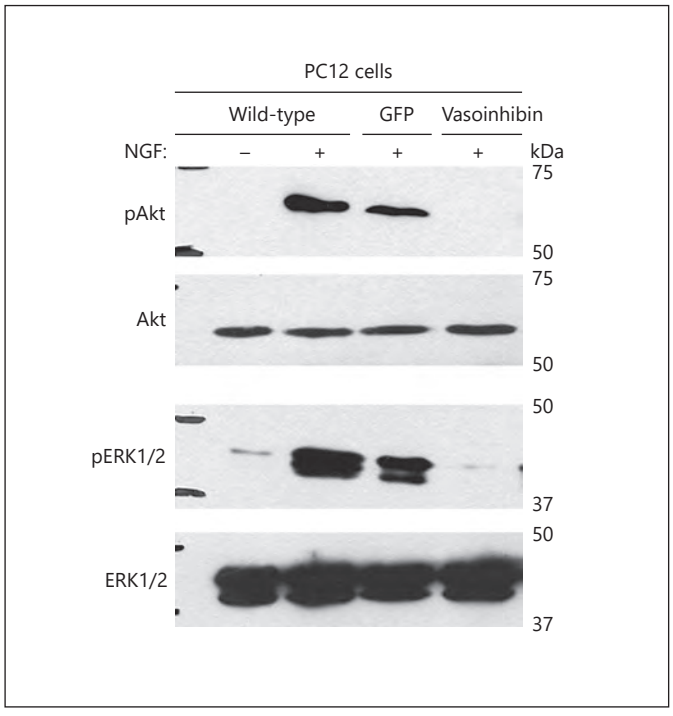

Fig. 7. Vasoinhibin prevented nerve growth factor (NGF)-induced activation of PI3K and MAPK in serum-deprived PC12 cells. NGF induced activation of Akt and ERK in PC12 cells and PC12 cells transduced with lentiviral vector to express green fluorescent protein (GFP) or vasoinhibin. Cells were serum starved and stimulated with NGF (50 ng/mL) for 10 min. Cell lysates were separated by SDS-PAGE and analyzed by immunoblotting. Activated PI3K and MAPK were specifically recognized with rabbit anti-phosphorylated Akt (pAkt) and anti-phosphorylated ERK1/2 (pERK1/2) antibodies. The blot was then reprobed with a rabbit antibody to total Akt or total ERK1/2. Total Akt and total ERK1/2 were used to verify equal protein loading in all lanes. Representative data from 3 independent experiments are shown.

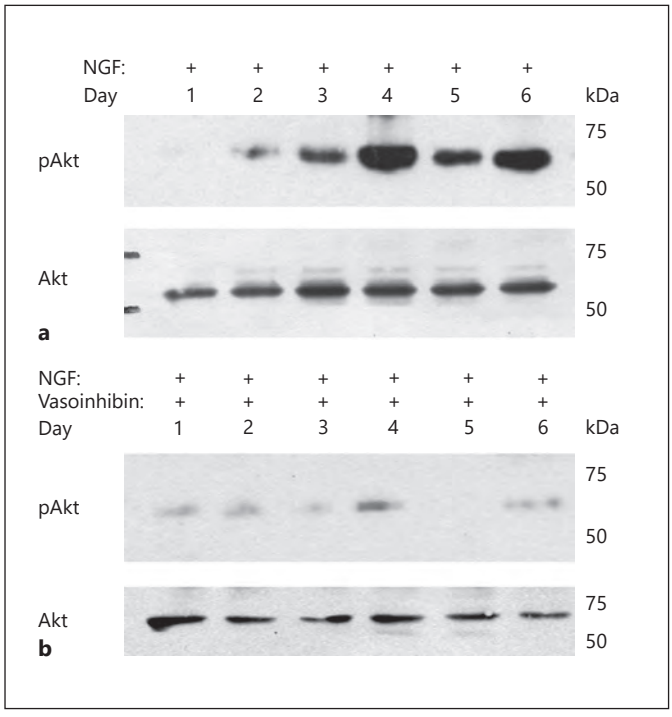

Fig. 8. Vasoinhibin prevented nerve growth factor (NGF)-induced activation of PI3K in serum-deprived PC12 cells. NGF induced activation of Akt in wild-type PC12 cells. **a** PC12 cells were serum starved and stimulated with NGF (50 ng/mL) for 1–6 days. **b** PC12 cells were serum starved and stimulated with NGF (50 ng/mL) and vasoinhibin (10 nM) for 1–6 days. Cell lysates were separated by SDS-PAGE and analyzed by immunoblotting. Activated PI3K was specifically recognized with a rabbit anti-phosphorylated Akt (pAkt) antibody. The blots were then reprobed with a rabbit antibody to total Akt. Total Akt was used to verify equal protein loading in all lanes. Representative data from 3 independent experiments are shown.

this hypothesis is true, vasoinhibin would suppress TrkA signaling and participate in the inhibition of neurotrophic actions induced by NGF. Due to the variable and complex in vivo environments, in the present study we used controlled, NGF-sensitive PC12 cells in vitro as our experimental model. PC12 is a cell line derived from the rat adrenal medulla, and it provides an exceptional experimental model system for the study of the neurotrophic actions of NGF [34]. When cultured in the presence of NGF, PC12 cells differentiate into morphological and functional sympathetic neuron-like cells [26].

The differentiation of PC12 cells in response to NGF is characterized by cell cycle arrest, neurite outgrowth, and the expression of neuron-specific differentiation markers [32, 35, 36]. In this report, we first confirmed that our PC12 cell line responded to NGF by showing that upon stimulation, TrkA signaling was activated and neurite outgrowths developed in these cells. Furthermore, incubation of serum-deprived PC12 cells with a recombinant human vasoinhibin resulted in severe inhibition of the enhanced neurite outgrowth promoted by NGF. Moreover, we succeeded in generating a stable pool of vasoinhibin-expressing PC12 cells via lentiviral vector-mediated cell transfer and found similar results regarding cell differentiation than in vasoinhibin-treated cells. Vasoinhibin expression completely prevented NGF-mediated neurite outgrowth. These results are in line with previous observations regarding vasoinhibin and primary sensory neurons [15], suggesting that vaso-

inhibin may have a potent inhibitory effect on the NGF promotion of neurite outgrowth in all neurons, a very important morphological change in synaptic formation during CNS development and post-injury axon path finding.

Vasoinhibin triggers antiproliferative and proapoptotic processes in different cell types. It promotes the apoptosis of mammary gland epithelial cells [37] and of anterior pituitary lactotropes [38]. Moreover, vasoinhibin inhibits the survival of endothelial cells and fibroblasts [for reviews see 2, 3] by activating proapoptotic proteins of the Bcl-2 family and the NF-κB-mediated activation of caspases [9, 39, 40]. These observations led us to hypothesize that vasoinhibin may also have antisurvival and proapoptotic effects on neurons in general, and on PC12 cells in particular. Consistent with this notion, we showed that vasoinhibin reduces the survival of PC12 cells, and that this effect occurs via activation of the caspase apoptosis signaling pathway. In this report, vasoinhibin prevented the protective action of NGF on the viability rate of serum-deprived PC12 cells. Interestingly, no change in PC12 cell survival was observed in PC12 cells cultured with serum, either in response to vasoinhibin alone or to co-treatment with NGF and vasoinhibin. Therefore, the sensitivity of PC12 cell viability to vasoinhibin was restricted to just NGF-stimulated response, and it did not occur regarding survival in response to other serum factors.

We showed a robust increase in apoptosis (as measured by TUNEL) and in caspase 3 activation in response to vasoinhibin in NGF-induced PC12 cells for 7 days. TUNEL staining and immunoreactive cleaved caspase 3, which is essential for stimulation of DNA fragmentation, were reduced by the action of NGF in comparison with serum-deprived PC12 cell cultures, and co-incubation with vasoinhibin blocked the antiapoptotic action of NGF. In agreement with these results, NGF blocked the increase in DNA fragmentation measured by ELISA in serum-deprived PC12 cells, and vasoinhibin stimulated DNA fragmentation in a dose-dependent manner in PC12 cells cultured for 7 days with or without NGF. Therefore, the sensitivity of PC12 cell DNA fragmentation to vasoinhibin is greater than the sensitivity of PC12 cell viability to vasoinhibin.

Our work provides information on the molecular mechanisms involved in the actions of vasoinhibin. It is well documented that neurotrophin-triggered signaling pathways in neurons are heavily redundant. ERK and Akt mediate many cellular processes including proliferation, differentiation, development, survival, and apoptosis [33, 36, 41, 42]. NGF-induced differentiation is accompanied by activation of the ERK1/2 cascade. In particular, there is compelling evidence that sustained ERK1/2 signaling is required for the neuronal differentiation of PC12 cells induced by NGF [41, 43]. On the other hand, neuronal survival and cessation of proliferation signals induced by TrkA are mediated by activation of PI3K and its main downstream mediator Akt [18, 44, 45]. In the present study, NGF treatment of PC12 cells and of PC12 cells transduced to express GFP led to a rapid increase in phosphorylated Akt and ERK1/2 levels within 10 min. NGF-induced phosphorylation of both Akt and ERK1/2 was severely blunted in PC12 cells transduced to express vasoinhibin, showing that the actions of vasoinhibin and NGF on PC12 cells share the downstream PI3K/Akt and MAPK/ERK axes. Furthermore, treatment with a recombinant vasoinhibin also blocked the long-term phosphorylation of Akt induced by NGF in PC12 cells. These findings indicate that vasoinhibin inhibits the NGF-induced activation of the PI3K/Akt and MAPK/ERK1/2 pathways, suggesting that the blockage of these signaling axes by vasoinhibin may be responsible, at least in part, for the inhibitory action of vasoinhibin on neuritogenesis and neuronal apoptosis.

PC12 cells are particularly well suited for elucidating the action of vasoinhibin on differentiating neurons in neuritogenesis, apoptosis, and the signal transduction pathways involved. Although our findings showing the action of vasoinhibin on PC12 cells are robust, they must be extended to central neurons, where vasoinhibin is known to trigger neuroendocrine and behavioral responses. The nature of the signaling cascades, the precise cross-talk modulating neurotrophin action, and, especially, the physiological context of such interactions need to be mapped and elucidated. Thus, much work is required to help establish whether the effects of vasoinhibin counteracting the differentiating and prosurvival actions of NGF can be generalized to neurons other than PC12 cells.

Perspectives and Significance

Our work demonstrates that vasoinhibin inhibits the neurotrophic effects of NGF that promote the survival and differentiation of PC12 pheochromocytoma cells. We suggest that vasoinhibin acts by blocking NGF-induced activation of TrkA signaling, leading to phosphorylation/activation of the MAPK/ERK and PI3K/Akt pathways. These findings expand the understanding of interactions between vasoinhibin and NGF and suggest that similar mechanisms operate on central neuronal populations, warranting further research.

Abstract

Mitochondrial uncoupling proteins (UCP) transport protons from the intermembrane space to the mitochondrial matrix uncoupling oxidative phosphorylation. In mammals, these proteins have been implicated in several cellular functions ranging from thermoregulation to antioxidant defense. In contrast, their invertebrate homologs have been much less studied despite the great diversity of species. In this study, two transcripts encoding mitochondrial uncoupling proteins were, for the first time, characterized in crustaceans. The white shrimp *Litopenaeus vannamei* transcript *LvUCP4* is expressed in all tested shrimp tissues/organs, and its cDNA includes a coding region of 954 bp long which encodes a deduced protein 318 residues long and a predicted molecular weight of 35.3 kDa. The coding region of *LvUCP5* transcript is 906 bp long, encodes a protein of 302 residues with a calculated molecular weight of 33.17 kDa. Both proteins share homology with insect UCPs, their predicted structures show the conserved motifs of the mitochondrial carrier proteins and were confirmed to be located in the mitochondria through a Western blot analysis. The genic expression of *LvUCP4* and *LvUCP5* was evaluated in shrimp at oxidative stress conditions and results were compared to some antioxidant enzymes to infer about their antioxidant role. *LvUCP4* and *LvUCP5* genes expression did not change during hypoxia/re-oxygenation, and no coordinated responses were detected with antioxidant enzymes at the transcriptional level. Results confirmed UCPs as the first uncoupling mechanism reported in this species, but their role in the oxidative stress response remains to be confirmed.

Keywords Hypoxia · Mitochondria · Re-oxygenation · Shrimp *Litopenaeus vannamei* · Uncoupling proteins

Introduction

Mitochondrial uncoupling proteins (UCPs) in the inner membrane mediate uncoupling of oxidative phosphorylation through a proton-transport mechanism that allows the return of protons to the mitochondrial matrix, dissipating the proton gradient and decreasing the organelle ability to produce ATP (Brand et al. 1994; Guerrero-Castillo et al. 2011). Although physiological uncoupling activity from mitochondria has been suggested to control the mitochondrial production of reactive oxygen species, no specific roles have been addressed to UCPs other than UCP1, which significantly contributes to the catabolic cascade of non-shivering thermogenesis in endotherms (Echtay 2007; Cannon et al. 2006). To date, the tissue-specific patterns of both, gene and protein tissue-specific expression patterns from UCPs, and their specific roles in mitochondrial function, are not fully understood even in the most commonly studied vertebrate model species such as rats or mice (Alan et al. 2009). This lack of information on the functionality of UCPs is far more conspicuous in ectotherm models including fish, invertebrates, and unicellular eukaryotes, where scarce information has been published (Bermejo-Nogales et al. 2010; Jarmuszkiewicz et al. 2010; Da-Ré et al. 2014).

To date, several functions have been suggested for mitochondrial proton leak including thermogenesis, control of body mass, regulation of metabolic energy, and control of reactive oxygen species (ROS) production. Although the physiological advantage of thermogenesis is evident for endotherms such as mammals, the contribution of proton leak reactions, and the basal proton conductance in isolated mitochondria of ectothermic organisms seems debatable.

INFORME DE LABORES 2019

Beside their leader role in ATP production, mitochondria are also the primary site producing non-enzymatic ROS such as the superoxide anion (O_2^-) (Guerrero-Castillo et al. 2011). As previously established, mitochondria may display as an initial response to avoid oxidative damage, the antioxidant defense system that includes active enzymes such as superoxide dismutase, catalase, peroxidase, low molecular weight antioxidants (ascorbate, glutathione, phenolics, tocopherols), and several electron carriers (ubiquinone, CoQ). In addition, mild and soft uncoupling mechanisms may produce a small decrease in the mitochondrial membrane potential, as the result of a natural antioxidant response to regulate O_2^- through the activation of uncoupling proteins (Echtay 2007; Mailloux and Harper 2011).

UCPs belong to a large family of mitochondrial anion carriers. UCPs catalyze proton leaking into the matrix, and dissipate the proton electrochemical gradient built up during electron transport through the mitochondrial respiratory chain. In mammals, five members of this group have been described including SLC25A7 (UCP1), SLC25A48 (UCP2), SLC25A9 (UCP3), SLC25A27 (UCP4), and SLC25A14 (UCP5) with a partially overlapping expression in various organs (Kim-Han et al. 2001; Krauss et al. 2005).

Even though there is no evidence for the existence of either UCP1, UCP2, and UCP3 in arthropods, it has been proposed that UCP4 and UCP5 homologs are present in these species (Sokolova and Sokolov 2005); however, the functional characterization and physiological relevance of UCP proteins in this group of animals is still poorly understood.

Earlier studies have been focused on the UCPs of the fruit fly *Drosophila melanogaster*, the cockroach *Gromphadorhina coquereliana*, the beetle *Zophobas atratus*, and the blood-sucking bug *Rhodnius prolixus* (Hanák and Ježek 2001; Fridell et al. 2004; Slocinska et al. 2011, 2012; Alves-Bezerra et al. 2014; Da-Ré et al. 2014). These studies have confirmed that UCP4 and UCP5 homologs, which are highly conserved among insects, may play a significant role in regulating both, the mitochondrial respiratory rate and ROS production. Since crustaceans and insects share a common ancestor, it may be inferred that crustacean UCPs may accomplish very similar functions to those described in insects.

This study aimed to identify and characterize for the first time in crustaceans, the cDNA sequence of two UCPs homologs, *LvUCP4* and *LvUCP5,* in the white shrimp *Litopenaeus vannamei*. Their phylogenetic relationships were established, and their expression profile at the transcriptional level in various shrimp tissues/organs was determined. Also, changes in the mRNA relative amounts of *LvUCP4* and *LvUCP5* were determined in shrimp under oxidative stress conditions as hypoxia and re-oxygenation, and the results were compared with the expression levels of four genes encoding shrimp antioxidant enzymes. Both UCPs were confirmed to be expressed in the isolated mitochondria of shrimp.

Materials and methods

Shrimp total RNA isolation and cDNA synthesis

Gills, pleopods, midgut gland, eye stalk, heart, nerve cord, gut and muscle were individually dissected from juvenile, healthy shrimp. Total RNA was isolated from 100 mg of each organ/tissues, used to amplify and sequence UCPs transcripts, and for determination of UCPs mRNA presence in shrimp tissues/organs. Total RNA was isolated by using TRIzol® reagent (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions, and both, concentration and purity of RNA samples were determined spectrophotometrically at 260/280 nm (Nanodrop® ND-1000 v 3.5.2). Total RNA integrity was determined by electrophoresis in a 2% agarose gel as follows: 2.5 μg total RNA were added to 2.5 μL RNA-loading buffer (0.25% bromophenol blue, 0.25% xylene cyanol FF, and 30% glycerol), and heated at 65 °C for 10 min before it was loaded.

Genomic DNA contamination was eliminated from total RNA samples by using DNAse I (Roche, USA; 1 U/μg RNA) following the manufacturer's instructions. Afterwards, cDNA was synthesized from 5 μg of total RNA using the GoScript™ Reverse Transcription System kit (PROMEGA, USA). Briefly, total RNA was added to a mix containing oligo$(dT)_{15}$ (0.5 μg/reaction), incubated for 5 min at 70 °C, and cooled on ice for 1 min. Then 4 μL of GoScript™ 5X reaction buffer, 4 μL of 25 mM $MgCl_2$, 1 μL of 0.5 mM dNTP's mix, 1 μL recombinant RNasin® ribonuclease inhibitor and 1 μL of GoScript™ reverse transcriptase were added to the mixture, gently mixed and incubated at 25 °C for 5 min, 42 °C for 60 min. The reaction was completed by incubating at 70 °C for 15 min, and samples were immediately placed on ice.

Shrimp cDNA was used as a template in PCR reactions to sequence UCPs, to determine their expression in different shrimp tissues, and for the quantitative analysis by qRT-PCR of genes expression under oxidative stress conditions.

LvUCP4 and LvUCP5 cDNA sequences

Specific oligonucleotides were designed using previously reported sequences from other species, and some unidentified sequences (ESTs) found in the GenBank database (EX487810.1), in the Penaeus Genome Database (GO073506.1), and shrimp transcriptome (Ghaffari et al. 2014; comp38567_c1_seq1, comp41251_c0_seq4; Table 1).

The PCR amplification of cDNA encoding shrimp UCPs transcripts were carried out in a DNA Engine Thermocycler® Peltier Cycler (Bio-Rad, USA). The Taq PCR master mix kit (Qiagen, USA) was used, and each PCR reaction included: 12.5 μL of 2X Top Taq PCR master mix, 2.5 μL of 10X coral dye, 1 μL of each 20 μM forward and reverse oligonucleotides, cDNA as template (250 ng total RNA equivalents), and water to a total volume of 25 μL. Cycling conditions were:

94 °C for 1 min (1 cycle), 94 °C for 1 min, 55 °C for 1 min, 72 °C for 3 min, 94 °C for 1 min, 42 °C for 1 min, 72 °C for 3 min, 94 °C for 1 min, 55 °C for 1 min and 72 °C for 1 min (33 cycles), and a final extension step at 72 °C for 10 min. PCR products were analyzed in a 1% agarose gel stained with SYBR Safe DNA gel stain® (Invitrogen, USA).

To confirm the sequence of each transcript untranslated regions (UTRs), oligonucleotides SMART and CDS III/3 from the SMART cDNA library construction kit (Clontech, USA) were used according to the method of Jimenez-Gutierrez et al. (2013). PCR reactions were carried out in the following conditions: 95 °C for 3 min (1 cycle); 95 °C for 15 s, 68 °C for 6 min, and 95 °C for 15 s (25 cycles). The resulting PCR products were analyzed in 2% agarose gels, and stained with SYBR Safe DNA gel stain® (Invitrogen). PCR products were purified using the Nucleospin Extract II purification kit (Macherey-Nagel, Germany) according to the manufacturer's instructions, and sequenced at the Laboratory of Molecular and Systematic Evolution Facility at the University of Arizona (Tucson, AZ, USA). The nucleotides and deduced amino acid sequences of LvUCP4 and LvUCP5 were analyzed at Expasy (http://au.expasy.org/tools), and using Blast (N, X and P; Altschul et al. 1990), and Clustal Ω algorithms (Sievers et al. 2011).

Phylogenetic analysis of LvUCP4 and LvUCP5

Phylogenetic relationships of shrimp UCPs were determined including the complete protein sequences of LvUCP4 and LvUCP5. A total of 30 different vertebrate and invertebrate UCPs encoding sequences retrieved from the GenBank database were included in the analysis. A multiple alignment analysis was performed using the Clustal Ω algorithm (Sievers et al. 2011), and the phylogenetic tree was constructed using the Neighbor-Joining algorithm with partial deletion (Saitou and Nei 1987). Evolutionary distances were calculated using the matrix method based on JTT (Jones et al. 1992). The bootstrap method was used to assess the confidence analysis of clades based on 1000 replicates. Evolutionary analysis was conducted using the MEGA software version x (Kumar et al. 2018).

In silico structural model of LvUCP4 and LvUCP5

The predicted three-dimensional models of LvUCP4 and LvUCP5 were generated using homology modeling procedures and the coordinates of mouse UCP2 protein (PDB codes: 2lck.1; Berardi et al. 2011) as template, with 36 and 38% identities for LvUCP4 and LvUCP5, respectively. The

predicted model coordinates were built using the SWISS-MODEL server (Guex and Peitsch 1997; Schwede et al. 2003), and Phyre2 software (Kelley et al. 2015; http://swissmodel.expasy.org/ and http://www.sbg.bio.ic.ac.uk/~phyre2/). Visualization of theoretical models of LvUCP4 and LvUCP5 was performed in the PyMOL(™) molecular graphics system (V1.7.5.0), and CCP4MG (2.10.6) software (McNicholas et al. 2011).

LvUCP4 and LvUCP5 mRNA expression in shrimp tissues/organs

To determine whether shrimp UCPs transcripts were expressed in different shrimp tissues/organs including pleopods (Pl), midgut gland (MG), gills (G), muscle (M), eyes stalk (ES), heart (H), nerve cord (NC) and gut (I), the cDNAs from the previously isolated total RNAs were synthesized as described above, and used as template in the PCR amplification of each shrimp UCP. PCR reactions included 250 ng of total RNA equivalents, specific oligonucleotides (UCP4Fw3 and UCP4Rv5) for *LvUCP4*, (UCP5Fw2 and UCP5Rv2) *LvUCP5*, and (L8LvFw3 and L8LvRv3) for the ribosomal L8 protein as internal control (20 μM each, Table 1) in 25 μL volume reactions, PCR conditions were identical to those mentioned above. The PCR products were loaded into a 1% agarose gel, and image was documented in a Gel Doc EZ (Bio-Rad, USA), using the Image Lab TM software (Bio-Rad, USA).

LvUCP4 and LvUCP5 identification in shrimp isolated mitochondria by Western blot analysis

To confirm the LvUCPs location in shrimp mitochondria, these organelles were isolated and solubilized from shrimp pleopods following the method of Rodriguez-Armenta et al. (2018). The soluble protein of mitochondrial fractions was measured by Bradford method (1976), using γ-globulin as a standard. Samples (50 μg) were diluted in a 4 X buffer (0.5 M Tris, pH 6.8, 10% glycerol, 10% SDS, 0.05% beta-mercaptoethanol, and 0.01% bromophenol blue), boiled for 5 min and separated on 10% SDS-polyacrylamide gels (Laemmli 1970). Electrophoresis was run at 100 V for 10 min, 150 V for 10 min, and 200 V to the end.

Gels were electrotransferred into a PVDF membrane using transfer buffer (25 mM Tris, 192 mM glycine and 20% methanol, pH 7.0) (Towbin et al. 1979) and a Wet electroblotting system (BioRad, USA). Membranes were blocked with 5% Blotto nonfat dry milk in TBS-T (50 mM Tris, 104 mM NaCl, pH 7.6, 0.1% Tween 20) for 1 h, and incubated overnight at 4 °C with the primary monoclonal antibodies: UCP4 (A-5; sc-365,295) or BMCP1/KMCP1 (F-3; sc-376,172) (Santa Cruz Biotechnology, USA) diluted 1:1000 (*v*/v). Membranes were washed with TBS-T and incubated at 37 °C for 1 h with peroxidase-conjugated AffiniPure Goat Anti-Mouse IgG (H + L) secondary antibody (Jackson ImmunoResearch, USA) diluted in TBS-T 1:10,000 (v/v). Membranes were washed again and the bands were developed by chemiluminescence using an ECL kit (Amersham Biosciences, GE, Healthcare).

Hypoxia/ re-oxygenation assay

To evaluate and compare the genic expression of shrimp UCPs and antioxidant enzymes, shrimp samples from a hypoxia/re-oxygenation assay were obtained and analyzed. Briefly, 90 adults of *L. vannamei* (30 ± 1 g each) were maintained in laboratory conditions at CIBNOR in La Paz, BCS, Mexico. All shrimp were randomly distributed in 6 plastic tanks (1000 L capacity) with 300 L of seawater each. During acclimatization (8 days), experimental shrimp were maintained at 28 °C, 35 ppt salinity and a dissolved oxygen concentration in the water of 6 mg/L (normoxia). Shrimp from each tank ($n = 15$) were fed twice a day with pelletized food (35% protein), and 50% of total seawater was daily exchanged.

After acclimation, shrimp were fasted for 24 h prior to the experiment. Three tanks were kept at normoxia (6 mg/L) as controls, and hypoxia/re-oxygenation was induced in the remaining 3 tanks. To induce hypoxia in seawater, the air stones were removed from tanks and oxygen was replaced by bubbling nitrogen gas. The 3 tanks at hypoxia were covered with plastic sheets, and oxygen concentration was continuously monitored using a submersible digital oximeter (Ohaus, USA).

All along the assay, 3 organisms were sampled from each tank at different oxygen concentrations (6, 2, 1.5, 7 mg/L), and samples from shrimp at normoxia were taken at the same time than those at hypoxia/re-oxygenation. During hypoxia, the dissolved oxygen concentration of water decreased up to 2 mg/L, then it was maintained at this concentration for 6 h more, and shrimp were sampled; afterwards, oxygen decreased to 1.5 mg/L and after 6 h samples were taken. Finally, oxygen concentration was gradually increased by introducing air stones to reach a final oxygen dissolved concentration of 7 mg/L and after 6 h shrimp samples were taken.

A total of 400 μL of hemolymph were extracted from the base of the fifth pereiopod from each sampled shrimp using a 1 mL syringe containing two volumes of pre-cooled shrimp anticoagulant solution containing 450 mM NaCl,10 mM KCl, 10 mM Na_2-EDTA, 10 mM HEPES, pH 7.3 (Vargas-Albores et al. 1993). Each hemolymph sample was centrifuged at 700 *x g* for 10 min at 4 °C, plasma and hemocytes were separated and stored at −80 °C until use. Subsequently, shrimp were sacrificed and dissected. The dissected tissues/organs were immersed in liquid nitrogen and stored at −20 °C.

INFORME DE LABORES 2019

Lactate concentration measurement in shrimp plasma at hypoxia and re-oxygenation

Shrimp plasma L-lactate concentration was measured to confirm the hypoxia and re-oxygenation effect on experimental shrimp. Individually collected samples from the assay were used and the commercial kit LACTATE-PAP (RANDOX, UK), according to the manufacturer protocols using a Synergy micro plate reader (Bio-Tek Instruments). Briefly, each sample was tested in a final volume reaction of 200 μL, including 10 μL of plasma and 190 μL of reaction solution, absorbance was followed at 550 nm in triplicates. L-lactate concentration in plasma was determined in shrimp at normoxic, hypoxic and re-oxygenated conditions.

Determination of shrimp UCPs and antioxidant enzymes- relative genes expression by qRT-PCR

Specific TaqMan® probes for *LvUCP4, LvUCP5,* manganese superoxide dismutase *(MnSOD),* thioredoxin *(TRX),* glutation peroxidase *(GPX),* catalase *(CAT),* and the ribosomal protein L8 (as a reference gene) were used to amplify shrimp transcripts (Table 2). The relative quantification of genes expression in shrimp gills was done in triplicates using a Step One real-time PCR System (Applied Biosystems). Total volume reactions of 20 μL included 10 μL of 2x Brilliant II qRT-PCR OneStep master mix (Stratagene, USA), 1 μL of TaqMan® probe (20X), 0.8 μL of enzyme RT/RNase block enzyme mix, 150 ng of total RNA free of gDNA and water. Amplification conditions were 50 °C for 30 min, 95 °C for 15 min, followed by 45 cycles at 95 °C for 15 s and 60 °C for 1 min. Fluorescence was taken at 60 °C after each amplification cycle. Each transcript evaluation included a no-template control to confirm no contamination.

The PCR efficiency (E) of each evaluated transcript was determined by the formula $E = 10^{(-1/slope)}$ through a dynamic-range evaluation, and efficiency results were compared between transcripts to be equal. The $2^{-(\Delta\Delta CT)}$ method (Livak and Schmittgen 2001) was used to calculate mRNA changes in the expression of each transcript, relative to the reference gene L8 following the formula: $2^{-(\Delta\Delta Ct)} = 2^{-(mean\ CtGenX - mean\ CtL8)hypoxia) - (mean\ CtGenX - mean\ CtL8)normoxia)}$. Data were analyzed for normality and variances homogeneity. Statistical significance was evaluated by one way-ANOVA, the post hoc analysis was done using the Tukey test. Statistical significance was considered at $p < 0.05$. Analyses were performed using the NCSS 2007 software.

Results

LvUCP4 and LvUCP5 cDNA sequence

Two different nucleotide sequences were identified in the transcriptome of the white shrimp *L. vannamei* as putative uncoupling proteins UCP4 and UCP5 (Ghaffari et al. 2014). The cDNA sequence of *LvUCP4* consists of 1868 pb, the start codon ATG is found at position 1, and the stop codon is found at position 955 followed by a 3′-UTR of 911 pb that contains a polyadenylation signal TAAAT at position 1823, and a polyA tail at position 1840. The coding region of 954 bp encodes a deduced protein LvUCP4 of 318 amino acids, with a predicted molecular weight of 35.3 kDa, and an isoelectric point (pI) of 9.65 (Fig. 1).

The protein primary sequence shares identity with invertebrates such as the fruit fly *D. melanogaster* (44% isoform 4A, NP_573246.1; 53% isoform 4B, NP_608977.1; and 39% isoform 4C, NP_608976.1), the louse *Pediculus humanus corporis* (52%, XP_002429177.1), the pea aphid *Acyrthosiphon pisum* (55%, XP_001944640.1), the parasitic crustacean *Caligus rogercresseyi* (52%, ACO11693.1), the nematode *Caenorhabditis elegans* (43%, CCD68613.1), and various UCP4 vertebrate homologs such as the mouse *Mus musculus* (54%, NP_082987.1), domestic cow *Bos taurus* (54%, NP_001193123.1), and human *Homo sapiens* (54% isoform 1, NP_004268.3, and 50% isoform 2, NP_001190980.1).

The *LvUCP5* cDNA sequence consists of 2332 pb, the start codon is found at position 1, and the stop codon is found at

INFORME DE LABORES 2019

Both, LvUCP4 and LvUCP5 sequences, share a 27% identity between them, and include the signatures of the mitochondrial carrier family (Figs. 1 and 3). The repeated motifs in the cytosolic, transmembrane and matrix helices, were identified in both shrimp UCPs as shown in Figs. 2 and 4 (Ježek and Urbánková 2000). Both proteins show the conserved negatively charged residues Glu34 (UCP4) and Glu20 (UCP5) located in the transmembrane helix 1 (TMH1), which is involved in proton binding to UCPs (Echtay et al. 2000). Additionally, both proteins have three Pro residues in the odd-numbered helices (TMH1, −3 and − 5), and three Arg residues in the even-numbered helices (TMH2, −4 and − 6), all of them suggested as essential for purine nucleotides binding (Figs. 2 and 4).

Fig. 3 UCP5 cDNA sequence and deduced amino acid UCP5 from white shrimp *L. vannamei*. The start and stop codons are framed. Double underlined nucleotides indicate the poly A signal and poly A tail; The mitochondrial carrier family signatures are shadowed in gray (Ježek 2002)

Phylogenetic relationships of UCPs of shrimp

A total of 53 protein sequences of UCP1, UCP2, UCP3, UCP4 and UCP5 from 31 different species from various taxa were included in the phylogenetic analysis, among these proteins 11 sequences of the dicarboxylate carrier protein SLC25A10 (DIC) were added since it is a member of the superfamily of mitochondrial solute carriers, and it has been proposed UCP4 and UCP5 are more closely related to oxoglutarate/malate and dicarboxylate carrier proteins (Palmieri 2013; Gaudry and Jastroch 2018). The resulting tree shows that both, UCP5 and UCP4, were grouped into different clades. Shrimp and insect UCP4 proteins were grouped into a single clade, which is separated from mammals, nematodes and the parasitic copepod *C. rogercresseyi* (Fig. 5).

The deduced protein LvUCP5 is grouped with the UCP5 proteins from insects, but vertebrate homologs including the various human isoforms were separated in a different clade (Fig. 5). Results confirm that the sequenced deduced proteins of *L. vannamei* are UCP4 and UCP5, sharing higher similarities with their vertebrates homologs UCP4 and UCP5, than to UCPs 1 to 3.

Predicted 3D structure of LvUCP4 and LvUCP5

Shrimp protein conformation resembles mouse UCP2. Both predictive models for LvUCP4 and LvUCP5 show secondary elements with a tripartite structure (Fig. 6a and 7a) and a central channel, this consists of three hydrophobic regions made up of two transmembrane α-helices each, extended through the MIM six times (transmembrane helices TMH 1–6). The two adjacent helices that form each repeated region are connected by an amphipathic helix (APH) matrix-oriented (Fig. 6b and 7b). The mitochondrial carrier family signature PxD/ExxK/RxK/R-(20–30 residues, where x is any residue) was observed in both shrimp UCPs (Ježek and Urbánková 2000). This motif is found in each repeated region, including slight modifications in one or both sequences signing some carriers (Krauss et al. 2005; Nury et al. 2006). The three repeated regions were located at positions 39–47, 142–150, and 243–251 in the LvUCP4 sequence, and at positions 25–33, 127–135, and 222–230 in the LvUCP5 sequence.

The N- (dark blue) and C-terminal (red) ends of these proteins are oriented toward the intermembrane space (Fig. 6 and 7a). The analysis of arginine conserved residues

INFORME DE LABORES 2019

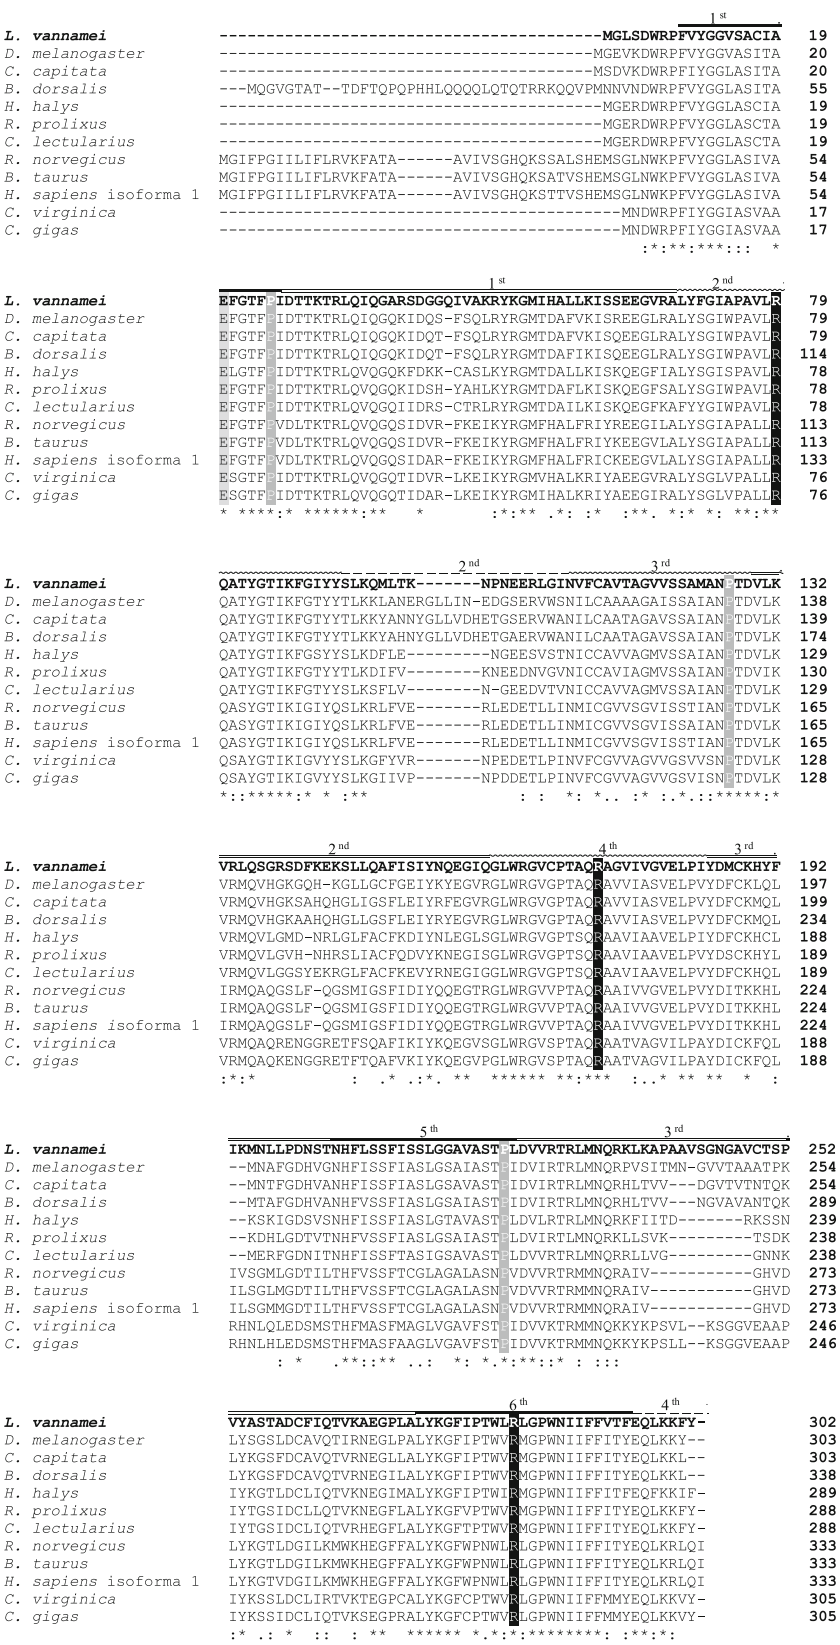

Fig. 4 UCP5 multiple protein alignment. Mitochondrial carrier family signatures (Ježek 2002) are shadowed in gray. Residues marked with (*) identical residues; (:) conservative substitutions; and (.) semiconservative substitutions. Underlined residues with (·– –·) are the cytosolic segments, (▬) transmembrane segments, (═) matrix segments, and (〰) are the transmembrane helices (Ježek and Urbánková 2000). Proline residues are shadowed in light gray; negatively charged residues in gray, and residues involved in the binding site of purine nucleotides are shadowed in black

in UCPs, which are known to be essential for purine nucleotide binding were located in the LvUCP4 model at positions R92 (TMH2), R194 (TMH4), and R294 (TMH6) (Fig. 6c), and in the LvUCP5 model at positions R79 (TMH2), R173 (TMH4), and R283 (THM6) (Fig. 7c). According to the arginine residues position in the predictive models of shrimp

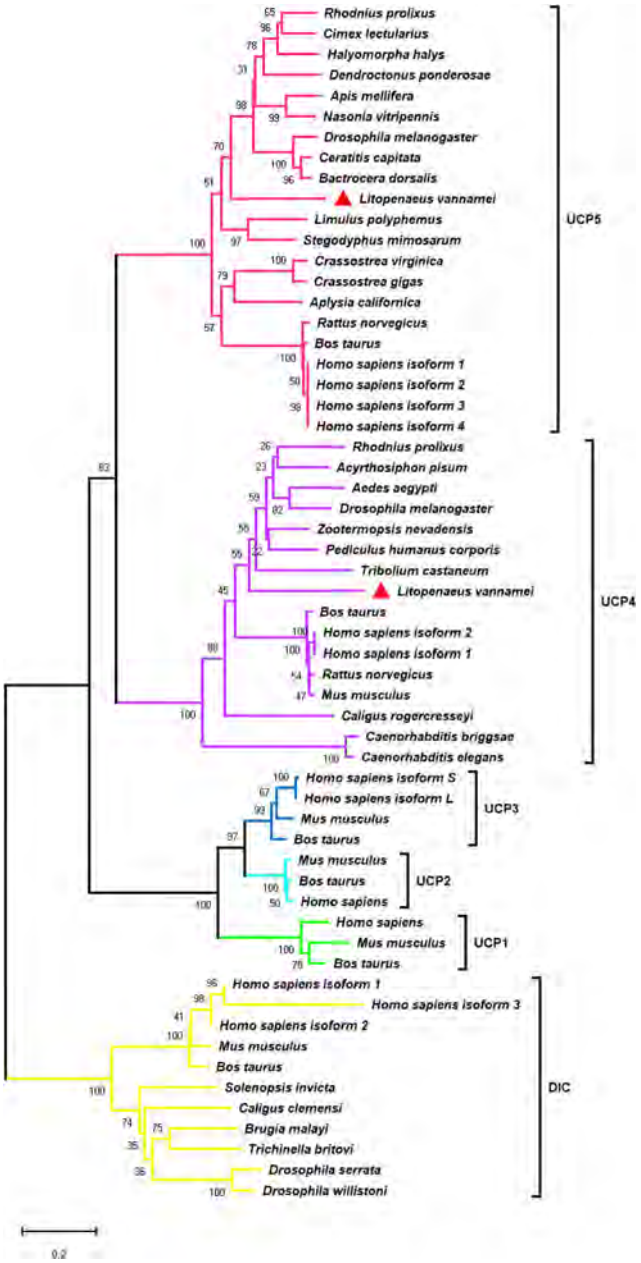

Fig. 5 Shrimp UCPs phylogenetic tree topology using neighbor-joining method with partial deletion from amino acid sequences. Numbers above/below the nodes indicate nonparametric bootstrap values (1000 replicates)

UCPs, the average distance between these three residues is >10 Å (Fig. 6c and 7c). Two additional residues, D202 in LvUCP4, and E181 in LvUCP5 were identified in the purine nucleotide binding sites (Fig. 6d and 7d).

LvUCP4 and LvUCP5 genes expression in shrimp tissues/organs

LvUCP4 was found to be ubiquitously expressed in all tested shrimp tissues and organs, being pleopods and gills, the sites where higher expression was detected. On the other hand, *LvUCP5* was observed to be only expressed in three of all tested organs including pleopods, gills, and muscle, being the gills the organ that expresses both transcripts and the one selected to determine *LvUCPs* genes expression (Fig. 8).

LvUCP4 and LvUCP5 identification in shrimp mitochondria

Western blot analysis confirmed that LvUCP4 and LvUCP5 are located in the isolated mitochondria of shrimp organs. Pleopods were used since higher amounts of mitochondria can be isolated from these appendages, and both transcripts were expressed in these organs. The isolated mitochondria protein fractions include both proteins, LvUCP4 and LvUCP5 in their monomeric and dimeric forms, with molecular masses of ~36 and 70 kDa, respectively (Fig. 9).

L-lactate concentration measurement in shrimp plasma at hypoxia and re-oxygenation

L-Lactate concentration in shrimp plasma significantly increased after 12 h at hypoxia (1.5 mg/L) ($p < 0.05$; Fig. 10). As hypoxia persisted, lactate levels increased becoming up to 11 times higher than at normoxia (6 mg/L); however, when the system was re-oxygenated to 7 mg/L, lactate concentration significantly diminished but it did not decrease to its initial concentration at normoxia.

Relative gene expression of UCPs and antioxidant enzymes from shrimp at hypoxia/re-oxygenation

The genic expression of *LvUCP*4 and *LvUCP5* and four antioxidant enzymes showed significant differences when shrimp were exposed to hypoxia and re-oxygenation. (Fig. 11a-f). No significant differences were detected in the *LvUCP4* and *LvUCP5* mRNA levels from shrimp at normoxia, hypoxia and re-oxygenation conditions ($p > 0.05$; Fig. 11a and b); however, the mean mRNA levels at hypoxia (2 mg/L) decreased 35% for *LvUCP4*, and 20% for *LvUCP5* when compared to normoxia, and these decreases continued at hypoxia (1.5 mg/L) and after re-oxygenation.

Among the mRNA changing levels of antioxidant enzymes, statistical differences were detected only for catalase (*CAT*) and glutathione peroxidase (*GPX*) transcripts ($p < 0.05$; Fig. 11d and e). However, some similarities were observed in the changing patterns of the four antioxidant enzymes along the assay. The *MnSOD*, *CAT* and *GPX* mRNA levels increased at hypoxia 2 mg/L and decreased at hypoxia 1.5 mg/L; however, no significant changes were detected in the transcripts levels at re-oxygenation, except *CAT*. These trends do not correspond to those for *LvUCP4* and *LvUCP5*, suggesting different regulation levels, different response times (whether ROS control is considered), or different functions in *L. vannamei*.

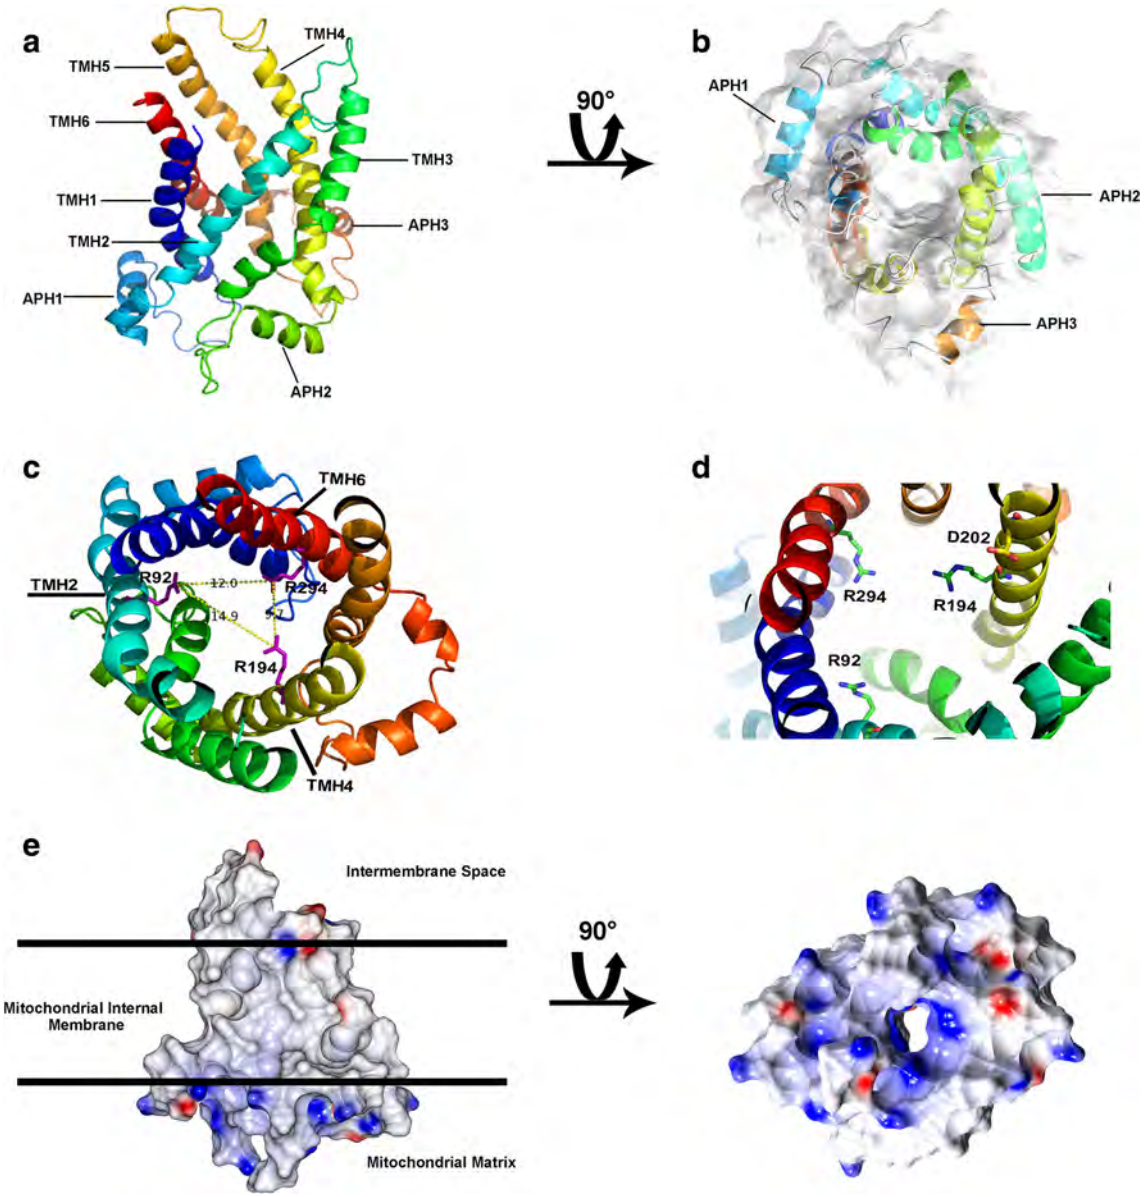

Fig. 6 Predictive structural model of *Lv*UCP4. **a** Secondary structure **b** View of the channel from the matrix with secondary structures and surface representation. **c** Conserved arginine residues. **d** View from the intermembrane space of conserved arginine residues. **e** Surface representation

Discussion

The mitochondrial ability to uncouple seems to be essential in cell physiology. Mitochondrial function is regulated by the transmembrane potential and proton gradient dissipation, which lead to control oxidative phosphorylation to synthesize ATP. Although different extrinsic and intrinsic uncoupling mechanisms have been described in eukaryotic cells (Guerrero-Castillo et al. 2011), to date no evidence exists that describes whether mitochondria from crustaceans exhibit physiological uncoupling. Previous studies have confirmed that isolated mitochondria from various shrimp species and artemia do not enter an uncoupled transition permeability state after a calcium overload (Menze et al. 2005; Holman and Hand 2009; Konrad et al. 2012; Rodriguez-Armenta et al., submitted). Additionally, no alternative oxidases or reductases were found as an uncoupling mechanism in the mitochondrial respiratory chain of the white shrimp L. vannamei (Rodriguez-Armenta et al. 2018).

Mitochondrial uncoupling proteins are widely distributed in nature, and this may suggest that regulating oxidative phosphorylation efficiency through physiological uncoupling mechanisms may be a general and helpful strategy (Miroux et al. 1993). Up to five different UCP isoforms, and some additional UCP-homologs have been described in birds, amphibians, fishes, insects, plants and unicellular organisms (Sokolova and Sokolov 2005); however, to our knowledge, no records for any crustacean UCP have been reported adequately described to date.

INFORME DE LABORES 2019

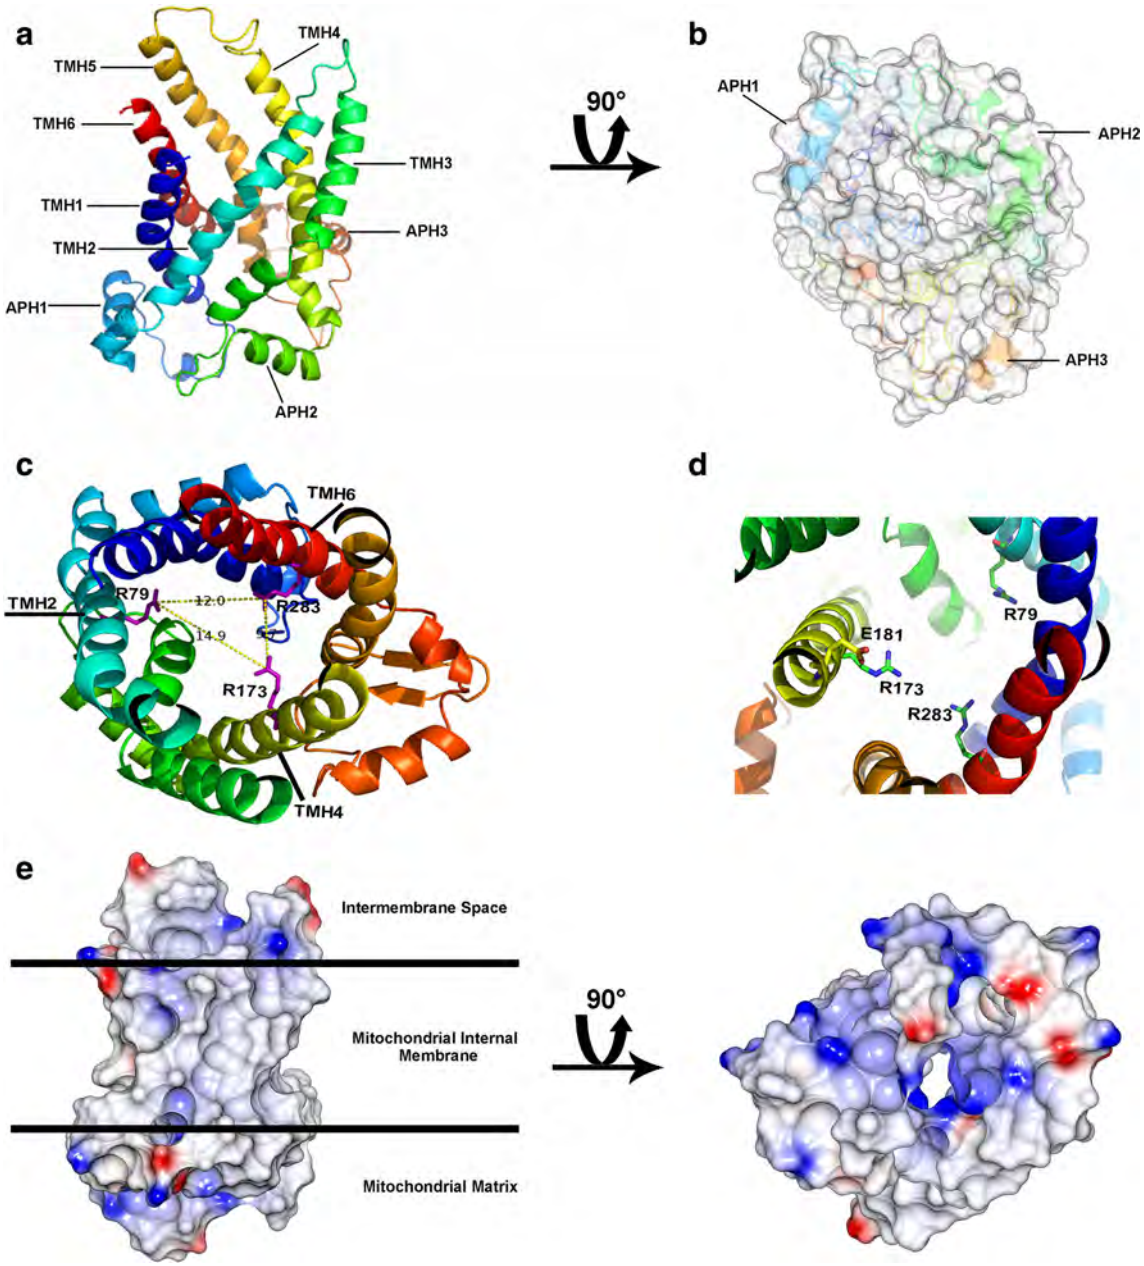

Fig. 7 Predictive structural model of *Lv*UCP5. **a** Secondary structure **b** View of the channel from the matrix with secondary structure and surface representation. **c** Conserved arginine residues. **d** View from the intermembrane space of conserved arginine residues. **e** Surface representation

In this study two transcripts, LvUCP4 and LvUCP5, were identified as uncoupling proteins in the white shrimp *L. vannamei*. This agrees with previous reports in other arthropod genomes /transcriptomes, that suggest that only UCP4 and UCP5 homologs are present in invertebrates (Sokolova and Sokolov 2005). Based on their phylogenetic

analysis, these two proteins are closely related to insect UCPs, and other invertebrate homologs, but they differ from the vertebrate proteins as the mammalian UCP1, UCP2 and UCP3 (Krauss et al. 2005). Their evolutionary origin seems to be clearly related to the ketoacid carriers subfamily as dicarboxylate carriers (DIC) since they share important amino acid similarities (Haferkamp and Schmitz-Esser 2012).

The *LvUCP4* transcript was found to be expressed in an ubiquitous manner, and *LvUCP5* was only expressed in specific organs mainly related to the high energy requirements of shrimp pleopods to swim, and to the respiratory activity of gills. Similar results with differentially expressed UCPs were obtained in the insect *R. prolixus*, whose *RpUCP4* mRNA was highly expressed in the anterior midgut and flight muscle (Alves-Bezerra et al. 2014), and in the gut of the fruit fly *D. melanogaster* larvae showing high gene expression of a UCP4 homolog (Da-Ré et al. 2014).

Structurally, LvUCPs share the main signatures of mitochondrial carriers and contain a high amount of basic and acid residues inserted in the transporter channel. Most arginine residues are located inside the channel, facilitating the purine nucleotide binding to a specific site to be inhibited. In this region, shrimp LvUCPs include the four conserved amino acids: three Arg residues and a Glu181 in LvUCP5, which in LvUCP4 is substituted by Asp202. The Glu residue acts as an interaction barrier between the three arginine residues and the acid groups of nucleotides as a result of the saline bonds formation. Once the glutamic acid is protonated, phosphate groups in nucleotides are able to interact with the three arginine residues, producing a tight complex (Luevano-Martinez and Uribe-Carvajal 2008).

The identity similarities of transcripts, and the structural characteristics of the predicted shrimp proteins described above suggests that these two deduced proteins are putatively UCP4 and UCP5, which may have the ability to transport protons through the MIM and to bind purine nucleotides being sensitive to their inhibitory effect (Echtay et al. 2000).

All previous results in addition to the confirmed presence of LvUCP4 and LvUCP5 in the isolated mitochondria of shrimp pleopods, allowed us to present this as the first report

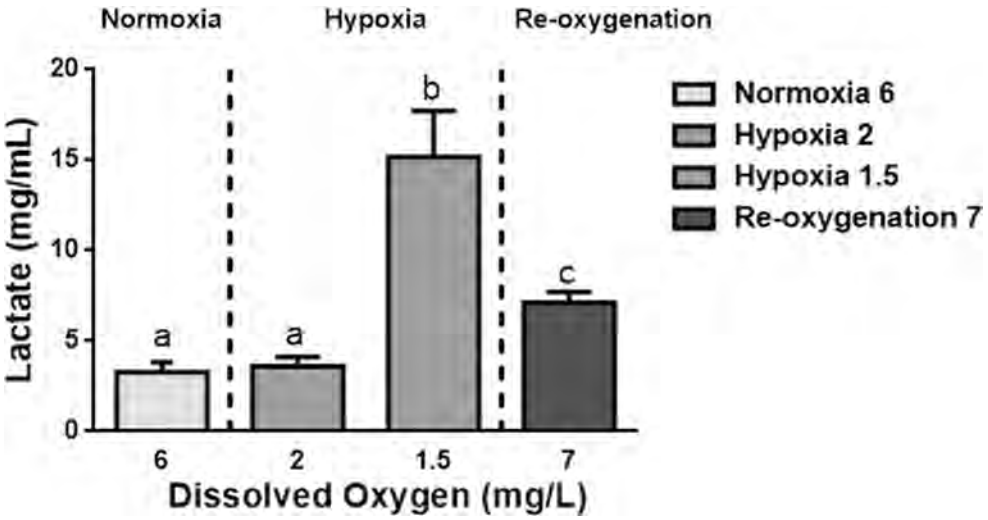

Fig. 10 Plasma L-lactate concentration in the white shrimp *L. vannamei* exposed to normoxia, hypoxia and re-oxygenation. Different letters show significant difference at $p < 0.05$. Bars represent means ± SEM

that characterizes UCPs in crustaceans, to propose the proteins as the first uncoupling mechanism reported in shrimp mitochondria to dissipate protons gradient, and to hypothesize that this mechanism will also participate in controlling mitochondrial production of ROS, as it was observed in the mitochondria of *R. prolixus* (Alves-Bezerra et al. 2014), and *G. coquereliana* (Slocinska et al. 2011).

Hypoxia/re-oxygenation events represent an important physiological challenge for shrimp life, both in nature and culture systems. It has been suggested that the daily environmental changes in dissolved oxygen concentrations of seawater allow organisms to display highly specialized mechanisms to deal with ROS production when oxygen levels raise (Li et al. 2016).

Previously, it has been postulated that enzymes including catalase, glutathione peroxidase, peroxiredoxin, thioredoxin, and cytosolic manganese superoxide dismutase are part of an efficient initial antioxidant response that allows adapted marine invertebrates to survive after repetitive cycles of hypoxia/re-oxygenation by counteracting ROS production and, thus, preventing oxidative stress (Parrilla-Taylor and Zenteno-Savín 2011).

According to our results, hypoxia and re-oxygenation do not significantly affect any of the antioxidant enzymes as *MnSOD* and *TRX*, nor LvUCPs at the transcriptional level; however, *GPX* and *CAT* gene expression changed significantly according to the environmental oxygen concentration. In 2013, Trasviña-Arenas et al. reported the gene expression and activity of catalase in the gills of shrimp at hypoxia and re-oxygenation. The activity and transcript levels of the enzyme increased at both conditions being these results similar to those found in this study. TRX has also been reported as an

efficient electron donor to glutathione peroxidase, acting as a cofactor to thioredoxin peroxidases, known as peroxiredoxins, leading to the effective detoxification processes in humans. *TRX* gene expression is known to be regulated by the hypoxia-inducible transcription factor (HIF 1-α) in humans (Maulik and Das 2008). In the white shrimp *L. vannamei,* Aispuro-Hernandez et al. (2008) reported similar results to those observed in this study at hypoxia and re-oxygenation. Although no significant differences were observed in the *TRX-1* mRNA levels at hypoxia and re-oxygenation, they reported that the antioxidant capacity of recombinant TRX of *L. vannamei* exceeds that of glutathione, suggesting that a small amount of *TRX-1* may still be enough to maintain oxidative balance and protection from ROS-mediated cellular damage.

No comparable data were found about *MnSOD* and *GPX* genes expression at oxidative stress, but previous reports indicate that in *L. vannamei* hepatopancreas, gills and hemolymph, hypoxia promotes an increase in the activity of MnSOD and GPX, and re-oxygenation decreases both enzymes activity below those values observed at normoxia (Li et al. 2016). These two enzymes are known to play central roles in maintaining the balance of free radicals avoiding oxidative damage (Echtay 2007). At this point, our results indicate that changes in the antioxidant response to hypoxia and re-oxygenation are not all detected at the transcriptional level, but probably at post-translational level affecting enzymes activity.

In mammalians, reperfusion following ischemia results from an abnormal heart function, it induces a strong up-regulation of *UCP2* mRNA expression in rats kidney, which increased by 2.8-fold at day 1 after reperfusion and recovered to baseline at day 4 (Yoshida et al. 2002). This gene is involved in the modulation of superoxide anion radical and hydrogen peroxide generation in mitochondria, and is considered as an intracellular regulator of oxidative stress (Nègre-Salvayre et al. 1997).

In 2006, Mark et al. reported in the ectothermic fish *Zoarces viviparous* that *UCP2* expression is temperature dependent; authors found a general up-regulation during warm and cold adaptation, respectively. Up-regulation includes mRNA and protein expression levels, which showed the same trends in tissues of both high and low metabolic activities. They hypothesized that UCP holds an important position within mitochondrial energy metabolism of ectotherms, and especially during thermal stress may function as a regulatory protein, controlling the mitochondrial membrane potential to balance ROS formation and ATP production.

In contrast to rat and fish *UCP2*, in this study both shrimp *UCP4* and *UCP5* genes expression showed similar slight changes in response to hypoxia and re-oxygenation; differences were not statistically significant probably due to the endogenous individual variability, that promoted transcriptional levels remained unaffected, but also no changes may result from the shrimp mitochondrial oxyconformer response (Chimeo 2017), and to the hypoxia-tolerance this species display (Martinez-Cruz et al. 2017) as the consequence of repetitive exposure to cyclic variations in oxygen concentrations that these organisms face daily (Puente-Carreon 2009).

Finally, whether UCPs participate in controlling ROS production besides the efficient antioxidant system of shrimp cells (Zenteno-Savin et al. 2006) remains to be confirmed through additional evidence; their specific expression pattern suggest a primary role in the mitochondrial energy synthesis when animals respond to stress factors, however additional evidence on the functionality of shrimp UCPs including proteins expression, protein activation and inhibition responses, and RNAi experiments will help to better understand these proteins role in shrimp mitochondria.

Virulence

ABSTRACT

The regulation of gene expression in response to increased levels of reactive oxygen species (ROS) is a ubiquitous response in aerobic organisms. However, different organisms use different strategies to perceive and respond to high ROS levels. Yeast Yap1 is a paradigmatic example of a specific mechanism used by eukaryotic cells to link ROS sensing and gene regulation. The activation of this transcription factor by H_2O_2 is mediated by peroxiredoxins, which are widespread enzymes that use cysteine thiols to sense ROS, as well as to catalyze the reduction of peroxides to water. In filamentous fungi, Yap1 homologs and peroxiredoxins also are major regulators of the antioxidant response. However, Yap1 homologs are involved in a wider array of processes by regulating genes involved in nutrient assimilation, secondary metabolism, virulence and development. Such novel functions illustrate the divergent roles of ROS and other oxidizing compounds as important regulatory signaling molecules.

1. Introduction

Aerobic respiration is one of the most important traits acquired during the evolution of life. In eukaryotes, respiration occurs in the mitochondria and it involves the use of oxygen as the final acceptor of the electrons that feed the electron transport chain, and the production of ATP. The incomplete reduction of O_2 to water generates the anion superoxide ($O_2^{\cdot -}$), which in turn generates hydrogen peroxide (H_2O_2), either spontaneously or by the activity of superoxide dismutase enzymes. Through different reactions, H_2O_2 can produce other reactive oxygen species (ROS) such as the hydroxyl radical ($^{\cdot}OH$). ROS can react with many different biomolecules, causing enzyme inactivation and degradation, lipid peroxidation and DNA damage. To avoid this, organisms evolved mechanisms to perceive and decompose ROS through coordinated cellular responses, collectively called the antioxidant response. Typical responses involve the up-regulation of ROS-decomposing enzymes such as superoxide dismutases (SOD), catalases (CAT), glutathione peroxidases (Gpx), glutathione S-transferases (GST) and peroxiredoxins (Prx), as well as enzymes involved in the production of reducing compounds such as NADPH and glutathione (Halliwell and Gutteridge, 2007).

For a long time, only the cell damaging aspects of ROS were considered as biologically relevant. Currently, increasing evidence from studies in many different biological systems supports our early view, in which ROS were proposed as signaling molecules important for cell differentiation (Aguirre et al., 2005; Hansberg and Aguirre, 1990), and several mechanisms for ROS perception, ROS signal transduction and ROS-induced gene regulation have been identified. Many of the regulatory roles of ROS are based on their ability to modify the activity of proteins sensitive to redox modifications. In turn, many of these modifications are mediated by the oxidation of cysteine residues, since its sulfhydryl group can be reversibly oxidized to form intra- or intermolecular disulfide bonds, affecting protein structure and function (D'Autreaux and Toledano, 2007; Holmstrom and Finkel, 2014).

2. Yap1, a paradigm in ROS signal transduction

Saccharomyces cerevisiae Yap1 is a transcription factor first identified as a member of the jun family, which includes AP-1 in mammalian cells (Harshman et al., 1988), which represents a paradigmatic example of the mechanisms that a cell utilizes to perceive and transduce ROS signals. YAP1 was also found as a gene

INFORME DE LABORES 2019

critical to survive the oxidative stress caused by H_2O_2, diamide (Kuge and Jones, 1994), cadmium and other heavy metals (Schnell and Entian, 1991). In addition, it was reported that Yap1 overexpression conferred pleiotropic drug resistance (Hertle et al., 1991).

There are excellent and recent reviews on Yap1 and its homologs in yeasts (Dantas Ada et al., 2015; Garcia-Santamarina et al., 2014). Here we describe a comparative analysis between Yap1 and its homologs in filamentous fungi. Yeast Yap1 contains five characteristic domains: a "b-ZIP" DNA binding domain, a N-terminal nuclear localization sequence (NLS), a C-terminal nuclear exportation sequence (NES), and two cysteine-rich (CRD) regions (Fernandes et al., 1997; Harshman et al., 1988). The first CRD (nCRD domain) contains Cys-303, Cys310 and Cys-315, while C-terminal CRD (cCRD domain) contains Cys-598, Cys-620 and Cys-629 (Fig. 1), and the oxidation of these cysteines is critical to regulate Yap1 nuclear localization (Delaunay et al., 2000; Kuge et al., 1997; Yan et al., 1998). When yeast cells are treated with H_2O_2, a Yap1 stepwise oxidation is initiated by the oxidation of the catalytic cysteine of the peroxiredoxin Gpx3, which then reacts with Yap1 Cys-598, forming a mixed Gpx3-Yap1 intermediate that immediately resolves in the formation of an intra-molecular bridge between Yap1 Cys-598 and Cys-303 (Delaunay et al., 2002). This generates a conformational change that hides the NES region and prevents its interaction with the Crm1 nuclear export factor, resulting in the accumulation of Yap1 in the nucleus (Delaunay et al., 2000; Kuge et al., 1997). The protein Ybp1 is necessary for this disulfide relay, very likely acting as a molecular scaffold protein and as a sulfenic acid chaperone (Bersweiler et al., 2017). Additionally, intermolecular disulfides Cys310−-Cys629 and Cys315−-Cys620 have been identified, all of which appear necessary for full Yap1 activation (Gulshan et al., 2005; Okazaki et al., 2007; Wood et al., 2003). Oxidized nuclear Yap1 is subject to phosphorylation, but the responsible kinase and the physiological consequences of this are yet unknown (Delaunay et al., 2000). However, the fact that *Candida albicans* Yap1 homolog Cap1 is also phosphorylated, suggests that this modification is physiologically important (Kos et al., 2016).

Yap1 cCRD cysteines can also be oxidized directly by synthetic as well as natural electrophilic compounds such as diamide, diethylmaleimide, menadione (Azevedo et al., 2003; Kuge et al., 1997; Wemmie et al., 1997), methylglyoxal (Maeta et al., 2004) and the garlic compound allicin (Gruhlke et al., 2017). This process is independent of Gpx3 and Ybp1 and also results in hiding of the NES motif and Yap1 nuclear accumulation. However, these two Yap1-activation mechanisms lead to the expression of different sets of genes and different adaptive responses. Indeed, Yap1 oxidation by H_2O_2 regulates the expression of around ~100 genes, including genes required for glutathione biosynthesis and redox balance proteins such as γ-glutamylcysteine synthetase GSH1, glutathione reductase GLR1 (Gasch et al., 2000) and thioredoxin gene TRX2 (Kuge and Jones, 1994). In contrast, Yap1 oxidation by electrophilic compounds results in the induction of genes related to xenobiotic detoxification, such as genes encoding major facilitator and ATP-binding cassette transporters (Alarco et al., 1997; Wemmie et al., 1994). Consistent with this, H_2O_2 and N-ethylmaleimide do not induce cross-protection against each other (Ouyang et al., 2011). The mechanism by which different oxidized forms of Yap1 regulate different sets of genes is not well understood. Part of the explanation involves Yap1 interaction with other transcriptional regulators such as Skn7, a response regulator also involved in the antioxidant response, and the mediator complex. About half of the genes regulated by Yap1 require its interaction with Skn7, while the other half is Skn7-independent (Lee et al., 1999; Mulford and Fassler, 2011). Mediator is a highly conserved multi-subunit protein complex involved in the transcriptional activation of many genes, including genes involved in multidrug resistance (Shahi et al., 2010; Uthe et al., 2017). The Yap1-mediated induction of the TRX2 gene depends on the mediator component Rox3 and a proper disulfide bonding between Yap1 n-CRD and c-CRD domains (Gulshan et al., 2005). Yap1 oxidized by either H_2O_2 or electrophilic compounds is subject to degradation (Gulshan et al., 2012) and can be reduced back by thioredoxin Trx2 and then translocated to the cytosol (Delaunay et al., 2000). In fact, deletion of *trx1* and *trx2* thioredoxin genes results in constitutive activation of Yap1 (Izawa et al., 1999).

Yap1 homologs Pap1 and Cap1 show very similar regulation in response to H_2O_2 in *Schizosaccharomyces pombe* (Toda et al., 1991; Toone et al., 1998) and *C. albicans* (Kos et al., 2016), respectively. However, in *S. pombe*, it is peroxiredoxin Tpx1 the enzyme which oxidizes Pap1, hiding the NES region and leading to Pap1 nuclear accumulation (Calvo et al., 2013), and the expression of ~50 genes (Chen et al., 2008) involved in the antioxidant response (catalases, peroxiredoxins, sulforedoxins), cellular detoxification and multiple drug resistance (Calvo et al., 2009). In *C. albicans*, peroxiredoxin Gpx3 and interacting protein Ybp1 are needed to relay H_2O_2 signaling to Cap1 (Patterson et al., 2013). Like Yap1, Pap1 regulates the expression of two subsets of genes. Notably, one subset requires Pap1 nuclear accumulation but not its oxidation, and includes genes related to multidrug resistance like *caf5*, which encodes an efflux pump to exclude drugs from the intracellular compartment. The second subset includes antioxidant genes such as catalase and thioredoxin reductase and depends on Pap1 nuclear localization as well as its oxidation and heterodimerization with Prr1, the Skn7 ortholog. Consistent with this, Pap1 binding to drug tolerance promoters is Prr1-independent, while Pap1 association with Prr1 enhances its affinity for antioxidant gene promoters (Calvo et al., 2012).

As indicated before, H_2O_2 signal is relayed to Yap1, Pap1 and Cap1 by specific peroxiredoxins (Prxs). Prxs constitute a large family of thiol-dependent peroxidases originally discovered as enzymes catalyzing the reduction of H_2O_2, alkyl hydroperoxides and peroxinitrite (Chae et al., 1994b; Jacobson et al., 1989; Peshenko and Shichi, 2001). All Prxs contain a conserved cysteine residue, designated as the peroxidatic cysteine (Cys_P), which is oxidized by peroxides (Choi et al., 1998; Ellis and Poole, 1997). Most, but not all Prxs contain an additional cysteine, designated as the resolving cysteine (Cys_R). Depending on their catalytic mechanism, Prxs are classified into three types: typical 2-Cys, atypical 2-Cys and 1-Cys Prxs. Each catalysis cycle can be divided into three steps. The first step, peroxidation, is where the sulfur atom of the Cys_P residue exerts a nucleophilic attack on the O—O bond of the peroxide substrate, releasing the corresponding molecule of alcohol or water, at the cost of Cys_P being oxidized to the cysteine sulfenic acid form. The second step, resolution, occurs when the Cys_R attacks the sulfenic acid, resulting in the formation of an inter- or intramolecular disulfide bond for typical and atypical 2-Cys Prxs, respectively, and the release of a water molecule. This step is omitted in 1-Cys Prxs, as they do not have a Cys_R residue and move directly to the third step, recycling, which occurs when the oxidized Prx is reduced by thiol-containing electron donors such as thioredoxin (Chae et al., 1994a). The regenerated Prx can then go through another catalytic cycle.

Clearly, the basic mechanisms by which Yap1 regulates gene expression in response to oxidative stress are well conserved in yeast fungi. However, as we will see below, is not clear yet to what extent these mechanisms are conserved in filamentous fungi, which are more complex organisms, containing about twice as many genes and showing more complex patterns of growth and cell differentiation.

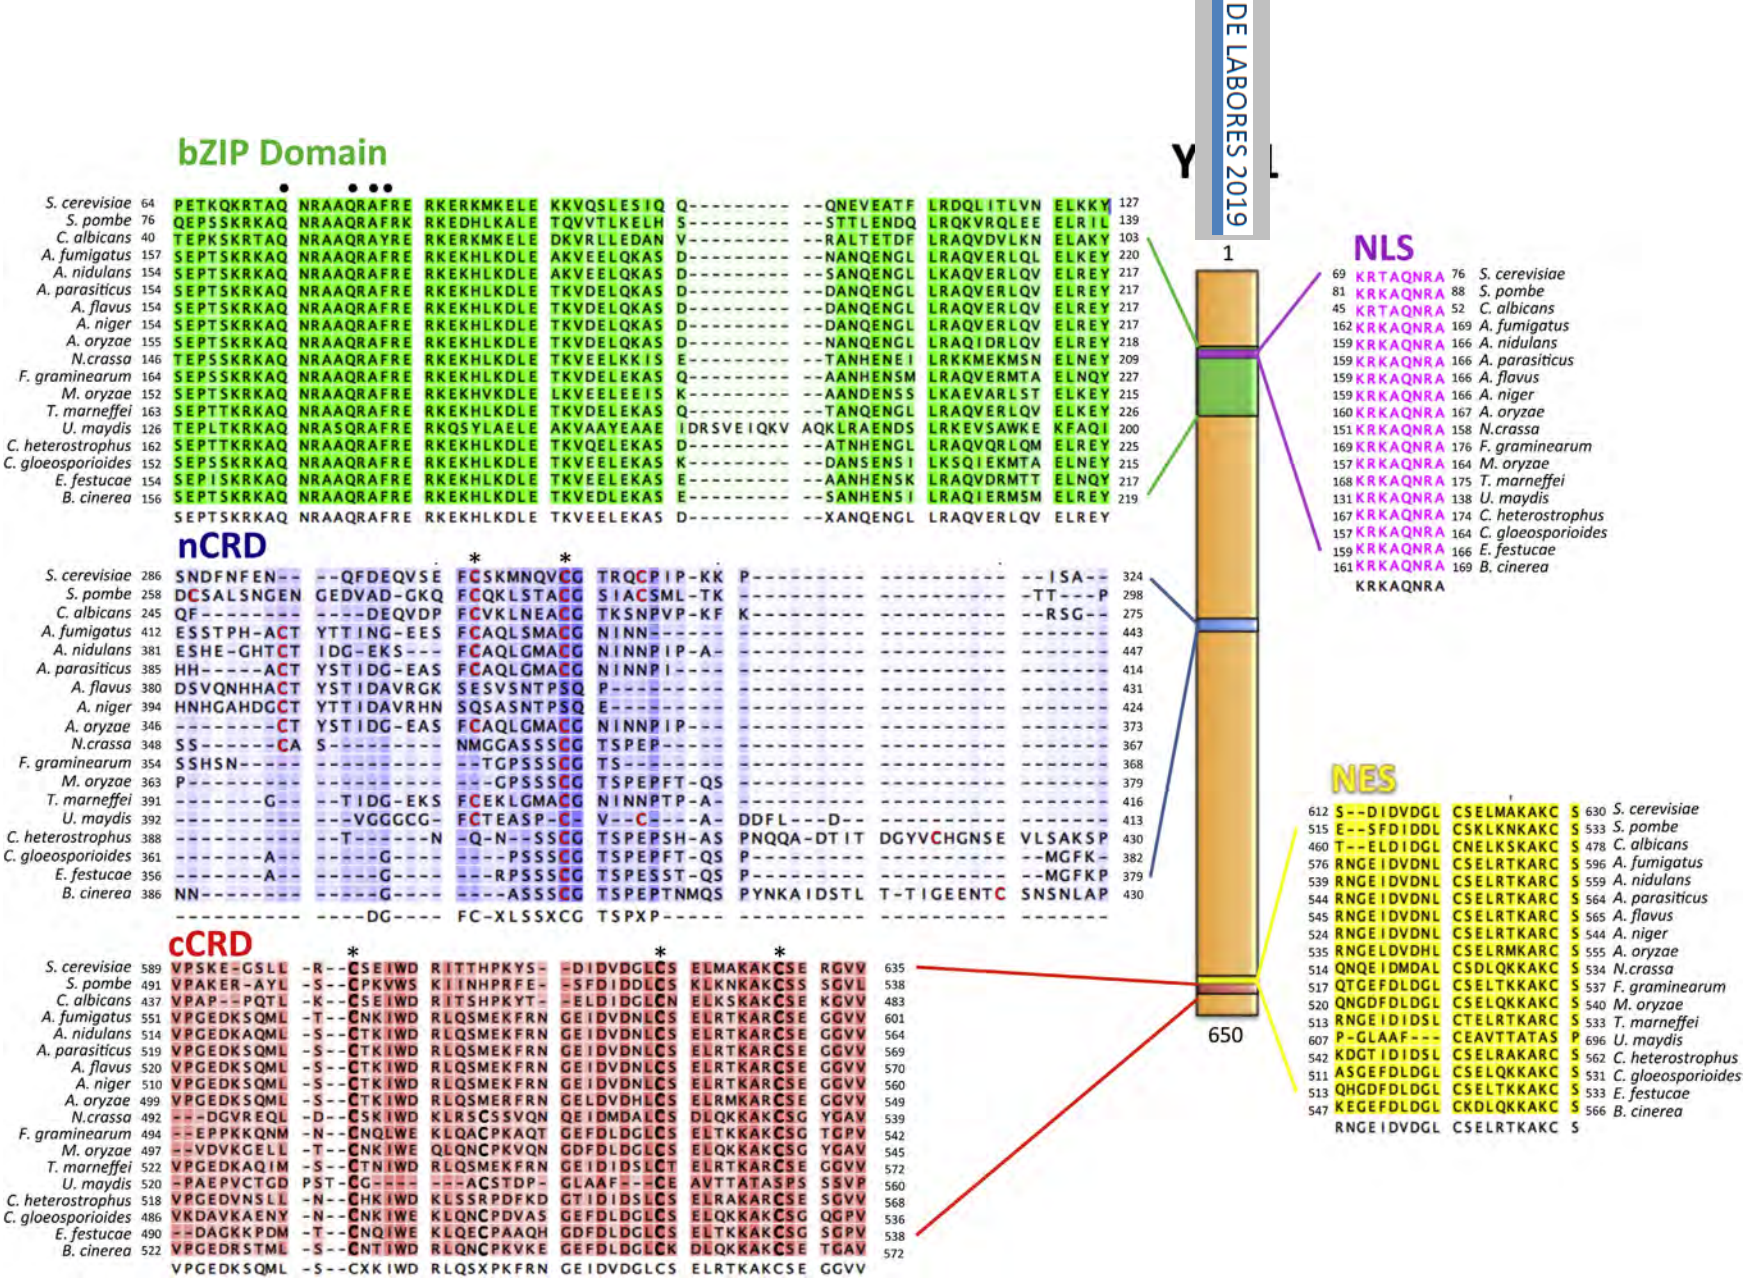

Fig. 1. Yap1 homologs from filamentous fungi contain the same domains described in yeast Yap1. The amino acid sequence of *Saccharomyces cerevisiae* Yap1 is aligned to homologous proteins from *Schizosaccharomyces pombe* (SPAC1783.07c), *Candida albicans* (C3_02220W), *Aspergillus fumigatus* (Afu6g09930), *Aspergillus nidulans* (AN7513), *Aspergillus parasiticus*, (P875_00065012), *Aspergillus flavus* (AFLA_129340), *Aspergillus niger* (An11g07980), *Aspergillus oryzae* (AO090001000627), *Neurospora crassa* (NCU03905), *Fusarium graminearum* (FGSG_08800T0), *Magnaporthe oryzae* (MGG_12814), *Talaromyces marneffei* (PMAA_063050), *Ustilago maydis* (um02191), *Cochliobolus heterostrophus* (estExt_Genewise1Plus.C_130082), *Colletotrichum gloeosporioides* (CGLO_14059), *Epichloe festucae* (KC121577) and *Botrytis cinerea* (FM957543). The b-ZIP binding domain is indicated in green and characteristic residues are indicated by black dots. The nuclear localization sequence (NLS) and nuclear exportation sequences (NESs) are indicated in pink and yellow, respectively. N-terminal cysteine rich domain (nCRD) is labeled in blue and conserved cysteines are indicated with asterisks. C-terminal cysteine rich domain (cCRD) is indicated in red and conserved cysteines are labeled with asterisks. The alignment was generated using software T-coffee (Notredame et al., 2000) and edited using CLC Sequence Viewer (https://www.qiagenbioinformatics.com/products/clc-genomics-workbench-direct-download/). INFORME DE LABORES 2019

3. Yap1 homologs in filamentous fungi are also involved in the antioxidant response

Filamentous fungi contain Yap1 homologs, which contain the same domains described in Yap1 (Fig. 1). The b-ZIP domain covers a highly conserved region of about 64 amino acids with characteristic residues Q73, Q78, A80, F81 (Fernandes et al., 1997). NLS and NES regions with lengths of about 8 and 21 residues, respectively, are also conserved. However, there are clear differences in the total number of cysteines, as well as in their distribution within putative nCRD and cCRD domains (Fig. 1 and Table 2). The total number of cysteines in the Yap1 homologs studied up to now in filamentous fungi ranges from 4 in *Aspergillus niger* to 8 in *Ustilago maydis*. Within the nCRD, the number of cysteines varies from 1 in *Epichloe festucae* to 3 in several fungi, and from 3 to 4 in the cCRD domains (Fig. 1).

As indicated, the number and localization of cysteines is important because in Yap1 different cysteines are oxidized in response to different oxidizing agents (Kuge et al., 1997). However, it is not clear how these differences in cysteine number and distribution affect the function of Yap1 homologs in filamentous fungi. In fact, cysteine function has only been studied in *U. maydis* Yap1, where the simultaneous replacement of Cys399 and Cys407 by alanine resulted in sensitivity to H_2O_2, as in the null mutant, and a lack of nuclear localization (Molina and Kahmann, 2007).

Despite this limited information, most Yap1 null mutants reported in filamentous fungi are sensitive to some type of oxidant, such as H_2O_2, *t-butyl* hydroperoxide (*t*-BOOH) or menadione, indicating that the involvement of this transcription factor in the antioxidant response is highly conserved in fungi. However, there are interesting differences, likely related to differences in Yap1 structure and fungal life styles (Tables 1 and 2). *ΔyapA* mutants of endophytic fungus *E. festucae* show mycelial sensitivity to menadione (Md) and diamide, while only conidia are sensitive to H_2O_2 (Cartwright and Scott, 2013). In the animal pathogen *Aspergillus fumigatus*, *ΔAfyap1* mutants are susceptible to H_2O_2 and Md, but not to diamide (Lessing et al., 2007). In contrast, *Aspergillus parasiticus ΔApyapA* mutants show only slight growth defects in the presence of H_2O_2, Md and cumenehydroperoxide (CH), despite the fact that they showed reduced activity of antioxidant enzymes like SOD, GPX (glutathione peroxidase) and HPR (Hydrogen peroxide reducing enzymes) (Reverberi et al., 2008). Likewise, *Magnaporthe oryzae* mutants lacking MoAP1 show only mild sensitivity to H_2O_2 (Guo et al., 2011). In contrast, *Aspergillus nidulans* NapA is essential for resistance to H_2O_2 and Md in conidia, as well as in mycelia (Asano et al., 2007; Mendoza-Martinez et al., 2017). Although *ΔnapA* spores do not show a reduction in catalase CatA activity, mycelial CatB induction by H_2O_2 depends on both NapA and the Skn7 homolog SrrA (Mendoza-Martinez et al., 2017; Vargas-Perez et al., 2007). The differential sensitivity to H_2O_2 *vs.* electrophilic compounds could reflect the extent to which cysteines in these Yap1 homologs are available for either peroxiredoxin-mediated or direct oxidation. However, whether or not a peroxiredoxin is directly involved in Yap1 oxidation in filamentous fungi has not been answered yet. In *E. festucae*, double mutants lacking *S. cerevisiae* Gpx3 and *S. pombe Tpx1* homologs were still able to accumulate Yap1 in the nucleus in the presence of H_2O_2, ruling out these proteins as possible mediators of Yap1 oxidation (Cartwright and Scott, 2013). Likewise, in *A. nidulans* peroxiredoxins GpxA, TpxA and TpxB were not required for resistance to H_2O_2 or menadione, indicating that these proteins are not needed for NapA activation (Mendoza-Martinez et al., 2017). Similarly, the phenotypes of *A. fumigatus* mutants lacking PrxA, PrxB or PrxC are different from mutants lacking Yap1, arguing against the participation of these peroxiredoxins in Yap1 activation (Rocha et al., 2018). For a long time it was considered that fungi did not contain 2-Cys peroxiredoxins. However, PrxA has been characterized in *A. fumigatus* as Aspf3 (Hillmann et al., 2016) and in *A. nidulans* as PrxA (Xia et al., 2018), showing that it belongs to a family of atypical 2-Cys peroxiredoxins homologous to yeast peroxiredoxin Ahp1 (Lian et al., 2012). More recently, we (Mendoza-Martinez and Aguirre; unpublished) and others (Xia et al., 2018) have found that *A. nidulans* mutants lacking peroxiredoxin PrxA are highly sensitive to H_2O_2, opening the possibility that PrxA might regulate NapA in this fungus.

The Yap1 pathway is connected to other oxidative stress signaling pathways in yeast cells. For example, in *S. pombe*, Pap1 activation by Tpx1 occurs only at low H_2O_2 concentrations, while at high H_2O_2 concentrations Tpx1 is inactivated by over-oxidation of its catalytic cysteine. These conditions lead to the activation of the Sty1/Spc1 MAPK pathway, triggering a complementary antioxidant response (Vivancos et al., 2005). Therefore, differences in oxidative stress sensitivities observed in Yap1 mutants in filamentous fungi could also indicate different interactions among stress signaling pathways. Indeed, in addition to NapA (Mendoza-Martinez et al., 2017), Skn7 homolog SrrA (Vargas-Perez et al., 2007) and the Hog1/Sty1/Spc1 homologs SakA (Jaimes-Arroyo et al., 2015; Kawasaki et al., 2002; Lara-Rojas et al., 2011) and MpkC (Garrido-Bazan et al., 2018) are part of the antioxidant response in *A. nidulans*.

4. Nuclear localization of Yap1 homologs in filamentous fungi

The nuclear localization of Nap1 homologs has been studied fusing Yap1 to a reporter fluorescence protein and expressing it from its own promoter or from strong constitutive promoters, using H_2O_2 (or *t*-BOOH) as stressor agent. Although H_2O_2 concentrations and treatment times varied (Table 1), in all cases Yap1 nuclear accumulation was induced by the oxidant treatment. However, in contrast to the high basal expression of YAP1 observed in yeast cells, in most cases in which *yap1* was expressed from its native promoter, the initial fluorescence signal was low and increased only after the oxidant treatment. This is particularly notable in *A. nidulans*, where *napA* mycelial basal expression was low, as determined by qPCR and NapA::GFP fluorescence expression. In this fungus, the CCAAT-binding complex represses *napA* expression in the absence of oxidative stress. Interestingly, H_2O_2 can induce the formation of an intermolecular disulfide in CCAAT-binding complex subunit HapC, which results in the transcriptional activation of *napA* (Thon et al., 2010), creating a double redox switch in the antioxidant response in this fungus. Whether a similar regulation occurs in other filamentous fungi is not known. In addition to H_2O_2, other conditions have been reported to induce Yap1 nuclear accumulation in filamentous fungi. In the plant pathogen *Cochliobolus heterostrophus*, where *Chap1* initial expression is high in conidia and germ tubes, plant phenolic compounds like cinnamic acid trigger ChAP1 nuclear accumulation but this results in only a slight up regulation of specific antioxidant genes (Shalaby et al., 2012; Shanmugam et al., 2010). In *A. nidulans*, menadione, osmotic stress, glucose starvation stress and growth on ethanol as sole carbon source also induced NapA nuclear localization (Mendoza-Martinez et al., 2017). In *A. fumigatus* AfYap1 is accumulated in the nucleus under hypoxia, which correlates with an increased production of ROS and protein cysteine oxidation, under these conditions (Shekhova et al., 2019). One possible interpretation of these results is that all these different types of stress lead to oxidative stress (Hansberg and Aguirre, 1990).

INFORME DE LABORES 2019

Table 1
The function of Yap1 homologs in filamentous fungi.

Organism (reference)	Oxidant sensitivity	Nuclear localization	Genes regulated	Fungi–host interaction	Developmental phenotype	Other
Ustilago maydis (Molina and Kahmann, 2007)	*Δyap1* and *yap1*^{C399A,407A}::3XeGFP mutants sensitive to H_2O_2.	Native *yap1* locus replaced by yap1:3XeGFP fusion. Low accumulation in vacuoles without H_2O_2. Nuclear accumulation after 1 mM H_2O_2 (1 h) or during early biotrophic growth.	221 Yap1-dependent genes induced by 5 mM H_2O_2, including genes encoding ROS detoxifying enzymes and enzymes involved in NADPH and glutathione biosynthesis.	*Δyap1* mutants formed appressorium but were virtually non-virulent.	Brown pigment accumulation.	
Cochliobolus heterostrophus (Lev et al., 2005; Shalaby et al., 2012)	*Δchap1* mutants sensitive to H_2O_2 and menadione.	GFP-CHAP1 fusion under its own promoter. Strong cytoplasmic expression without stress in germ tubes and conidia. Nuclear localization induced by 50 mM H_2O_2, 1 mM menadione and plant phenolic signals.	Genes encoding to Thioredoxin reductase (ChTRR1), γ-glutamylcysteine synthetase (ChGSH1), glutathione reductase (ChGLR1), glutathione synthetase (ChGSH2) and thioredoxin (ChTRX1).	Virulence not affected in *Δchap1* mutants.	Similar to WT.	
Colletotrichum gloeosporioides (Li et al., 2017; Sun et al., 2016)	*ΔCgAP1* mutants sensitive to H_2O_2, menadione and *t*-BOOH.	*CgAP1::eGFP* fusion expressed from its own promoter. Low diffuse cytoplasmic fluorescence without stress. High expression and nuclear localization after 60 min with *t*-BOOH.	Genes encoding glutathione disulfide reductase, cytochrome P450 monooxygenase and glutathione peroxidase. 1505 CgAP1-dependent genes.	*ΔCgAP1* mutants show attenuated virulence on poplar leaves and are non-pathogenic on mango.	Similar to WT.	
Epichloe festucae (Cartwright and Scott, 2013)	*ΔyapA* spores sensitive to H_2O_2. Mycelia sensitive to menadione and diamide, but not to H_2O_2, *t*-BOOH or KO_2.	YapA-EGFP expressed from native promoter. Diffuse cytoplasmic fluorescence without stress. Nuclear localization after 30 min with 16 mM H_2O_2 and 30 min post-inoculation in plant.	Catalase gene *catA*.	Symbiotic interaction not affected in *ΔyapA* mutants.		
Fusarium graminearum (Montibus et al., 2013)	*ΔFgap1* mutants sensitive to H_2O_2, $CdCl_2$, sorbitol and NaCl.	Not determined.	Down-regulation of *cat1*, *cat2* and *cat3* catalase genes and two Cu/ZnSOD genes. Expression of genes *Tri4* and *Tri101* slightly up-regulated.	Virulence not affected in *ΔFgap1* mutants.	Similar to WT.	Mycotoxin genes and toxin production increased in *ΔFgap1* mutants.
Aspergillus fumigatus (Lessing et al., 2007; Qiao et al., 2008)	*ΔAfyap1* mutants sensitive to H_2O_2 and menadione but not to diamide and DETANO.	*fyap1-eGFP* gene expressed from heterologous promoter. Low and diffuse cytoplasmic fluorescence without stress. Nuclear localization after 60 min with 2 mM H_2O_2.	57 protein spots, decreased or increased in intensity in *ΔAfyap1* mutants treated with 2 mM H_2O_2, including catalases, peroxidases and peroxiredoxins.	Virulence not affected in *ΔAfyap1* mutants.	Slight growth reduction on malt agar.	Cat1 and Cat2 activity reduced in *ΔAfyap1* mutants.
Aspergillus parasiticus (Reverberi et al. 2007, 2008)	*ΔApyap1* mutants sensitive to H_2O_2, Cumene Hydroperoxide and menadione.	Not determined.	SOD, HRP and GPX activities reduced and early expression of *aflR* and *norA* genes, involved in alfatoxin biosynthesis, in a *ΔApyap1* mutant. Increased expression of transcription factor Skn7.		Increased and premature conidiogenesis.	Increased aflatoxin production.
Talaromyces marneffei (Dankai et al., 2016)	Mutant sensitive to H_2O_2, menadione and $NaNO_2$.	Not determined.	Not determined.	YapA necessary for virulence.	Slow growth and smaller colonies with more red pigment. Fewer aerial hyphae and conidia.	Swollen cells and no internal fission.
Magnaporthe oryzae (Guo et al., 2011)	*Moap1* mutant mycelia sensitive to H_2O_2.	MoAP1::eGFP expressed from *trpC* promoter. Low fluorescence signal throughout the cell without stress. Nuclear localization after 2 mM H_2O_2 (2 h).	1179 *Moap1*-dependent genes, including genes putatively involved in ROS detoxification.	MoAP1 is required for growth of invasive hyphae and for pathogenicity.	Decreased growth of aerial hypha and conidiation. Abnormal morphology of conidia.	High expression in conidia.

INFORME DE LABORES 2019

Table 1 (*continued*)

Organism (reference)	Oxidant sensitivity	Nuclear localization	Genes regulated	Fungi–host interaction	Developmental phenotype	Other
Botrytis cinerea (Temme and Tudzynski, 2009)	*Δbap1* mutants sensitive to H_2O_2 and menadione.	Not determined	99 H_2O_2-induced and Bap1-dependent genes.	Virulence not affected in *ΔApyap1* mutants.	Similar to WT.	
Aspergillus nidulans (Mendoza-Martinez et al., 2017)	Mutant mycelia and conidia sensitive to H_2O_2 and menadione.	*napA::gfp* fusion from its own promoter. Very low expression without stress. Increased expression and nuclear localization after 1–2 h with 2 mM H_2O_2, glucose starvation, ethanol as carbon source or osmotic stress.	214 NapA-dependent genes in isolated conidia.		Decreased asexual sporulation and highly derepressed sexual development.	*ΔnapA* mutants unable to grow on ethanol, sorbose and fructose as sole carbon sources.
Neurospora crassa (Takahashi et al., 2010; Tian et al., 2011)	Mutant *ΔNcAp-1* sensitive to H_2O_2 $CdCl_2$ and Menadione.	*Nap-1-sGFP* expressed from heterologous *ccg1* promoter. Strong cytoplasmic fluorescence without stress. Nuclear localization after 5 min with 50 μM menadione or 30 min with 30 mM H_2O_2 or 10 mM CdCl for 30 min.	16 *nap-1*-dependent genes induced by menadione (microarray). 45 genes *NcAp-1* dependent genes induced by 6 mM H_2O_2 (transcriptional profiling).		Growth and asexual reproduction similar to WT.	

Table 2
Protein size and total cysteine content in Yap1 homologs from filamentous fungi.

Organism	Protein name	Protein size (aa)	Total cysteines	Identity to Yap1 (%)
Ustilago maydis	Yap1	758	C396, C399, C405, C407, C526, C532, C536 and C546	40
Cochliobolus heterostrophus	CHAP1	589	C394, C418, C529, C553 and C562	51
Colletotrichum gloeospoiroides	CgAP1	566	C367, C497, C507, C521, C530 and C557	44
Epichloe festucae	YapA	580	C363, C410, C499, C509, C523 and C532	45
Fusarium graminearum	Fgap1	588	C365, C491, C503, C513, C527, C536 and C564	44
Aspergillus fumigatus	AfYap1	615	C419, C431, C438, C562, C586 and C595	52
Aspergillus parasiticus	ApyapA	583	C346, C388, C400, C407, C530, C554 and C563	44

Botrytis cinerea	Bap1	601	C393 and C423, C533, C543, C557 and C566	44

5. Yap1 homologs in filamentous fungi and gene expression

Most studies showing that Yap1 regulates gene expression in response to oxidative stress in filamentous fungi have monitored the expression of specific antioxidant genes such as genes encoding catalases, peroxidases or genes involved in glutathione biosynthesis (Table 1). In more comprehensive studies, a proteomic study identified 29 proteins with decreased abundance in mutants lacking AfYap1 and treated with H_2O_2, including catalases, peroxidases, peroxiredoxins and chaperons (Lessing et al., 2007). Transcriptomic analysis in *Neurospora crassa* identified 16 NcAP-1-dependent genes induced by menadione (Takahashi et al., 2010) and 45 genes induced by H_2O_2 (Tian et al., 2011). Similar studies identified 99, 221, 214, 1179 and 1505 yap1-regulated genes induced by H_2O_2 in *Botrytis cinerea* (Temme and Tudzynski, 2009), *U. maydis* (Molina and Kahmann, 2007), *A. nidulans* (Mendoza-Martinez et al., 2017), *M. oryzae* (Guo et al., 2011) and *Colletotrichum gloeosporioides* (Li et al., 2017), respectively. By comparison, about 100 and 50 Yap1 and Pap1 regulated genes have been reported in *S. cerevisiae* (Gasch et al., 2000) and *S. pombe* (Chen et al., 2008), respectively. While most of these studies identified Yap1-dependent genes in response to oxidants, the transcriptomic study in *A. nidulans* analyzed NapA-dependent gene expression in isolated asexual spores, showing for the first time, a role for this transcription factor in developmental gene regulation. Notably, the set of genes that NapA regulates during conidiation is different from the set of genes normally induced by oxidants. Indeed, during conidiation NapA is required for full induction of 201 genes, which include genes encoding 12 putative transcription factors; 46 oxidoreductase enzymes; 32 membrane transporter proteins, putatively involved in sugar and amino acid transport, drug and metal detoxification; 29 predicted or confirmed hydrolases involved in ethanol and complex carbohydrate utilization, as well as 29 proteins with recognizable protein domains not included in the previous categories. Some of these enzymes would be involved in iron acquisition and the production of antibiotics and other secondary metabolites (Mendoza-Martinez et al., 2017). These results indicate that like in yeast cells, Yap1 homologs in filamentous fungi can regulate the expression of both antioxidant and drug detoxification genes. This might have clinical implications as in the opportunistic human pathogen *Aspergillus flavus* a Yap1 point mutation that would result in constitutive nuclear localization causes resistance to the antifungal voriconazole, mediated by the upregulation of the *atfR* gene, ecoding an ATP-binding cassette transporter (Ukai et al., 2018). In *Cryptococcus neoformans* CnYap1 is dispensable for virulence but required for resistance to the fungicide fluconazole (Paul et al., 2015) and for the fluconazole-mediated induction of the *AFR1* gene, encoding a major ABC-type pump critical for azole efflux (Chang et al., 2018).

INFORME DE LABORES 2019

6. Yap1 homologs regulate inter-kingdom communication in filamentous fungi

Major mechanisms of defense in plants and animals involve the production of ROS to prevent pathogen attack. Therefore, fungal pathogens need effective strategies for ROS detoxification, which could involve Yap1 homologs. In biotroph *U. maydis*, Yap1 is necessary for successful infection but not for the development of the infection structure called appressorium. H_2O_2 accumulation was detected at the plant infection point in *Δyap1* but not in WT strains, and the flavoenzyme inhibitor DPI prevented such H_2O_2 accumulation and restored *Δyap1* virulence, suggesting that Yap1 is essential to neutralize the ROS generated by the host NADPH oxidases (Molina and Kahmann, 2007). Similarly, in the hemibiotrophic pathogen *M. oryzae*, *Moap1* mutants are unable to infect the host plant but do form appressoria. In these mutants also the growth of invasive hyphae during infection was reduced and ROS accumulation was observed at the infection site (Guo et al., 2011), indicating that MoAp1 is necessary for ROS scavenging. Similar results were reported in hemibiotrophic *C. gloeosporioides*, where *ΔCgAP-1* mutants were unable to cause lesions on mango (Li et al., 2017) and showed decreased virulence on poplar leaves, despite not being affected in appresorium formation. Moreover, wild type CgAP1 was necessary to prevent ROS accumulation during early stages of biotrophic growth (Sun et al., 2016). Likewise, *Δ*Yap1 mutants of hemibiotrophic *Alternaria alternata* failed to incite necrotic lesions on wounded or unwounded Minneola leaves and the use of plant NADPH oxidase inhibitors partially restored virulence (Lin et al., 2009). However, Yap1 homologs are not essential for virulence or plant interactions in all pathogenic or symbiotic fungi studied. The biotrophic interaction of *E. festucae* with its host plant is not affected by the lack of Yap1, although Yap1 accumulates in nuclei during plant penetration (Cartwright and Scott, 2013). In *C. heterostrophus*, CHAP1 deletion does not affect virulence, despite that nuclear accumulation is induced from 2.5 to 30 h after infection (Lev et al., 2005). In necrotrophic *B. cinerea*, the deletion of *bap1* did not impact virulence (Temme and Tudzynski, 2009) and a *Fusarium graminearum Fgap1* deletion mutant was also not affected in pathogenicity (Montibus et al., 2013). These differences in Yap1 impact on fungal virulence may be related to the different type of associations established between plant and fungi, as Yap1 requirement for virulence appears to be more common in biotrophic and hemibiotrophic fungi. Biotrophic fungi establish a close association with the host through the development of specialized infection hyphae within living plant cells, from which nutrients are taken up (Mendgen and Hahn, 2002). Necrotrophic fungi secrete toxins and enzymes that kill host cells and then nutrients released from the dead tissue are taken up, while hemibiotrophic fungi combine both strategies (Horbach et al., 2011). An initial biotrophic phase, during which the host's immune system and cell death is actively suppressed, allows invasive hyphae to spread throughout the infected plant tissue. This is followed by a necrotrophic phase during which toxins are secreted by the pathogen to induce host cell death. For necrotrophs and hemibiotrophic fungi, ROS accumulation act as a virulence factor that induces cell death for successful infection (Mengiste, 2012). For most biotrophic fungi, the Yap1 pathway is probably sufficient and necessary to contend with ROS during the first stages of colonization, while necrotrophic fungi might use additional antioxidant pathways to counteract the oxidative stress produced by the host.

ROS also play critical roles in animal's immunity. Fungal human pathogens are usually opportunistic like *A. fumigatus*, which causes invasive pulmonary disease in immunocompromised patients. However, *Afyap1* mutants did not show attenuated virulence in a murine model (Lessing et al., 2007). In the dimorphic fungus *Talaromyces marneffei*, *ΔyapA* mutants showed decreased survival in human macrophages, suggesting that in this fungus YapA is important for virulence (Dankai et al., 2016).

7. Yap1 functions in secondary metabolism

Secondary metabolites are small non-essential molecules that work as chemical communication signals in complex ecosystems, defending the habitat from predators or inhibiting the growth of competitors. Fungal secondary metabolites like mycotoxins cause food contamination, affecting human health. In contrast, penicillin and others are used as medical treatment of infectious diseases, cancer, or as immunosuppressants (See (Keller, 2018) for a recent review).

In fungi, secondary metabolite production is generally related to developmental processes and in some cases development is regulated by secondary metabolites (Marquez-Fernandez et al., 2007; Soid-Raggi et al., 2016). In *A. nidulans*, *napA* overexpression results in increased tolerance to oxidative stress and decreased production of secondary metabolites, including sterigmatocystin, emericellin, asperthecin, shamixanthone, and epishamixanthone and a shift from sexual to asexual development (Yin et al., 2013). Consistent with this, *A. parasiticus ΔpyapA* mutants produce more hydroperoxides and aflatoxin during growth on maize seeds, compared to the wild type strain (Reverberi et al., 2007). These results suggest that NapA regulates secondary metabolism genes in a negative way. However, during development, NapA is necessary for the induction of several secondary metabolism genes in *A. nidulans*. During sexual development, NapA is needed for expression of a specific polyketide synthetase involved in the production of the cleistothecial melanin (Mendoza-Martinez et al., 2017), and during asexual development it is required for the conidial accumulation of mRNAs corresponding to two polyketide synthases genes and other genes involved in the biosynthesis of secondary metabolites such as sterigmatocystin, penicillin, monodictyphenone and prenyl xanthones, all with antimicrobial activity (Mendoza-Martinez et al., 2017). These results indicate that in filamentous fungi Yap1 homologs can repress as well as activate secondary metabolism genes, perhaps depending on the developmental stage. Further research is needed to determine the specific mechanisms.

8. ROS and Yap1 regulate development in filamentous fungi

Hansberg and Aguirre (1990) proposed that increased (localized) ROS levels, beyond certain threshold, induce cell differentiation. Such increase is a transient process as much as ROS induce the expression of ROS scavenging systems (Aguirre et al., 2005; Hansberg and Aguirre, 1990). In filamentous fungi, the nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOX) connect ROS and cell differentiation processes. These enzymes transfer electrons from NADPH to produce superoxide, which can readily produce H_2O_2. NOX homologs are widely distributed in animals, plants and many multicellular microorganisms (Aguirre and Lambeth, 2010). The link between NOX activity and cell differentiation in fungi was first established in *A. nidulans*, where NoxA was shown to be necessary for fruiting body development (Lara-Ortiz et al., 2003). Similar results were obtained in *Podospora anserina* (Malagnac et al., 2004), *N. crassa* (Cano-Dominguez et al., 2008) and other fungi. In *B. cinerea*, NoxA and NoxB are necessary for the differentiation of sclerotia (Segmuller et al., 2008). Additional evidence indicating that ROS regulate fungal sexual development comes from experiments in *A. nidulans* showing a drastic increase in the production of fruiting bodies in mutants that either overexpress NoxA (Lara-Ortiz et al., 2003), lack catalases CatA, CatB

INFORME DE LABORES 2019

and CatC (Lara-Ortiz, 2004), or lack NapA (Mendoza-Martinez et al., 2017).

In different fashions, ROS and NapA have also been related to asexual development in filamentous fungi. In *A. alternata*, mutants lacking NoxB or its regulatory subunit NoxR show a drastic decrease in conidiation and YAP1 expression appears reduced in these mutants (Yang and Chung, 2012, 2013). In *T. marneffei*, *yapA* mutants produce conidiophores with fewer phialides and conidia, and conidia show decreased germination rates, while yeast cells fail to undergo binary fission (Dankai et al., 2016). In *M. oryzae* MoAP1 deletion led to a reduction of aerial hyphal growth, abnormal conidium morphology and reduced conidiation (Guo et al., 2011). In *A. nidulans*, NapA is also needed for full conidiation (Mendoza-Martinez et al., 2017), and the normal accumulation of 201 mRNAs in conidia. Lower conidiation in *ΔnapA* mutants might be related to their lower expression of *gmcA* gene, encoding a putative glucose-methanol-choline oxidoreductase required for early stages of conidiophore development (Etxebeste et al., 2012). In *A. fumigatus*, *gmcA* ortholog AFUA_3G01580 is induced by H_2O_2 in an AfYap1-dependent manner (Lessing et al., 2007), suggesting that *gmcA* regulation by NapA is conserved, at least in the *Aspergilli*.

9. Yap1 in nutrient assimilation

In *S. pombe* glucose limitation induces both, the activation of the stress activated MAPK Spc1/Sty1 pathway, and the nuclear accumulation of Pap1 (Madrid et al., 2004). *S. cerevisiae* Yap1 was also identified in a two-hybrid screen for proteins interacting with Sip2, a β subunit of the Snf1 protein kinase, which is important for adaptation to glucose. Yap1 also shows nuclear accumulation on glycerol as carbon source (Wiatrowski and Carlson, 2003) and *A. nidulans ΔnapA* mutants are unable to grow on ethanol or arabinose and show very reduced growth on fructose, as sole carbon sources. Consistent with their lack of growth on ethanol, *ΔnapA* mutant conidia show notably decreased levels of *alcR*, *alcA* and *aldA* mRNAs, and the corresponding proteins are essential for ethanol utilization (Mendoza-Martinez et al., 2017). Such connections between Yap1, oxidative stress and nutrient assimilation deserve a more detailed exploration in both, yeasts and filamentous fungi.

10. Concluding remarks

It is clear that Yap1 homologs in filamentous fungi regulate the antioxidant response, as well as virulence, secondary metabolism, development and nutrient assimilation. However, it is not clear if the same regulatory mechanisms operate under all these conditions. It is critical to determine which Yap1 nCRD and cCRD cysteines are critical for H_2O_2 *vs.* electrophilic compound oxidation and to determine if peroxiredoxins are involved in H_2O_2-mediated oxidation. As mentioned before, natural plant phenolic compounds like cinnamic acid can trigger ChAP1 nuclear accumulation but only a slight up regulation of specific antioxidant genes in *C. heterostrophus* (Shalaby et al., 2012; Shanmugam et al., 2010). This raises the possibility that phenolic compounds produced during fungal development (i.e conidiation, sexual development) could physiologically induce Yap1 direct oxidation, as opposed to H_2O_2-induced peroxiredoxin-dependent oxidation. Such possibility is supported by the fact that L-phenylalanine ammonia-lyase (PAL) activity, which catalyzes the deamination of phenylalanine to form *trans*-cinnamic acid and ammonia, and PAL-encoding genes have been detected not only in plants, but also in fungi, including *A. nidulans* (Hyun et al., 2011). Moreover, AfeA enzymes related to plant 4-coumarate ligases (4CL), have also been reported to regulate development in *A. nidulans* and be present in other fungi (Soid-Raggi et al., 2016). 4CL is the third enzyme in the phenylpropanoid biosynthesis pathway in plants and forms coenzyme esters from hydroxycinnamic acids such as coumaric, caffeic, or ferulic acids (Hahlbrock and Grisebach, 1970). Moreover, other Yap1 oxidizing physiological compounds like methylglyoxal could accumulate during development and induce the expression of drug detoxification genes. Finally, it is critical to determine if some Yap1 functions depend on its association with Skn7 homologs or other proteins, as it occurs in yeast cells, and to delimitate such functions.

ABSTRACT

Diabetes mellitus is a metabolic disease that leads to several complications which include retinopathy. Neuronal abnormalities have been reported to appear before microvasculature alterations. We analyzed the expression levels of GlyR subunits in the retina at 7, 20, and 45 days after streptozotocin-induced diabetes to gain insight into the pathogenesis of diabetic retinopathy. We determined the mRNA and protein expression by qPCR and western blot, respectively. The mRNA and protein expression of the α1 subunit was not altered over the study period; however, they were slightly reduced in α2 yet statistically significant. While protein expression of α3 subunit was only reduced at 45 days diabetes. The mRNA and protein expression of the α4 subunit was remarkably decreased since day 7 of diabetes, remaining only ~20% on day 45 of diabetes. Surprisingly, the mRNA of the β subunit was highly increased, while its protein levels were not changed. The decrease in GlyR α subunits expression in the retina from diabetic animals suggest a perturbation in the inhibitory glycine signaling pathway, which might be related to the visual alterations observed in diabetes.

1. Introduction

Diabetic retinopathy is one of the most common complications of diabetes mellitus and it causes blindness in working-age adults [1]. Diabetic retinopathy usually refers to vascular abnormalities, but increasing evidence indicates the occurrence of neural alterations which precedes the microvascular pathology observed at later stages of the disease [2–4]. Abnormalities in oscillatory potentials and b waves of the electroretinogram, as well as in contrast sensitivity have been reported in diabetic patients and rodents [5–10]; in spite of this information, the underlying neural mechanisms involved are largely unknown.

Retina excitatory neurotransmission is modulated by glycine and GABA, the major inhibitory neurotransmitters in retina, localized in different types of amacrine cells, which carry out specific roles in the processing of visual signals [11]. Around 50% of the amacrine cells are glycinergic, which make synaptic contacts with bipolar, ganglion, and other amacrine cells [12,13].

The postsynaptic glycine receptors (GlyR) are pentameric ligand-gated chloride channel composed by α (1–4) and β subunits, assembled as homomeric (α subunits) or heteromeric (α-β subunits) receptors [14]. The β subunit is considered essential for clustering GlyR at synapses due to its direct interaction with the cytoplasmic clustering protein gephyrin [15]. All five subunits are expressed in the inner plexiform layer of the adult mammalian retina [16–18] and their characteristic distribution across the inner plexiform layer and neuronal subtype localization suggests they are involved with different neuronal circuits [13]. Therefore, the aim of the present study was to investigate whether changes on glycine receptor subunits expression occur in the retina at early diabetes induction in the rat.

INFORME DE LABORES 2019

2. Methods

2.1. Animals

Female adult Long Evans rats (180–200 g) were used for the experiments. Diabetes was induced by a single intraperitoneal injection of streptozotocin (STZ) (90 mg/kg) [19]. No insulin was administered. Animals were considered diabetic if blood glucose levels were higher than 250 mg/dl. Rats were sacrificed after 7, 20, and 45 days after diabetes induction, along with non-treated animals (normal). Blood was collected and the eyes dissected. Eyes were equatorial sectioned and the retinas were shed away from the eye cups using fine pincers.

This study was carried out in strict accordance with the recommendations of the Mexican Institutes of Health Research (DOF. NOM-062-Z00-1999). The protocol was approved by our Institutional Laboratory Animal Care and Use Committee (CICUAL, in Spanish, Comité Institucional para el Cuidado y Uso de los Animales de Laboratorio del Instituto de Fisiología Celular de la Universidad Nacional Autónoma de México), Protocol Number RSS18-14; this was done in accordance with the Office of Laboratory Animal Welfare (OLAW), Assurance Number A5281-01.

All efforts were made to minimize animal suffering and to reduce the number of rats employed.

2.2. RNA extraction

Total retina RNA was extracted with TRIZOL and cDNA was synthesized with the RevertAid H Minus First Strand cDNA Synthesis Kit (Thermo Scientific) following the manufacturer instructions. RNA integrity and concentration was verified by spectrophotometry (NanoDrop1000, Thermo Scientific) and 2% agarose gels.

2.3. Quantitative real-time PCR

Absolute quantification of mRNA was performed according to the method described by Pffafl [20]. A standard curve was constructed from serial dilutions (51, 0.51, 0.0051, 0.000051, and 0.00000051 pg) of the purified 18S (18S ribosomal RNA) gene and it was run with each GlyR subunit: α1-α4 or β. PCR conditions were: holding stage (50 °C (2 min); 95 °C (2 min); forty cycles (95 °C, 15 s); TM (1 min); Melt curve (95 °C, 15 s); 60 °C (1 min); 72 °C (1 min). Primers were designed with the Primer 3 tool (Koressaar and Remm, 2007; Untergasser et al., 2012) and purchased from Oligo T4 (Guanajuato, Gto. Mexico). 18S (TM = 75.6 °C): Forward: Reverse: α1 (TM = 63.4 °C) Forward: 5´-ACTCTGCGATTCTACCTTTGG-3´, Reverse: 5´-ATATTCATTGTAGGCGAGACGG-3´. α2 (TM = 60.4 °C): Forward; 5´-CAGAGTTCAGGTTCCAGGG-3´, Reverse: 5´-TCCACAAACTTCTTCTTGATAG-3´. α3 (TM = 62.8 °C): Forward 5´-GTGAGACACTTTCGGACACTAC-3´, Reverse: 5´-GATGGGTCGAGGTCTAATGAATC-3´. β (TM = 65.1 °C): Forward: 5´-CTGTTCATATCAAGCACTTTGC-3´, Reverse: 5´- GGGATGACAGGCTTGGCAG-3´. The α4 subunit was amplified by using the Prime® qPCR Primers (Rn.PT.56a. 12226027; Exon location 7e8) from Integrated DNA Technologies (Coralville, IA, USA) Time Agarose gels (2%) were run to corroborate the specific amplification.

2.4. Western blotting

Retinas were homogenized in RIPA buffer (50 mM Tris-HCl pH 7.2, 150 mM NaCl, 2% triton X-100, 0.2% SDS) containing proteases and phosphatases inhibitors. Proteins were resolved through 10% SDS-PAGE and electro blotted to immobilon membranes. The membranes were blocked for 3 h in 5% no-fat milk, and incubated overnight at 4 °C with the primary antibodies prepared in Bovine serum albumin 5%: Rabbit anti- α1, 1:3000 (Synaptic Systems); rabbit anti- α2, 1:3000 (abcam); rabbit anti- α3, 1:1000 (abcam); rabbit anti- α4, 1:3000 (Biorbyt); rabbit anti- β, 1:2000 (abcam). After washing thoroughly, the membranes were incubated with the corresponding horseradish peroxidase-conjugated secondary antibodies (Amersham ECL Anti-Rabbit-HRP 1:45,000 for anti-α1; 1:30,000 for anti-α2, anti-α3, anti-α4 and 1:15,000 for anti-β).

The immunoreactive bands were visualized using a Chemiluminescent HRP Substrate (Immobilon Western Chemiluminescent HRP Substrate, Millipore Corp.) according to the manufacturer's instructions. Western blot densitometric analysis was normalized to the amount of actin, using a mouse monoclonal anti pan-actin 1:2000 (abcam) and Anti-Mouse-HRP 1:15,000 (Amersham). Densitometric images and data obtained with Alpha DigiDoc RT (Alpha Innotech, San Leandro, CA) were analyzed using Graph Pad Prism5 software (San Diego, CA, USA).

2.5. Statistical analysis

Data are expressed as the mean ± SEM. Statistical significance was determined by one way ANOVA analysis followed by Tukey´s test multiple comparison using Graph Pad Prisma 5. Statistical significance was assumed at $P \leq 0.05$.

3. Results

3.1. Metabolic state of streptozotocin-treated rats

The existence of diabetes in streptozotocin treated rats was inferred from hyperglycemia, impaired growth, polydipsia and polyuria (Table 1), (Sánchez-Chávez et al. 2008).

3.2. qPCR studies

mRNA GlyR subunits (α1- α4 and β) were evaluated by qPCR. Expression of all subunits was found in the normal rat retina, where the predominant subunits were α2 (5.7 ± 0.15 pg) and α1 (3.14 ± 0.85 pg), followed by α3 (1.33 ± 0.86 pg) and α4 (1.0 ± 0.07 pg); the β subunit showed high expression levels (5.0 ± 0.4 pg) [21]. The relative changes of each GlyR subunit mRNA in the diabetic stage are shown in Fig. 1. The α1 and α3 mRNA expression was not statistically significant over the diabetes study period (Fig. 1). Bizarrely, levels of α3 mRNA expression were founds significantly higher at 20-days of diabetes. On the contrary, the expression of the α2 mRNA expression showed a considerable reduction (30%) from 7 days after STZ administration (Fig. 1). Meanwhile, the α4 mRNA expression displayed a prominent and continuous decrease from day 7 of diabetes, showing values almost undetectable on day 45 of the STZ treatment. Regarding the β subunit mRNA expression values, these were remarkably increased (~2 folds) from early stages of diabetes (Fig. 1).

3.3. Western blotting studies

Western blot for normal rat retina revealed a band of 48–51 kDa for

Table 1
Characteristics of streptozotocin-diabetic rats.

Days	Body weight		Blood glucose	Water intake
	Control	STZ	mg/dl	% of increase
7	190 ± 10	173 ± 10	382 ± 18*	340 ± 25*
20	270 ± 22	180 ± 22*	480 ± 15*	300 ± 20*
45	370 ± 30	166 ± 20*	520 ± 29*	370 ± 15*

Values are the mean ± SEM of 7–12 animals per group. Glucose blood levels of normal (control) rats were 114 ± 4 mg/dl. Water intake in 12 h by normal rats was 33 ± 3 ml. *P < 0.01 compared to normal non streptozotocin treated rats.

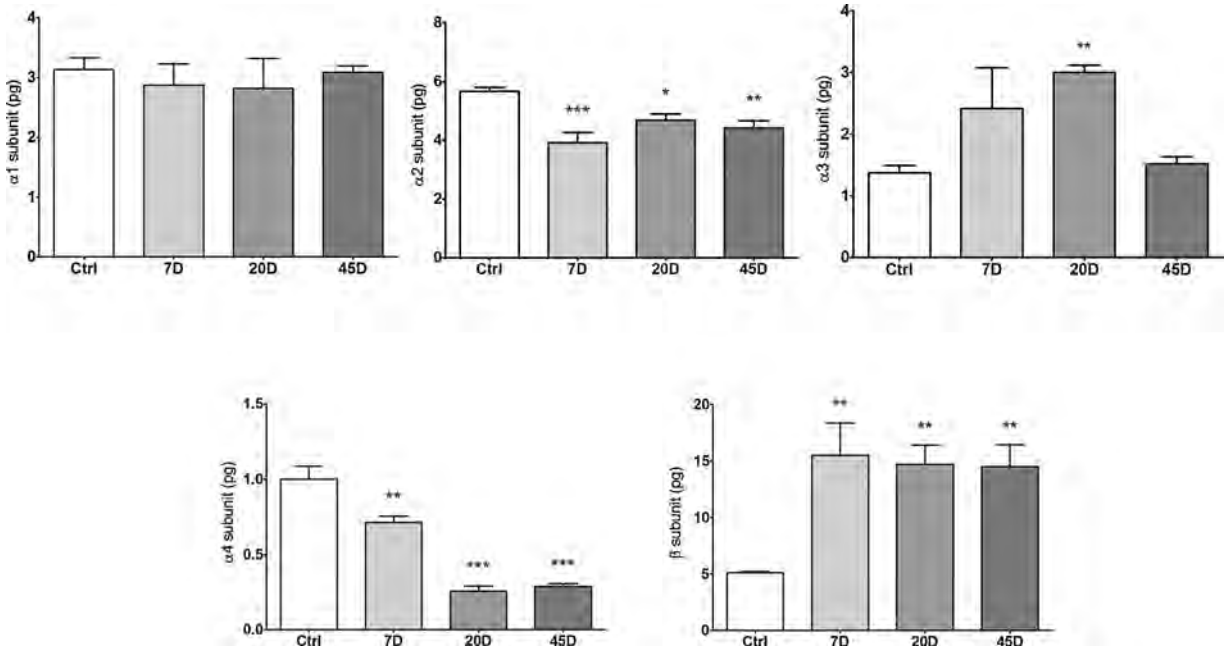

Fig. 1. Expression of GlyR subunits mRNAs in normal and diabetic rat retina. qRT-PCR analysis of GlyR α1 (A), α2 (B), α3 (C), α4 (D), and β (E) subunits in normal (N) and after 7, 20, and 45 days of diabetes induction. Data (± SEM) represent the results from six to nine different retinas carried out in duplicate. *P < 0.05, **P < 0.007, ***P < 0.0001 compared to normal non streptozotocin treated rats at the same ages.

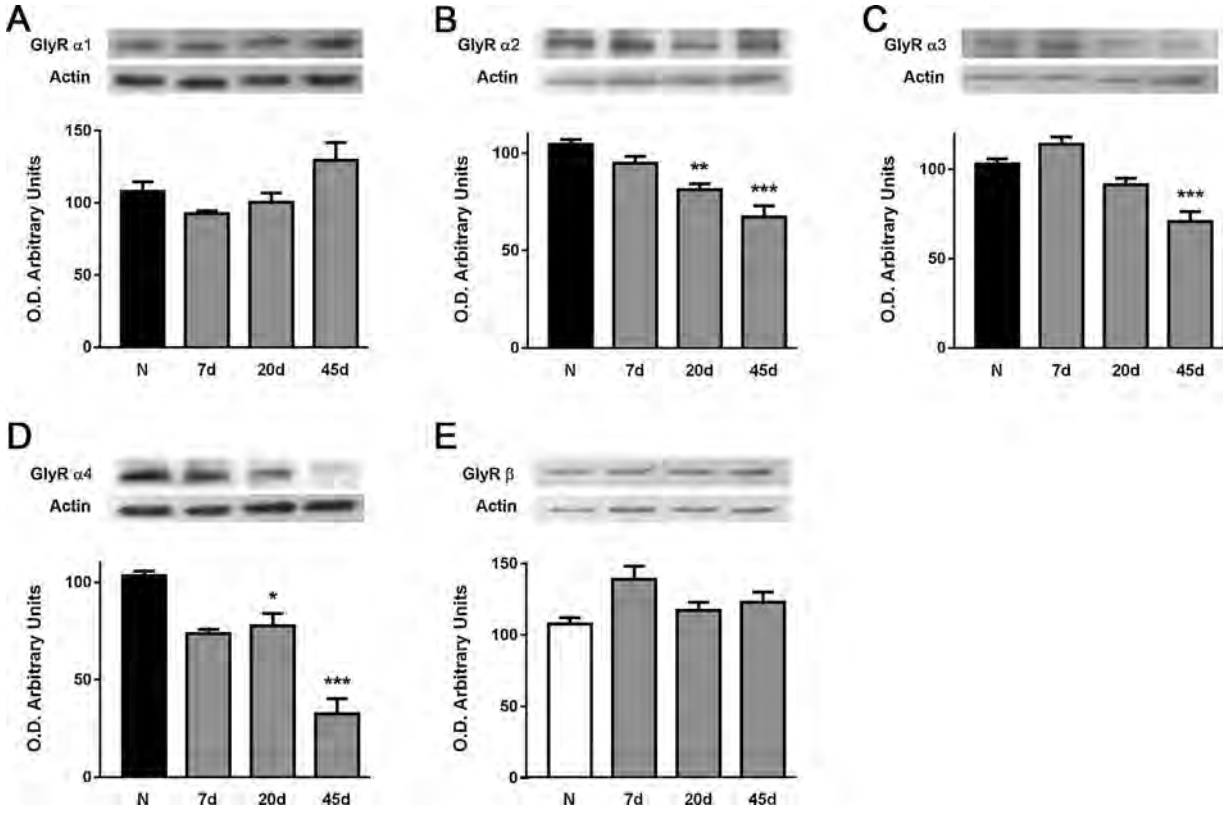

Fig. 2. Expression of GlyR subunits in rat retina at different periods of diabetes induction. Upper part, representative western blot analysis of GlyR subunits (48–49 kDa) and actin (43 kDa) in rat retina homogenates. Lower part, densitometric analysis of western blots of GlyR α1 (A), α2 (B), α3 (C), α4 (D), and β (E). The relative expression between the GlyR subunits normalized to actin was obtained considering as 100% the optical densities from the normal non-streptozotocin treated rats (N). Values are mean ± S.E.M. from three to five (7d), seven to eleven (20d, 45d) different retinas. *P < 0.0135, **P < 0.0014, ***P < 0.0001, compared to normal non-streptozotocin treated rats at the same ages.

INFORME DE LABORES 2019

all α subunits. The α1 and α2 subunits showed the higher expression, followed by the α3 and α4 (not shown), as previously reported [21].

Similar to that observed at mRNA level, the α1 GlyR subunit did not show expression changes under diabetic conditions (Fig. 2A), while the expression of the other α subunits was significantly reduced. The α2 subunit modestly decreased (20–30 %) at 20- and 45-days of diabetes (Fig. 2B), and the α3 subunit showed a considerable decrease (34%) at 45 days (Fig. 2C). Interestingly, the α4 subunit expression significantly decreased (25%) from day 7 of diabetes induction, remaining only 30% on day 45 of diabetes (Fig. 2D). Concerning the β subunit, western blot analysis revealed a 48.7 kDa protein band in both normal and diabetic rat retina. In the normal retina, the relative β subunit expression was around 5–6 folds higher than the α2 subunit (not shown). In the diabetic rat retina, the β subunit expression showed a small not significant increase over the period study (Fig. 2E).

4. Discussion

Diabetic retinopathy is clinically diagnosed by the onset of vascular disorders, suggesting that it is solely a microvascular disease [22,23]. However, early visual defects in diabetes appear to be a result of an impairment of the neural retina [2–4]. Abnormalities in the electroretinogram components have been reported in humans and rats with diabetes [5,8,9,24,25]. These alterations are accompanied by deficits in light and color sensitivity in patients at early diabetic retinopathy [6,7,10]. In addition, ganglion cell degeneration has been reported in diabetic patients as well as in animal models at long-term diabetes [2,26].

The glycinergic amacrine cells are known to generate inhibitory output into bipolar cells, ganglion cells and other amacrine cells. This signaling is essential in regulating the response properties of different classes of retinal ganglion cells [27–29]. Considerable evidence indicates that glycinergic inhibition modulates light responses of retinal neurons and is also involved in specificity, preferentially by crossover inhibition between the ON- and the OFF-channels. Glycine exerts its action through strychnine- sensitive ionotropic receptors, the GlyR, which open a chloride channel leading to hyperpolarization of the cell. GlyR are formed by α (1–4) subunits and a single β subunit, which are considered to form heteromeric receptors with stoichiometry of 2α/3β subunits [30]. The five subunits have been identified in the mammalian retina where they are expressed in the inner plexiform layer (IPL) [16,17,31]. Therefore, we aimed at analyzing whether diabetes influences retinal glycinergic neurotransmission to determine the expression of GlyR subunit isoforms.

We found that both mRNA and protein expression of α1 subunit, which is a main input to light transmitting ganglion cells [32], was not modified over the diabetes study. However, while the mRNA expression of the retina predominant α2 subunit [21] decreased over the diabetes study period, its protein dropped after 20–45 days of diabetes. It has been demonstrated that GlyRα2 is expressed by bipolar cell axon terminals and amacrine cells, and almost all ganglion cells [17]. Meanwhile, α3 mRNA expression was variable, but protein expression was reduced on the day 45 of the STZ treatment. The α3 subunit is distributed widely throughout the inner plexiform layer; in fact, all amacrine express α3β GlyR [13]. Although slight, the reduction in the expression of these subunits may be relevant, given that there is evidence that GlyRα2 and GlyRα3 inhibition enhance ganglion cells excitatory center responses, and GlyRα2 modulates crossover inhibition in both the ON and OFF pathways. In addition, GlyRα2 crossover and GlyRα3 serial inhibition are additive and independent in the ON retinal pathway.

Noteworthy, both the mRNA and protein expression of the α4 subunit were significantly reduced from very early diabetes stages. The GlyRα4 subunit is localized throughout the inner plexiform layer with highest density in cholinergic amacrine cells (starburst amacrine cells, SAC) [18], which play key roles in the direction selectivity [33,34]. Indeed, pharmacological studies showed that SAC lose direction selectivity in the absence of inhibition [35]. Interesting, decrease of cholinesterase activities were found in STZ-diabetic rats [36], and death of cholinergic cells in Ins2-Akita mice [37]. Remarkable, double labeling immunohistochemical experiments revealed that approximately 30% of the α4 containing synapses also express α2 subunit [18]. Therefore, our results suggest a decrease in α4- GlyR signaling in SAC and other amacrine and/or ganglion cells.

The β subunit is expressed throughout the IPL, which is expected, since β subunit is required for agonist binding [30], and all GlyR receptors appear to require the β subunit to target the membrane by means of its linking to gephyrin [15]. Biochemical evidence indicates that the β subunit does not assemble as pentameric homomers [38]; therefore, its higher mRNA expression must likely suggest changes in its synthesis and /or degradation, which has to be further studied.

5. Conclusion

We found a decrease in the expression of α4, α3, and α2 GlyR subunits in the rat retina at very early diabetes induction, suggesting alteration in retina glycinergic neurotransmission.

Statement of author contributions

R.S. designed the research.
E.M.C., M.A.V.F., G.S-CH., R.R.E-G performed the research.
E.M.C., M.A.V.F., G.S-CH., R.R.E-G, R.S. analyzed the data.
R.S. wrote the manuscript.
G.S-CH., M.A.V.F. made the figures.
All authors reviewed the paper.

Declaration of Competing Interest

The authors declare no conflict of interest.

Acknowledgments

This research was partially supported by the PAPIIT/UNAM, project IG200216 (RS), and FIS/IMSS/PROT/G17/1673 from Instituto Mexicano del Seguro Social (IMSS) (MAVF). The authors would like to thank the Animal Facilities and Molecular Biology Units, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México. Molecular Interplay Between the Sigma-1 Receptor, Steroids, and Ion Channels

Sara L. Morales-Lázaro[1], Ricardo González-Ramírez[2] and Tamara Rosenbaum[1]*

[1] Departamento de Neurociencia Cognitiva, División de Neurociencias, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, Ciudad de México, Mexico, [2] Departamento de Biología Molecular e Histocompatibilidad, Hospital General Dr. Manuel Gea González, Secretaría de Salud, Ciudad de México, Mexico

Cell excitability is tightly regulated by the activity of ion channels that allow for the passage of ions across cell membranes. Ion channel activity is controlled by different mechanisms that change their gating properties, expression or abundance in the cell membrane. The latter can be achieved by forming complexes with a diversity of proteins like chaperones such as the Sigma-1 receptor (Sig-1R), which is one with unique features and exhibits a role as a ligand-operated chaperone. This molecule also displays high intracellular mobility according to its activation level since, depletion of internal Ca^{+2} stores or the presence of specific ligands, produce Sig-1R's mobilization from the endoplasmic reticulum toward the plasma membrane or nuclear envelope. The function of the Sig-1R as a chaperone is regulated by synthetic and endogenous ligands, with some of these compounds being a steroids and acting as key endogenous modifiers of the actions of the Sig-1R. There are cases in the literature that exemplify the close relationship between the actions of steroids on the Sig-1R and the resulting negative or positive effects on ion channel function/abundance. Such interactions have been shown to importantly influence the physiology of mammalian cells leading to changes in their excitability. The present review focuses on describing how the Sig-1R regulates the functional properties and the expression of some sodium, calcium, potassium, and TRP ion channels in the presence of steroids and the physiological consequences of these interplays at the cellular level are also discussed.

INTRODUCTION

The Sigma-1 receptor (Sig-1R) is a protein mainly localized to the endoplasmic reticulum (ER), where it functions as a ligand-operated chaperone (Hayashi and Su, 2003, 2007). The first studies related to Sig-1R incorrectly classified it as an opioid-type receptor (Martin et al., 1976; Su, 1982), although, Sig-1R displays high affinity for (+)-benzomorphans (such as (+)-SKF 10047) and not for the negative enantiomers of these compounds (Tam, 1983; Largent et al., 1987).

It was also hypothesized that its structure contained two transmembrane segments (Hayashi and Su, 2007; Aydar et al., 2016), however, the recent crystallographic structure for Sig-1R, shows only one transmembrane segment (Schmidt et al., 2016; **Figure 1**). The C-terminus of Sig-1R was also elucidated by crystallography, and it was proposed to be located facing toward the cell cytoplasm (Schmidt et al., 2016). Nonetheless, *in vivo* experiments later suggested that it is found facing the lumen of the ER (Mavylutov et al., 2018).

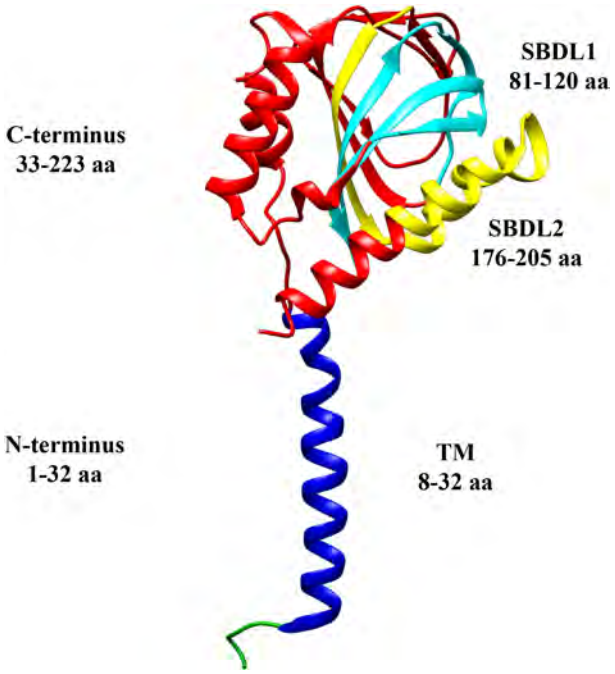

FIGURE 1 | Sigma-1 receptor topology. Structural domains of a monomer of the Sig-1R are shown in different colors: N-terminus (green and blue), transmembrane segment (TM, blue), C-terminus (red), and the two Steroid Binding Domain-Like (SBDL1, aqua, and SBDL2, yellow) which are located in the C-terminus. The amino acids (aa) comprising each domain are illustrated (PDB structure entry, 5HK).

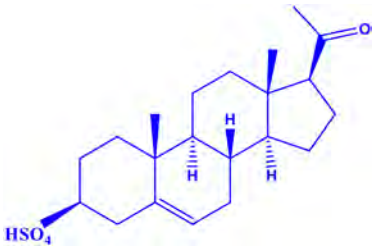
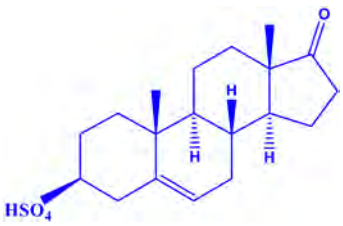
The high affinity of Sig-1R for dextrorotatory isomers of specific opiate benzomorphans like (+) pentazocine (Tam and Cook, 1984; Prezzavento et al., 2017), was exploited to purify it from guinea pig liver and characterize it as a ∼25 kDa protein (Hanner et al., 1996). It was determined that its sequence shares no homology with any other mammalian protein, that it contains a typical ER-retention signal within the N-terminus and, initial hydrophobicity analysis, provided the first sign of the presence of a single transmembrane segment (Hanner et al., 1996). Also, it was defined that the C-terminus of this receptor (residues 33–223) contains the ligand binding-sites (Kruse, 2017), two steroid-like binding domains (SBDL1-2) (Pal et al., 2007) and the chaperone domain (**Figure 1**; Hayashi and Su, 2007; Ortega-Roldan et al., 2013). Another essential feature of Sig-1R is its intracellular mobility, although it is mostly localized to the mitochondria-associated membrane (MAM) of the ER (a domain with high cholesterol content; Hayashi and Su, 2007), it still exhibits movement toward the plasma membrane and nuclear envelope (Hayashi and Su, 2003). Under basal conditions, Sig-1R forms complexes with another ER resident protein, BiP (or Gpr78) and calcium depletion from the ER derives in the dissociation of these two proteins. Then, Sig-1R becomes available to perform its chaperone functions by contributing to the stability of targets proteins, such as the inositol triphosphate (IP3) receptor (IP3R) and others, as will be here discussed (Hayashi and Su, 2007).

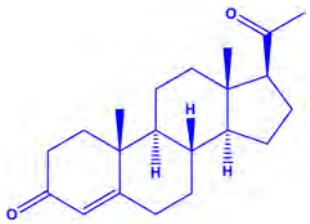
An important property of the function of this receptor is its regulation by synthetic and endogenous ligands (Hayashi and Su, 2004; **Table 1**). According to the physiological responses that these ligands elicit, they can play a role as agonists by potentiating some physiological responses or by normalizing alterations produced during some pathological conditions. On the other hand, antagonists block these effects. For example, PRE084 is considered to be a Sig-1R agonist since it improves learning impairments induced by MK-801 (a non-competitive antagonist of NMDA receptors), while this effect is suppressed by a Sig-1R antagonist, haloperidol (Maurice et al., 1994). Another example of this is the psychomotor responsiveness induced by cocaine, which is Sig-1R-dependent, an effect that is prevented by the co- or pre-administration of Sig-1R antagonists (Kourrich et al., 2013).

It has been reported that some ligands allow for the dissociation of the Sig-1R/BiP complexes, facilitating the interaction of Sig-1R with other proteins (for example, ion channels), similar to what is described above for calcium (Hayashi and Su, 2007). Examples of ligands that promote the dissociation of Sig-1R from BiP are (+)-pentazocine, (+)-SKF 10047, PRE084, fluoxetine and cocaine (Hayashi and Su, 2007). In contrast, other Sig-1R ligands can preserve it in a silent state, either associated with BiP or by producing its oligomerization (Hayashi and Su, 2007; Mishra et al., 2015). Compounds representative of the latter are haloperidol, methamphetamine and NE-100 (Hayashi and Su, 2007; Mishra et al., 2015).

Interestingly, most of the endogenous ligands for Sig-1R are steroids (Su et al., 1988; Maurice et al., 1996). Among them are steroids synthesized in the nervous system (neurosteroids) that modulate the physiology of neuronal tissues (Corpechot et al., 1981). Neurosteroids such as pregnenolone-sulfate (PREG-S) and dehydroepiandrosterone sulfate (DHEA-S) have a role as Sig-1R agonists (Maurice et al., 1998; **Table 1**). Conversely, progesterone is an endogenous antagonist of this receptor, that displays the highest affinity for Sig-1R, as compared to the other steroid-type ligands (Su et al., 1988; Maurice et al., 1998; **Table 1**). On the other hand, testosterone, a steroid whose specific actions on Sig-1R are still unclear, only shows a partial affinity for the receptor (Su et al., 1988). In addition, cholesterol, the precursor of all steroids, can regulate Sig-1R through its binding to the C-terminus of Sig-1R (Palmer et al., 2007).







Altogether, the use of Sig-1R ligands has allowed establishing its role in neuroprotection, neurogenesis, pain, addiction, neurodegenerative and cardiovascular diseases (reviewed in Tsai et al., 2009). This review article will focus on our current understanding of how the interactions between Sig-1R and steroids regulate some ion channels such as voltage-gated potassium and sodium channels, NMDA receptors and TRP channels as well as on the resulting physiological effects of such interactions (**Figure 2**).

ION CHANNELS

An early event of evolution was the appearance of a plasma membrane that functioned as a barrier to separate and protect

INFORME DE LABORES 2019

TABLE 1 | Steroid Sig-1R ligands that regulate some ion channels.

Effect on Sig-1R	Name	Structure	Ion Channel Target
Agonist	Pregnenolone Sulfate K_i = 3.196 ± 0.823		(–) L-type channels (+) NMDAr
	DHEA Sulfate K_i = 15.126 ± 7.69		(–) Na_v channels (+) NMDAr
Antagonist	Progesterone K_i = 0.175 ± 0.55		(–) TRPV1 channels (+) $Na_{v1.5}$ channels* (–) NMDAr** (–) hERG channels***

*K_i (μM) are indicated below the steroid name and represent the concentration of steroids necessary to inhibit in vitro binding of (+)-[3H]-SKF 10047 to brain homogenates (Su et al., 1988; Maurice et al., 1996). The column on the right indicates the ion channel that is the target of the steroid's actions through modulation of Sig-1R. (+) and (–) indicate the type of effect reported. *Progesterone prevents the inhibitory effects of DMT on Nav1.5 channels. **Progesterone disrupts the interaction between Sig-1R and NMDAr. ***This effect has not been directly demonstrated.*

the interior of cells from changes in the external conditions. This lipid barrier also allows for the separation of charges between the extracellular and intracellular regions, serving as a shelter for pore-forming proteins that allow for selective passage of ions from one side to the other which, in turn, results in the generation of a membrane potential (Hille, 2001). Some of these proteins, called voltage-gated ion channels (VGIC's; i.e., Na_v, K_v, and Ca_v), open their pores to ion conduction (sodium, potassium and calcium) in response to electrical changes, a phenomenon which is possible thanks to a voltage-sensitive domain that modulates the gating properties of these channels (Hille, 2001). Other channels are specifically activated by ligands (i.e., *N*-methyl-D-aspartate or NMDA receptors), which directly bind to certain regions of the channels modulating their gating (Hille, 2001). Also, there are polymodal ion channels, such as the Transient Receptor Potential or TRP channels, that are activated by several stimuli including those of thermal, chemical and osmotic natures (Li, 2017).

Different mechanisms can regulate the functions of ion channels that include specific pore blockers or modifiers of their gating properties (chemical compounds/toxins; Hille, 2001), post-translational modifications (phosphorylation, glycosylation) and interactions with other proteins, such as Sig-1R, among others.

Although several reports illustrate the regulation of ion channels by Sig-1R and its synthetic Sig-1R ligands, few studies have conclusively shown that endogenous Sig-1R ligands, such as steroids, modulate its interaction with some ion channels. Thus, examples of the latter will be discussed below.

STEROID-TYPE COMPOUNDS AS REGULATORS OF NA_V CHANNELS THROUGH SIG-1R

Voltage-gated sodium (Na_v) channels are molecular complexes primordial to cell depolarization in all excitable cells (Hille, 2001). They are constituted by α and β subunits (pore-forming and accessory subunits, respectively) and nine different Na_v channels have been identified ($Na_{v1.1-1.9}$) (Dhar Malhotra et al., 2001).

To date, it has been demonstrated that Sig-1R interacts with $Na_{v1.5}$ channels. These channels are expressed in the brain regulating neuronal excitation (Wu et al., 2002) and in cardiac tissue shaping the action potential in the heart (Veerman et al., 2015).

Balasuriya and collaborators demonstrated the association between Sig-1R and $Na_{v1.5}$ channels. They performed assays using HEK293 cells transiently expressing both, Sig-1R and $Na_{v1.5}$ channels, and determined, through atomic force microscopy (AFM) experiments, that Sig-1R directly interacts with $Na_{v1.5}$ tetramers with a 4-fold symmetry (Balasuriya et al., 2012).

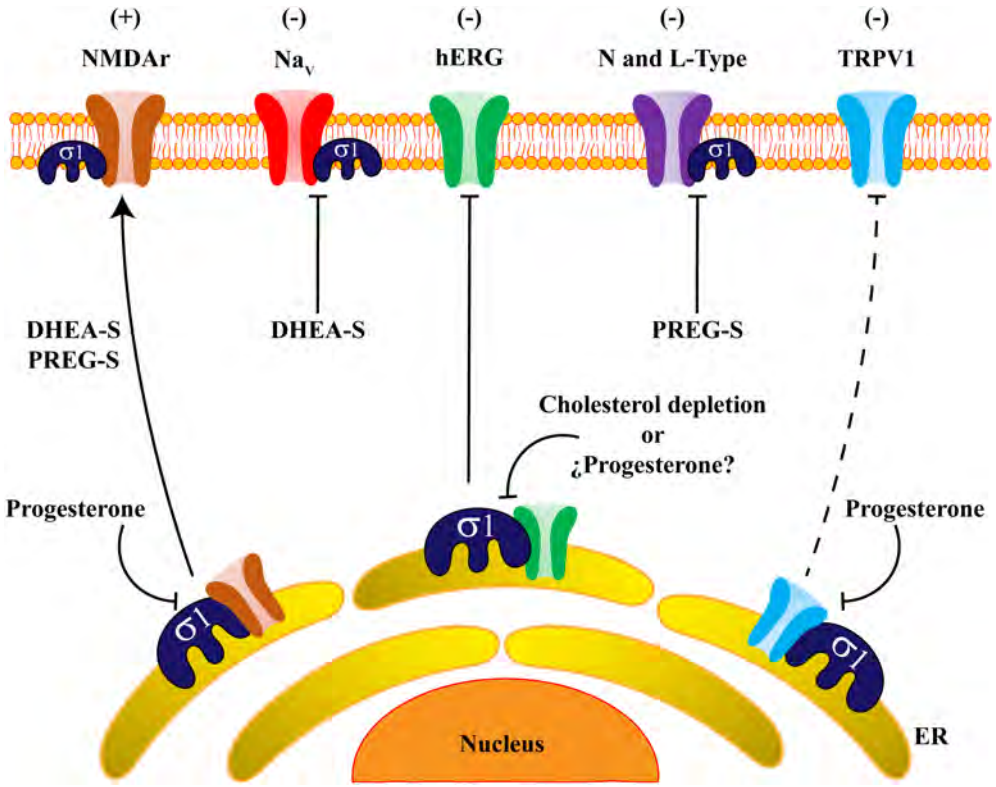


FIGURE 2 | Steroids regulate ion channels through Sigma-1 receptor actions. The scheme shows an overall view of ion channels regulated by the actions of steroids on Sig-1R. DHEA-S and PREG-S positively regulate (+) NMDAr trafficking and expression, whereas progesterone disrupts the association between NMDAr and Sig-1R and blocks the positive effects of the steroids on this channel's regulation. Otherwise, an adverse effect (–) is produced on Na^+ persistent currents by (DHEA-S). Indeed, hERG channels form protein complexes with Sig-1R, and this association is sensitive to cholesterol depletion. Also, L-type calcium channels are negatively regulated (–) by PREG-S in a strictly Sig-1R-dependent fashion. Finally, progesterone antagonizes Sig-1R which negatively regulates (–) the TRPV1 channel, producing protein instability of TRPV1 and reducing the amount of the channel in the plasma membrane. It is possible that progesterone has the same negative effects on hERG channel-expression.

This molecular association is disrupted by some of Sig-1R's synthetic ligands (haloperidol and pentazocine).

The physiological importance of the Sig-1R interaction with $Na_{v1.5}$ channels is exemplified in studies performed with some breast cancer cell lines, such as MDA-MB-231. This cell line constitutively expresses Sig-1R and $Na_{v1.5}$, where it has been shown that they form a protein complex (Aydar et al., 2016). The knockdown of Sig-1R expression reduces $Na_{v1.5}$ channels surface levels in this cancer breast cell line (Aydar et al., 2016), and the physiological consequence of this is a decrease in cell adhesion. This is a clear example of the importance of the Sig-1R/Nav1.5 protein complex in regulating the metastatic behavior of these cancer cells (Aydar et al., 2016).

Other studies have shown that the endogenous hallucinogen N,N-dimethyltryptamine (DMT) (Saavedra and Axelrod, 1972), is a ligand of Sig-1R (Fontanilla et al., 2009). DMT has been shown to reduce the activation of $Na_{v1.5}$ channels expressed in HEK293 cells and neonatal cardiac myocytes (Fontanilla et al., 2009). Effects of this Sig-1R agonist on Na^+ currents are strictly dependent upon Sig-1R expression since they are scarce in cells expressing low levels of Sig-1R, such as in the COS-7 cell line (Johannessen et al., 2009).

As for steroids and the roles of Sig-1R on the regulation of Na_v channels, it has been shown that DHEA-S negatively impacts on the function of persistent Na^+ currents. It is known that the increase of this type of currents leads to hyperexcitability of cells expressing these channels (Deng and Klyachko, 2016). The effects of DHEA-S on persistent Na^+ currents were evaluated in rat medial prefrontal cortex slices and were examined before and after DHEA-S perfusion (4.5 min) (Cheng et al., 2008). Whole-cell patch clamp recordings showed that DHEA-S reduces persistent Na^+ currents an action mimicked by carbetapentane citrate (a Sig-1R agonist) and blocked by Sig-1R antagonist (i.e., haloperidol) (Cheng et al., 2008). Although a change in the overall excitability of the tissue in question would have been expected in the presence of DHEA-S, this was not observed and the reasons for this remain unclear. Nonetheless, it has been suggested by the authors of this study that, such a lack of change in the tissue's excitability in the presence of DHEA-S, may be due to a positive effect of this compound on other molecular targets. This would lead to neutralization of the negative regulation of persistent Na^+ currents by DHEA-S and a neutral effect on neuronal excitability (Cheng et al., 2008).

Moreover, it has been suggested that the regulation of persistent Na^+ currents by DHEA-S, is probably relevant under pathological conditions such as brain ischemia. Under this scenario, negative regulation of persistent Na^+ currents by DHEA-S, through the actions of Sig-1R, would lead to a decrease in neuronal excitability, resulting in a neuroprotective effect. It has been proposed that DHEA-S may be a desirable candidate for therapeutic approaches directed toward relieving induced cerebral ischemia infarction (Yabuki et al., 2015).

In summary, there are only a few evidences showing the direct relationship between Sig-1R, steroids and Na_v channels. Nonetheless, available studies suggest that the negative role of synthetic Sig-1R ligands on Na^+ currents are similar to those promoted by steroidal Sig-1R agonists (i.e., DHEA-S) (**Figure 2**).

K_V CHANNELS ARE FUNCTIONAL TARGETS OF THE ACTIONS OF CHOLESTEROL ON SIG-1R

The generation of action potentials depends upon a fine-tuned coordination of different electrical phases, among which is repolarization. Through this process, the membrane potential is returned to negative voltage values to ensure that an excitable cell can respond to new stimuli. For repolarization to occur, the activation of voltage-gated K^+ channels (K_v) is essential (Hille, 2001; Kandel et al., 2012).

It has been shown that Sig-1R forms complexes with these ion channels regulating their function or abundance in the plasma membrane. Ligands of Sig-1R highly regulate the formation of some of these complexes. For instance, coimmunoprecipitation assays have demonstrated that Sig-1R is associated to $Kv_{1.4}$ in posterior pituitary nerve terminals from rat and also in Xenopus oocytes with heterologous expression of Sig-1R and $K_{v1.4}$ channels (Aydar et al., 2002). In the latter, whole-cell recordings showed that (+)-SKF 10047, downregulates $K_{v1.4}$ channel outward currents, indicating a negative role of Sig-1R on the function of these proteins (Aydar et al., 2002).

Conversely, cocaine triggers the dissociation of Sig-1R from BiP, leading to its interaction with $K_{v1.2}$ and facilitating channel translocation to the plasma membrane. As a result of this, $K_{v1.2}$ function is positively regulated, resulting in neuronal hypoactivity (Kourrich et al., 2013). These results highlight the physiological consequence of a cocaine-induced long-lasting association of these two proteins by which, an enduring experience-dependent plasticity phenomenon, occurs. This also pinpoints a mechanism that can shape neuronal and behavioral responses to cocaine, as suggested by Kourich and collaborators.

Despite the lack of direct experimental evidences showing the effects of steroids on the association of Sig-1R with K_v channels, some reports have demonstrated a possible interplay between them. For example, patch clamp experiments performed in the K562 leukemic cell line, which endogenously expresses Sig-1R and hERG channels (a K_v channel also expressed in cardiac tissues), showed that hERG currents are inhibited by igmesine and (+) pentazocine (both of which are Sig-1R ligands). In addition, silencing of Sig-1R using shRNA-based strategies, also demonstrated reduced hERG current-densities without affecting hERG-channel transcription, but rather by decreasing the amount of the mature form of the channel on the plasma membrane of the cells (Crottes et al., 2011).

It has also been reported that progesterone alters hERG-channel expression. By using HEK293 cells stably-expressing hERG channels and whole-cell voltage clamp recordings, it has been demonstrated that progesterone decreases hERG current-density. This effect was also observed in an hERG-channel endogenous expression system of rat neonatal cardiac myocytes (Wu et al., 2011). Confocal microscopy and western blot analysis of surface proteins showed that progesterone decreases the amount of the mature form of hERG-channel proteins in the plasma membrane and induces channel accumulation in the ER. Moreover, using filipin cell-staining techniques, it was shown that treatment with progesterone produces disruption of cholesterol homeostasis, impairing adequate hERG-channel folding and traffic to the Golgi compartment (Wu et al., 2011). Since progesterone is a Sig-1R antagonist, it could be hypothesized that these effects are produced through a disruption of the Sig-1R and hERG protein complexes. Alternatively, this could be the result of an alteration of cholesterol homeostasis, affecting the function or localization of Sig-1R. The consequences of both possibilities are an improper folding and traffic of hERG channels; thus, the overall effect of progesterone is negative regulation of channel expression in the plasma membrane (**Figure 2**).

Additionally, AFM imaging and homogenous time-resolved fluorescence experiments, have demonstrated that Sig-1R interacts with hERG channels with a 4-fold symmetry in the plasma membrane of HEK293 cells stably transfected with both proteins (Balasuriya et al., 2014). This is a similar scenario to the that reported for the formation of protein complexes between Sig-1R and $Na_{v1.5}$ channels (Balasuriya et al., 2012). Interestingly, this association is independent of Sig-1R's ligands but susceptible to cholesterol depletion (Balasuriya et al., 2014). Accordingly, it has been suggested that Sig-1R ligands can displace cholesterol from its binding site altering the distribution of the receptor in the cell and profoundly impacting on its association with other proteins (Palmer et al., 2007).

This experimental evidence suggests that Sig-1R supports a suitable assembly and folding of immature hERG channels in order to enable them to exit from the ER. Thus, it follows that progesterone and cholesterol affect Sig-1R actions and reduce hERG channel maturation.

Similar results have been obtained for SK3 channels, the small-conductance calcium-activated potassium channels, for which expression of these proteins is regulated by the cellular content of Sig-1R and cholesterol (Gueguinou et al., 2017). The molecular silencing of Sig-1R or the use of igmesine (a Sig-1R ligand) decreases the amount of SK3 channels localized to lipid-enriched nanodomains in breast cells. This, in turn, results in a reduction in the migration of these cancer cells (Gueguinou et al., 2017). Thus, these findings emphasize an interesting area of research in which, the regulation of Sig-1R activity, may be an alternative to control the metastatic potential of certain types of cancers where

the levels of Sig-1R are upregulated (i.e., colorectal or breast cancers) (Gueguinou et al., 2017).

REGULATION OF CA_V CHANNELS THROUGH SIG-1R'S ACTIVATION

Voltage-gated calcium channels (Ca_v) are the main transducers of membrane potential changes (Hille, 2001). Their activation produces the influx of Ca^{+2} ions to the cell, where they function as second messengers to activate different cell signaling pathways, leading to diverse physiological consequences. Ca_v channels are constituted by pore-forming subunits, α_1 (similar to Na_v channels) and by accessory subunits ($\alpha_2\delta$, β, and γ), which are necessary for a suitable function and expression of these channels. According to the types of Ca^{+2} currents that they generate, these proteins are classified as L-, N-, P/Q-, R-, and T-type calcium channels (reviewed in Catterall, 2000).

So far, there is interesting evidence about the interactions between Ca_v channels and Sig-1R. In this respect, the data show that Sig-1R activation by different synthetic agonists, negatively influences Ca_v channels functions, as shown in isolated intracardiac neurons of neonatal rats (Zhang and Cuevas, 2002). In this experimental model, Ca_v channel inactivation rates are increased, and the steady-state voltage-dependences of activation and inactivation are shifted to negative potentials.

The adverse effects of Sig-R ligands on Ca_v channel function have also been observed in cholinergic interneurons from the rat striatum. Here, agonists of Sig-1R such as (+)-SKF 10047 and PRE-084, inhibit N-type calcium currents and, as it would be expected, BD1047, a Sig-1R antagonist obliterates this phenomenon. FRET and coimmunoprecipitation experiments demonstrated that N-type channels and Sig-1R form protein-complexes when these proteins are expressed in HEK293 cells. The authors of this study proposed that Sig-1R agonists produce a conformational change in these protein complexes that negatively regulates N-type channels (Zhang et al., 2017).

Likewise, the negative roles of Sig-1R ligands on Ca_v channels have been observed in primary neuronal cultures from the hippocampus, where SA4503 (a Sig-1R agonist), inhibits N- and L-Type currents, producing an increase in axonal outgrowth (Li et al., 2017).

As for L-type ion channels, these have been shown to co-localize with Sig-1R in retinal ganglion cells (Mueller et al., 2013). Likewise, physical interactions between these proteins have also been demonstrated through coimmunoprecipitation assays in these cells (Tchedre et al., 2008).

Furthermore, an interplay between L-Type channels, Sig-1R and the neurosteroid, PREG-S, has been reported (Sabeti et al., 2007). This was evaluated using electrophysiological recordings from CA1 neurons of rat hippocampal slices perfused with PREG-S before and during the induction of long-term potentiation (LTP) of excitatory transmission. The data demonstrated that LTP increased in slices subjected to PREG-S perfusion. Suitably, nimodipine, an antagonist of L-type calcium channels, blocked PREG-S-induced LTP. Additionally, perfusion of PREG-S and BD1047, also blocked LTP in hippocampal slices, strongly supporting the role of PREG-S acting through Sig-1R in this process (Sabeti et al., 2007). Thus, in this neuronal context, regulation of the function of L-type channels confers synaptic plasticity (**Figure 2**).

REGULATION OF NMDA RECEPTORS BY NEUROSTEROID MOLECULES AND SIG-1R

The *N*-methyl-D-aspartate receptor (NMDAr) is a heterotetrameric ionotropic receptor formed by the assembly of two NR1 and two NR2 or NR3 subunits. NMDAr functions as a channel permeable to Ca^{+2}, its activation is produced by the binding of two different ligands (glutamate and glycine), profoundly impacting on neuronal plasticity, memory and learning processes (reviewed in Hansen et al., 2018).

Regulation of NMDAr by Sig-1R ligands has been extensively reported and, positive effects on their function, strongly correlate to Sig-1R's activation. A pioneering study by Monnet and collaborators demonstrated that a synthetic Sig-1R agonist potentiated neuronal activation induced by NMDAr in CA3 dorsal hippocampal neurons, an effect that was reverted by haloperidol (Monnet et al., 1990). Positive NMDAr regulation by Sig-1R's agonists leads to an improvement in learning and memory since it has been shown that PRE084, attenuates the impairment of learning in mice treated with an NMDAr antagonist (Maurice et al., 1994). A recent study showed that memory deficits produced in mice where brain ischemia was induced, were improved by the use of Sig-1R agonists while they were worsened by antagonism of the NR2 subunits (Xu et al., 2017).

Recently, a direct interaction between Sig-1R and the NR1 subunit of NMDAr has been revealed *in vitro* through the use of AFM imaging. Proximity-ligation assays also confirmed this interaction, supporting an *in vivo* association between these proteins (Balasuriya et al., 2013). This protein-complex is disrupted by some Sig-1R ligands such as BD1063, cannabidiol and progesterone, as demonstrated by pull-down assays (Rodriguez-Munoz et al., 2018). In addition, it has also been shown that the NR2 subunit of NMDAr is positively regulated by Sig-1R agonists, producing an upregulation in NR2-protein-expression and increasing traffic of NR2 to the plasma membrane (Pabba et al., 2014; **Figure 3A**). Finally, it has been shown that Sig-1R knockout mice display decreases in NMDAr-mediated currents and that these animals exhibit deficiencies in neurogenesis at the hippocampal dentate gyrus (Sha et al., 2013). These data suggest that Sig-1R activation positively influences NMDAr function during memory and learning processes.

Effects of steroid-type Sig-1R ligands on NMDAr functions have also been reported. For example, rats subjected to intraperitoneal injection of dizocilpine, (a competitive antagonist of NMDAr), exhibit spatial working and memory deficits. These effects are attenuated by DHEA-S and PREG-S or by a SA4503, all of which are Sig-1R agonists (**Figure 3B**). In contrast, progesterone or NE-100 (both of which constitute

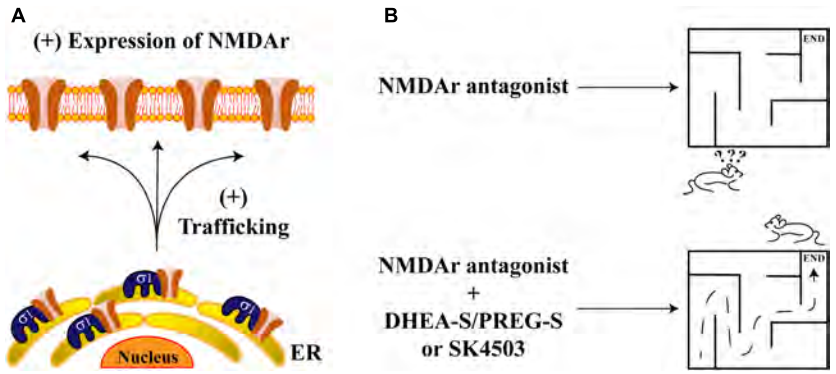

FIGURE 3 | Sigma-1 receptor and its endogenous ligands improve memory deficits. **(A)** The scheme represents the protein-complex between Sig-1R and NMDAr, which enhances the channel's trafficking to the plasma membrane. **(B)** NMDAr antagonism produces deficits in memory and spatial work (upper panel). Sig-1R's agonists such as DHEA-S, PREG-S, or SA4503, ameliorate memory impairments due to NMDAr antagonism (lower panel).

Sig-1R antagonists), block the ameliorative effects of DHEA-S and PREG-S on dizocilpine-induced memory deficits (Zou et al., 2000).

Similarly, some brain ischemia animal models display impairment of LTP at the hippocampal CA1 area, an effect that is prevented by DHEA-S. On the contrary, NE100 and progesterone revert the positive actions of DHEA-S in this model (Li et al., 2006). Finally, the protective effects of DHEA-S on spatial memory have also been reported and have demonstrated that they are dependent upon Sig-1R's actions (Li et al., 2009).

TRPV1: THE FIRST TRP CHANNEL SHOWN TO BE REGULATED BY SIG-1R

Transient Receptor Potential (TRP) ion channels allow for the influx of cations in a non-selective fashion. These proteins possess four subunits, giving rise to functional tetramers (reviewed in Ramsey et al., 2006). According to their structural features, these channels have been classified into seven subfamilies: TRPA (ankyrin), TRPC (canonical), TRPM (melastatin), TRPML (mucolipin), TRPN (no-mechanoreceptor potential C), TRPP (polycystic) and TRPV (vanilloid) (reviewed in Li, 2017). Several of the members of these subfamilies are implicated in the transduction of thermal, chemical and osmotic stimuli.

TRPV1 channels have been extensively studied for their roles in pain. They are mainly expressed by nociceptors (Aδ and C-Fibers) where they are essential for the transduction of noxious signals. These channels are activated by high temperatures ($\geq$ 42°C), irritant compounds (capsaicin, resiniferatoxin, allicin, etc.) (Caterina et al., 1997; Salazar et al., 2008) and by changes in extra- and intracellular pH (acid and basic, respectively) (Caterina et al., 1997; Jordt et al., 2000; Dhaka et al., 2009). Additionally, TRPV1's activation can also be achieved by some endogenous compounds released during inflammation or tissue injury, such as lysophosphatidic acid (LPA) (Nieto-Posadas et al., 2011), among other endogenous agonists (reviewed in Morales-Lazaro et al., 2013). Since TRPV1 exhibits a pivotal role in painful signal transduction, this channel has become a pharmacological target with several research groups around the world focusing on ways to regulate its function to relieve certain types of pain.

So far, several synthetic compounds and some of a natural origin (i.e., oleic acid) (Morales-Lazaro et al., 2016), have been described as negative regulators of TRPV1's activation. However, few studies have revealed alternative ways to regulate TRPV1's functions, including manipulating the abundance of this channel in the plasma membrane of nociceptors. Just recently, our group described that Sig-1R is a crucial molecular target that can regulate the amount of TRPV1 channels localized to the plasma membrane of cells, without affecting channel transcription (Ortiz-Renteria et al., 2018). This constituted the first report for a TRP channel as being regulated by Sig-1R, highlighting the role of a direct interaction between TRPV1 and Sig-1R in pain.

In this study, we found that a synthetic ligand of Sig-1R, BD1063, decreased TRPV1 protein levels in mice dorsal root ganglia (DRG) and HEK293 cells transiently expressing TRPV1. This effect was mimicked by the knockdown of Sig-1R expression in TRPV1-expressing HEK293 cells. Furthermore, progesterone also produced down-regulation of TRPV1 expression, as demonstrated by western blot assays. Worth noting is that the effects of progesterone on TRPV1 expression were found to be independent of its classical nuclear receptors (Ortiz-Renteria et al., 2018).

Also, whole-cell recordings showed that Sig-1R knockdown and the addition of BD1063 or progesterone to cell cultures, reduced the current-densities evoked by capsaicin, indicating that negative regulation of Sig-1R (either by reducing Sig-1R expression or using its antagonists), decreased the amount of TRPV1 localized to the plasma membrane. This negative effect on TRPV1 expression was prevented through the inhibition of proteasomal degradation, suggesting that Sig-1R is necessary for TRPV1 protein stability and confirms an independent effect of a transcriptional mechanism (Ortiz-Renteria et al., 2018).

Besides, we established a direct association between Sig-1R and the TRPV1 channel through coimmunoprecipitation and FRET experiments. We found that Sig-1R interacts with the transmembrane domain of TRPV1, similarly, to what had been previously reported for $K_{v1.3}$ ion channels (Kinoshita

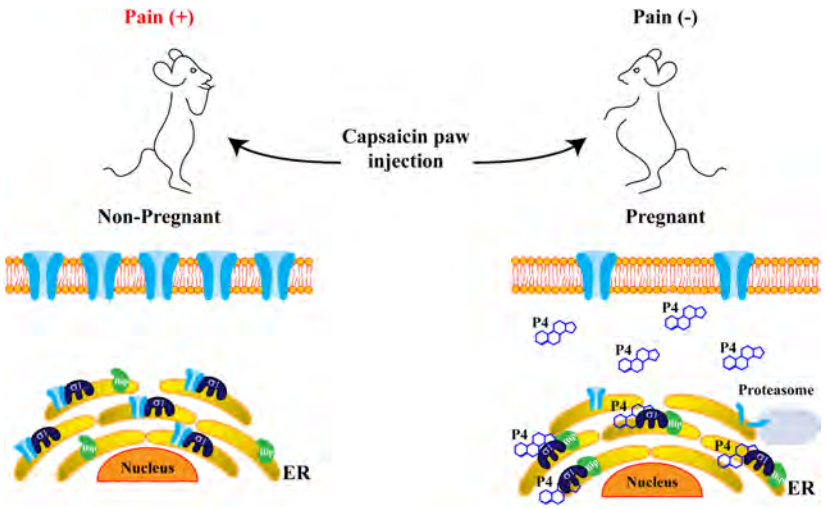

FIGURE 4 | Progesterone attenuates pain-related behavior through disruption of the Sig-1R/TRPV1 complex. Sig-1R and TRPV1 channels are physically associated in the endoplasmic reticulum (ER), improving TRPV1 stability and resulting in suitable TRPV1 expression in the plasma membrane, where the channel transduces painful signals. Consequently, non-pregnant mice display pain behaviors in response to capsaicin paw-injection (left). However, in pregnant mice (right), when progesterone levels considerably increase, the formation of the complex between Sig-1R and the Binding immunoglobulin protein (BiP), is promoted. This maintains Sig-1R in a sequestered state and blocks its association with the TRPV1 channel, improving protein instability and avoiding degradation through the proteasomal pathway. Thus, TRPV1 protein levels in the plasma membrane decrease, leading to an increased pain threshold in response to capsaicin in pregnant mice.

et al., 2012). Interestingly, this protein-complex was sensitive to Sig-1R ligands, since BD1063 and progesterone decreased the association between TRPV1 and Sig-1R. Furthermore, by confocal microscopy analysis, we observed that this protein-protein association is most prominent at the ER compartment and occurs less at the level of the plasma membrane. Together, all of these evidences pointed to a role of Sig-1R in conferring protein stability during the biogenesis of the channel, with Sig-1R preventing the misfolding of TRPV1 and avoiding its degradation by the proteasomal system (**Figure 4**).

Since, progesterone is the steroid with higher affinity for Sig-1R, its interactions with this receptor and the physiological consequences of such interplays have been a subject of focus in pregnancy, a physiological phase where progesterone levels are high (Bergeron et al., 1999). With this in mind, we explored if pain thresholds in response to capsaicin were different between non- and pregnant mice. The results indicated that, during pregnancy, pain-like behavior in response to the TRPV1 agonist was significantly decreased in mice, as compared to their non-pregnant counterparts (**Figure 4**). This led us to conclude that elevated levels of progesterone, such as those found during pregnancy, could confer protection against painful situations through the disruption of the protein complex between Sig-1R and TRPV1. This, in turn, would result in the downregulation of TRPV1's levels in the plasma membrane, ultimately decreasing the pain threshold associated with TRPV1's activation (**Figure 4**).

Several sources in the literature, together with our findings, have highlighted Sig-1R as a protein widely associated with nociception. For example, it has been reported that Sig-1R knockout mice, exhibit endurance to pain and mechanical allodynia induced by formalin and capsaicin, respectively (Cendan et al., 2005; Entrena et al., 2009).

Since Sig-1R is expressed in DRG neurons (Mavlyutov et al., 2016) and in specific regions of the spinal cord (Alonso et al., 2000), its actions are relevant at the pre and post-synaptic levels (reviewed in Romero et al., 2016). Thus, its roles in pain responses must involve more than one molecular target. For instance, several reports show that Sig-1R agonists induce and maintain central sensitization during painful states (Romero et al., 2012; Entrena et al., 2016; Choi et al., 2017). Some of Sig-1R's effects are through the upregulation or phosphorylation of the NR1 subunit of the NMDAr that lead to neuronal overexcitability (Roh et al., 2010). Conversely, antagonists of Sig-1R prevent or decrease pain in some neuropathic pain animal models since these compounds inhibit the upregulation of NR1 (Zhu et al., 2015). Besides it has been demonstrated that DHEA-S and PREG-S positively regulate the activity of P2X receptors resulting in the potentiation of the mechanical allodynia induced through these receptors (Kwon et al., 2016).

In conclusion, Sig-1R is essential for regulating peripheral and central sensitization by interacting with various molecular targets such as TRPV1 channels, P2X channels, NMDAr and it is possible that several other proteins involved in these processes, will be identified in the future.

Progesterone as a Prototypical Endogenous Ligand of Sig-1R

Up to this point, we have emphasized findings that link the actions of Sig-1R and steroids to the function of ion channels. It is important to stress that, the steroid concentrations used in most of the experiments here described, are well above the reported physiological range.

The low affinity of steroids to Sig-1R justifies the use of high concentrations of steroid ligands in different experimental systems. For example, a study by Su et al. (1988) showed that progesterone competes (Ki = 268 nM) with [H3](+)-SKF 10047 for the binding site in Sig-1R and exhibits higher affinity for this receptor. However, other steroids are required at much higher concentrations than those of progesterone to displace [H3](+)-SKF 10047 (Su et al., 1988). Nevertheless, this progesterone concentration is still too high to be normally circulating in blood but, in pregnancy, the circulating levels os this steroids can rise to 400 nM (Neill et al., 1969), reaching concentrations high enough to regulate Sig-1R.

In agreement with the results obtained by Su et al. (1988), Maurice et al. (1996) showed that progesterone displaces the binding of (+)-SKF 10047 to rat brain homogenates with a Ki of 175 nM. They showed that [H3](+)-SKF 10047 binding is significantly reduced in the hippocampus and the cortex from pregnant mice, as compared to non-pregnant female or male mice (Maurice et al., 1996).

These findings, together with ours where we showed that pregnant female mice display high pain-thresholds as compared to unpregnant mice (Ortiz-Renteria et al., 2018), suggesting that high circulating progesterone levels in pregnancy are enough to modify pain thresholds in mice.

Recently, a new high-affinity Sig-1R selective radiotracer ([^{18}F] FPS) has been developed. This compound has been used to perform PET studies in Rhesus monkeys showing high uptake of the radiotracer in brain regions where there are moderate densities of Sig-1R (Mach et al., 2005). Interestingly, animals pre-injected with progesterone displayed a significant reduction in the uptake of the radiotracer in the brain of the monkeys, confirming that progesterone displaces the radiotracer from Sig-1R's binding sites (Mach et al., 2005). In addition, this radiotracer was used to perform *in vitro* binding assays in rat forebrain homogenates showing that progesterone inhibits the binding of the radiotracer to Sig-1R. Notably, the Ki for progesterone is of 36 nM, a concentration of progesterone achieved during the luteal phase of the menstrual cycle (Neill et al., 1969). This finding further strengthens the notion that low progesterone levels also play a role in the activity of Sig-1R and that this steroid functions as an endogenous ligand of this receptor (Waterhouse et al., 2007).

CONCLUSION

Regulation of ion channel physiology has been a subject of intense research for several decades. The implications of such modifications of ion channel function are extremely diverse and important, and they are exemplified by the roles that these proteins play under normal physiological conditions but also in pathophysiological scenarios. Not only do these essential proteins regulate muscle contraction, neuronal excitability, and hormonal secretion but changes in their expression and function during pathological conditions lead to severe diseases such as epilepsy, diabetes, ataxia, pain, itch, etc. For many years, studies have focused on identifying molecular targets of synthetic and naturally-produced agents to regulate the activity of ion channels.

In addition to the identification of chemicals that specifically bind to members of different ion channel families to alter their biophysical properties, research groups have also focused on determining how protein-protein interactions regulate these. Among the proteins that can bind and change ion channel function and expression are chaperones and their roles and the consequences of their misfunctions are being studied in several diseases (Broadley and Hartl, 2009). The Sig-1R has been shown to play essential roles for the adequate function of several types of cells (Tsai et al., 2009), including those that are electrically excitable and hence express ion channels. Thus, from these studies and those discussed here, it is evident that a mechanism by which we may regulate ion channel physiology is through tools that allow us to manipulate the interactions between Sig-1R and these other proteins if this was to be possible without other severe consequences. But utmost important is that, by studying the interactions of Sig-1R with ion channels, we have gained valuable knowledge on how this receptor regulates ion channels. In turn, this has also helped us understand the physiological consequences of modifying the interplays between Sig-1R and ion channels for the function of the cells where these proteins are expressed.

Cholesterol as a Key Molecule That Regulates TRPV1 Channel Function

Sara L. Morales-Lázaro and Tamara Rosenbaum

Abstract Cholesterol is the one of the major constituents of cell membranes providing these structures with a certain degree of rigidity. Proteins, such as ion channels, are molecules inserted in cell membranes and their activity is regulated by cholesterol and other molecules of a lipidic nature present in them. The molecular mechanisms underlying the regulation of ion channels by lipids and similar molecules have been an object of study for several years. A little over two decades ago, the first mammalian member of the Transient Receptor Potential (TRP) family of ion channels was cloned. This protein, the TRPV1 channel, was shown to integrate several types of noxious signals in sensory neurons and to participate in processes associated to the generation of pain. Thus, TRPV1 has become the target of intense research directed towards finding potential inhibitors of its activity in an effort to control pain. To date, several activators and positive modulators of the activity of TRPV1 have been described. However, very few naturally-occurring inhibitors are known. An endogenously-produced molecule that inhibits the activity of TRPV1 is cholesterol. This chapter focuses on describing the mechanisms by which the activity of TRPV1 can be regulated by this sterol.

such noxious signals. Some of these ion channels can be activated, in a polymodal fashion, by thermal, chemical and mechanical signals. The activation of these multimeric proteins allows the fast passive diffusion of ions across cell membranes, converting different noxious messages into electrical signals [1].

The family of Transient Receptor Potential (TRP) non-selective cation channels are classified into seven subfamilies: TRPA (Ankyrin), TRPC (Canonical), TRPM (Melastatin), TRPML (Mucolipin), TRPP (Polycystic), TRPV (Vanilloid) and TRPN (no mechanoreceptor) [2]. Most of these channels have been described in mammals, however the TRPN channel has only been identified in insects, nematodes, zebrafish and amphibians [2].

TRP channels are structurally similar to voltage-gated ion channels [3], consisting of four subunits that are associated as homo or heterotretramers [4] (Fig. 1a). Each subunit is a protein that consists of six transmembrane domains (S1-6), with amino- and carboxyl-termini located intracellularly and an ionic conduction pore formed in the tetramer by the linker located between the S5 and S6 [4] (Fig. 1b). As in all other proteins, TRP channels exhibit a tight relationship between their structure and their function and contain amino acid residues that give rise to regions that constitute activation sites for the channels by diverse stimuli.

TRP channels of mammals are abundantly expressed in sensory neurons from dorsal root and trigeminal ganglia (DRG and TG, respectively), among other several types of cells, where they enable the detection of harmful signals [5]. Among these TRP channels, we find TRPA1, TRPM8, TRPM3 and some members of the vanilloid receptors (TRPV1-4) [5, 6]. All of these proteins are termed thermo-TRP channels because they can be activated by cold (TRPA1 and TRPM8) [7, 8] or by warm or hot temperatures (TRPM3, TRPV1-TRPV4) [6, 9–12]. These polymodal ion channels can also be activated by several chemical compounds found in plants. For example, TRPA1 is activated by isothiocyanates in garlic and mustard oil [13]; TRPM8 is acti-

vated by menthol [8] and TRPV1 is activated by capsaicin, the pungent compounds found in chili peppers of the *Capsicum* genus [10]. Additionally, some endogenous compounds (of a lipidic and/or peptidic nature) released during tissue injury or inflammation, are potent activators of these channels [14]. Thus, pathological states where there is an upregulation of these inflammatory mediators are accompanied by pain due to the activation of these ion channels located in the surface of sensory neurons.

To date, a large number of compounds that activate these channels has been identified and there is ongoing research focused on finding inhibitory molecules, which will be of therapeutic value if they can counteract the pain associated with the activation of these proteins [15]. TRPV1 has been the most studied member of the TRP-channel family due to its roles in acute and chronic pain, as will be discussed in detail in the next section.

2 TRPV1: More than a Capsaicin Receptor

The vanilloid subfamily contains the better studied member of the family of TRP ion channels, the capsaicin receptor (TRPV1). This receptor was first cloned in 1997 [10] and identified as a channel directly activated or modulated by several noxious inputs such as hot temperatures (≥42 °C), natural irritant compounds (i.e., capsaicin, allicin), toxins from plants or spider venoms (resiniferatoxin and double-Knot toxin, respectively), extracellular acid or intracellular alkaline pH and by endogenous lipid mediators such as anandamide, lysophosphatidic acid (LPA), diacylglycerol, phosphatidylinositol 4,5-biphosphate (PIP_2), and arachidonic acid or lipoxygenase products [10, 16].

Furthermore, the first high-resolution structure of TRP channels to be resolved was that of TRPV1 [17]. The resolved three-dimensional structure was obtained by using single particle electron cryomicroscopy (cryo-EM), corroborating that TRPV1 exhibits a fourfold symmetry that surrounds a central pore formed by the extracellular linker located between S5–S6 [17] (Fig. 1a). The S1–S4 voltage-sensing like domains are contiguous to S5-S6 and tetrameric organization is enabled by interactions between the intracellular domains: the amino and carboxy ends [17]. Interestingly, S1–S4 domains provide a long surface for the interaction of lipophilic ligands such as capsaicin, anandamide, resiniferatoxin or lipid mediators [17] and allicin binds to an ankyrin repeat domain in the N-terminus [18].

In this regard, our group has described that oleic acid, a lipophilic ligand, binds to the same pocket as capsaicin does; however, in contrast to capsaicin, the effect of this interaction is the inhibition of the activity of TRPV1, constituting one of the scarce antagonists described for this channel [19]. In this respect, it has also been reported that another lipophilic molecule, namely cholesterol, modulates TRPV1 function and such modulation has been proposed as a two-pronged mechanism: cholesterol indirectly regulates TRPV1 through changes in the properties of the membrane [20–23] or through a direct interaction with a region in the structure of TRPV1 [24, 25]. The following sections will describe the current knowledge on the effects of cholesterol on TRPV1 function.

INFORME DE LABORES 2019

3 Effects of Membrane Cholesterol Depletion on TRPV1 Function

Plasma membranes are composed of lipid molecules and proteins and the major lipid constituent in animal membranes is cholesterol, an amphipathic molecule formed by a rigid planar tetracyclic ring with an angular methyl group on a side, an aliphatic chain (isooctyl) attached to C7 and a β-hydroxyl group at the C3 position [26]. The latter is a functional group important for H-bond formation.

Cholesterol distribution in the plasma membrane is confined to microdomains called lipid rafts, which are cholesterol- and sphingolipid-enriched membrane domains characterized by their insolubility in Triton X-100 detergent, thus, they are also known as detergent-resistant membranes (DRMs) [27]. These membrane rafts form functional platforms for regulating signal pathways where some protein receptors are clustered [28]. Interestingly, some ligand-gated receptors, such as some ion channels, have been shown to be localized in these kinds of microdomains [29]. For example, the TRPV1 ion channel has been suggested to be localized in lipid rafts from DRG [21] or TG neurons, while transiently-transfected TRPV1 in cell lines like HEK293, has not been shown to be present in these specialized membrane domains [24].

Experimental evidences show that membrane depletion of cholesterol modifies the activation of TRPV1 by capsaicin and protons [21]. This was determined by performing whole-cell patch-clamp recordings in DRG neurons pretreated with methyl β-cyclodextrin (MβCD, which removes membrane-bound cholesterol). In these experiments, this pretreatment significantly decreased the amplitude of capsaicin- and proton-evoked currents as compared to untreated neurons [21]. Additionally, TRPV1 clusters localized to the surface of DRG neurons was drastically decreased when neurons were depleted of cholesterol [21]. Thus, the integrity of cholesterol in the plasma membranes of cells determines the appropriate localization and function of the TRPV1 channel.

Similarly, it was demonstrated that the effects of capsaicin and resiniferatoxin are abrogated in neurons from trigeminal ganglia depleted of cholesterol, since Ca^{2+} influx decreased in cells pretreated with MβCD [22]. Notably, this decrease was also observed when the neurons were treated with compounds that disrupt other lipid raft components such as sphingomyelin, indicating that lipid raft disruption affects Ca^{2+} influx related to the activation of TRPV1 [22].

In addition to these observations, recently it has been shown that rat TRPV1 channels transiently expressed in F11 (rat embryonic dorsal root ganglion) cells, co-localized with specific markers of lipid rafts such as flotillin [25], confirming the presence of TRPV1 in these specialized microdomains. Thus, lipid raft disruption could be a key way for the attenuation of TRPV1 activation and of the physiological effects linked to the function of this ion channel.

These experimental evidences show that TRPV1 localization to DMRs is dependent upon the presence of cholesterol in the membranes from DRG neurons, the native expression system. However, under experimental conditions where there is

INFORME DE LABORES 2019

transient expression of TRPV1 in epithelial cell lines, such as HEK293 cells, TRPV1 has not been found in these specialized microdomains [24]. These could be explained by the fact that different cells exhibit varying cholesterol contents. It is possible that neurons are a subtype of cells that contain higher cholesterol levels in their plasma membranes as compared to other types of cells and that cholesterol depletion leads to severe changes on the localization of particular proteins.

4 The TRPV1 Channel is Regulated by Cholesterol Via Specific Interactions

To date, numerous ion channels whose function can be modified by cholesterol have been identified. However, there are few channels have been shown to be regulated by this sterol through direct and specific interactions [30]. Among these channels are some potassium (K_{ir}, BK_{Ca}) channels [31–34], ligand-gated channels (GABA, nAChR, P2X) [35–37], and TRPV1 [24].

Specific interactions of cholesterol with ion channels are largely attributed to the presence of CRACs, which stands for Cholesterol Recognition/interaction Amino acid Consensus []. This short linear motif has the sequence (L/V)-X_{1-5}-(Y)-X_{1-5}-(K/R), where X represents any of one to five amino acids [38]. In addition, cholesterol can bind to an ion channel by interacting with an inverted CRAC motif named the CARC domain. This motif (K/R)-X_{1-5}-(Y/F)-X_{1-5}-(L/V) [39] is different from the CRAC sequence in its orientation and because the central amino acid can be either a tyrosine (Y) or a phenylalanine (F) [39]. Moreover, another cholesterol binding motif has been described as the Cholesterol Consensus Motif (CCM) that, unlike the other two motifs whose sequences are found in a continuous segment, the sequence of the CCM motif is bipartite, being located in two adjacent helices: the first sequence (W/Y)-(I/V/L)-(K/R) found on one helix and the amino acid (F/Y/R) on the other helix [30, 40].

Some of these cholesterol-binding motifs have only been described for two members of the vanilloid receptors: TRPV1 and TRPV4 [24, 25, 41]; however, a direct interaction of the lipid and a TRP channel, as well as the consequences on the activation of the protein, has only been demonstrated experimentally for TRPV1 [24].

Previous reports using whole-cell experiments in DRG neurons depleted of cholesterol yielded two possibilities to explain the reduction on capsaicin generated current densities: alteration of the activity of TRPV1 in the plasma membrane or modifications on channel trafficking to the membrane. In a study performed by our research group, we sought to examine the effects of cholesterol on TRPV1 channels using excised membranes from HEK293 cells expressing this channel. These experiments provided a tool to exclude the possible involvement of cholesterol on cell-trafficking mechanisms and to explore direct effects of the sterol on the ion channels. Depletion of cholesterol from these membrane patches with MβCD showed that TRPV1 activation by capsaicin was not affected by this treatment, as

assessed using inside-out patches with the patch clamp technique. However, the addition of cholesterol to inside-out membrane patches produced a significant reduction in rat TRPV1 activation by capsaicin, temperature and voltage. Since cholesterol enrichment did not modify parameters such as the Hill coefficient and the $K_{1/2}$ for activation by capsaicin, we concluded that binding of this agonist to TRPV1 was unmodified in the presence of cholesterol and not responsible for the effects of this lipid on channel function [24] .

To further detail the effects of cholesterol on rat TRPV1 function, we performed noise analysis experiments in inside-out patches from HEK293 cells expressing TRPV1 before and after cholesterol depletion in these excised patches. The results showed that the open probability (Po) of TRPV1 remained similar before and after cholesterol enrichment. However, the number of functional channels (*N*) decreased considerably [24]. These results were confirmed by excised patch single channel recordings, where cholesterol did not alter the magnitude of the single-channel currents nor the open probability of the channel. Nonetheless, after a few minutes of membrane enrichment with cholesterol we observed that the number of capsaicin-responsive channels decreased during our electrophysiological recordings [24].

In order to determine whether the reduction of the number of functional TRPV1 channels in cholesterol-enriched membranes was due to specific interactions of cholesterol with the channel, we searched sequences that resembled a possible CRAC motif and we found an inverted CRAC sequence (CARC motif) located in the S5 of TRPV1: $\underline{\mathbf{R}}_{579}F_{580}M_{581}\underline{\mathbf{F}}_{582}V_{583}Y_{584}\underline{\mathbf{L}}_{585}$ [24] (Fig. 2). We next evaluated the effects of cholesterol on rat TRPV1 mutant versions where the amino acids corresponding to the CARC motif were individually substituted by other residues. Our experiments showed that a charge reversal of the positive amino acid R576 to an aspartate (D), and the change of the aromatic F582 to a polar amino acid such as glutamine (Q), partially inhibited the effects of cholesterol on TRPV1 function [24]. Moreover, when L585 was changed to an isoleucine (I), the inhibitory effects of cholesterol on TRPV1 activity were completely abolished.

In order to demonstrate the stereospecificity of the interaction between cholesterol and TRPV1, we used a synthetic chiral cholesterol analogue, epicholesterol, which has the hydroxyl group in position 3α instead of position 3β. Membrane

Fig. 2 Alignment sequence between the CRAC and CARC domains from rat and human. Consensus sequence for the CARC motif found in rat TRPV1 channel, (NP_114188) alignment with the from human TRPV1 isoform 1 (iso1-hTRPV1) (NP_542435) and the genetic variant from human TRPV1, var-hTRPV1 (ABA06605.1). The alignment also shows that the CRAC motif is conserved between human and rat TRPV1 channels

INFORME DE LABORES 2019

patch incubation with epicholesterol did not modify capsaicin evoked currents, indicating that the effects of cholesterol on rat TRPV1 function are stereospecific [24].

The specificity of cholesterol interactions within the TRPV1 channel was simulated by molecular docking using the recently reported TRPV1 cryo-EM structure (Fig. 3). These molecular simulations suggest that TRPV1 interactions with cholesterol are mediated by CH-π stacking between the rings of cholesterol (α-face) and the aromatic ring of the tyrosine or phenylalanine residues located in the middle of the CARC domain in the channel; whereas leucine or valine make Van der Waals contacts with the aliphatic chains (methyl and isooctyl groups) located in the β-face of cholesterol (Fig. 3). Although the β-OH group of cholesterol on the CRAC motif is putatively capable of forming H-bonds with the phenol group of the tyrosine, this is impossible for the CARC motif (contained in the TRPV1 channel), since the aromatic ring of the phenylalanine lacks a hydroxyl group. However, it is possible that the hydroxyl group of cholesterol forms a H-bond with R585 at the inner leaflet, as has been recently described for other arginine residues located at the inner leaflet within the TRPV1 channel [25].

Finally, we also evaluated cholesterol effects on the human TRPV1 channel and found that the isoform 1 of human TRPV1 (iso1-hTRPV1, NP_542435) lacks the leucine in position 585 that is present in the rat TRPV1 sequence, Fig. 2. By further examining the literature on reported human TRPV1 sequences, we found a genetic variant (var-hTRPV1) with a single nucleotide polymorphism that contained a valine in this position (SNP: rs8065080) [42] (Fig. 2). This is an amino acid that actually forms part of the CARC motif, so we hypothesized that this variant would exhibit a similar behavior in response to cholesterol to the one we had observed in the rat TRPV1. Furthermore, isoform 1 human TRPV1 contains an isoleucine at position 585, a residue similar to the one we had introduced in the rat TRPV1 (L585I) and that

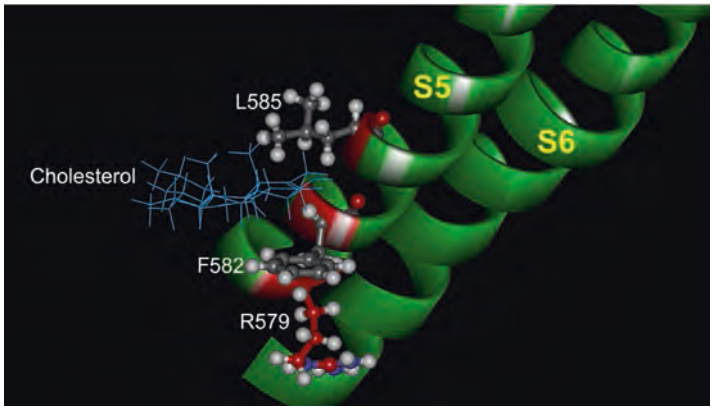

Fig. 3 Molecular docking simulation of cholesterol bound to TRPV1. Simulation using the cryo-EM structure of TRPV1 in the closed state (PDB 3J5P, chain a). Docking simulation shows the proximity between cholesterol and amino acids F582 and L585 located in the CARC motif of TRPV1

had produced channels resistant to inhibition by cholesterol. Indeed, it was not surprising to find that activation of the human TRPV1 isoform 1 was not inhibited by cholesterol. We also found that the substitution in this isoform 1 of I585 by a valine (as the one present in var-hTRPV1) rendered the channel partially susceptible to cholesterol [24]. Furthermore, when I585 from the iso1-hTRPV1 was mutated to leucine (emulating the amino acid contained in the rat TRPV1), this amino acid substitution conferred a marked susceptibility to cholesterol, producing iso1-hTRPV1-I585L channels that were inhibited in their activation by capsaicin when the membrane patches were enriched with this sterol [24].

The iso1-hTRPV1 does not contain a CARC domain at the same position where the rat TRPV1 CARC domain is located. So, it is possible that human or rat TRPV1 channels contain CRAC, CARC or CCM motifs in other sequence positions. Consistent with this idea, it was recently reported that human TRPV1 has two CRAC motifs (located in aa's 349-356 and 553-557), two CARC motifs (located in aa's 304-316 and 535-542) and one CCM motif (in aa's 433-447). Of these cholesterol-binding regions, the CRAC motif located in the S4 and linker S4-S5 region (553-557 aa) (Fig. 2) and the CCM motif, are the most conserved between TRPV1 channels from several species [25]. However, until now, there are only docking simulations showing the interaction of cholesterol with R557 located in the conserved CRAC motif and the functional significances of these motifs remain unresolved [25].

5 Cholesterol Depletion Modifies TRPV1 Permeability to Large-Cations

Plasma membranes properties can be modified according to their lipid composition (i.e. by cholesterol depletion or enrichment) [43]. Two important features of ion channels are their gating properties and their ion selectivity and both are highly dependent upon the membrane lipid content.

Ion selectivity has been considered as a fixed parameter for each channel, however, it has been described that some of them have dynamic pores, leading permeability to large cations, this process has been known as pore dilation [44–46]. Although, this concept has been reconsidered [47], there are experimental data demonstrating that some ion channels, such as TRPV1, can permeate large molecules under specific conditions.

In 2003 Meyers et al., provided the first evidence for the permeation of a large molecule, the nontoxic fluorescent cationic dye (FM1-43,) through the pore of TRPV1 [48]. Furthermore, Binshtok et al., demonstrated that when TRPV1 was activated by capsaicin, the permeation of a local cationic anesthetic QX-314 (a Na^+ ion channel blocker) is allowed, producing local pain inhibition without affecting other sensations [49]. Additionally, Chung et al., found that sustained TRPV1 exposure to capsaicin or protons induced a dilated pore allowing for the uptake of YO-PRO1 and FM1-43 into cells [45]. All these examples show how the TRPV1 can be modified, rendering the channel permeable to the passage of large cationic molecules.

INFORME DE LABORES 2019

Interestingly, these dynamic changes in the TRPV1 pore are susceptible to changes in the cholesterol content of membranes [20]. This was demonstrated in CHO cells (Chinese hamster ovary cells) with inducible human TRPV1 expression. The cholesterol content in these cells was depleted by ~54% through the treatment with MβCD:cholesterol (10:1) and whole cell patch clamp recordings were used to evaluate the effects of cholesterol depletion on the permeability to *N*-methyl-D-Glucamine (NMDG, a large monovalent cation) [20]. Sustained TRPV1 activation by capsaicin, under hypocalcemic conditions in cells depleted of cholesterol, decreased permeability to NMDG, indicating that cholesterol reduction in membrane affects the ion-permeability properties of the channel [20]. In addition, it has been shown that sustained TRPV1 activation by capsaicin in CHO cells, leads to YO-PRO1 uptake and cholesterol depletion decreases the uptake of this cationic large dye [20]. Similar effects were observed whether the channels are activated by protons under sustained and hypocalcemic conditions [20]. In contrast to these results, the permeability to these large cationic molecules in cells depleted of cholesterol were unaffected if TRPV1 was activated by temperature [20], indicating that the properties on TRPV1 ion-permeability also depend on the type of noxious stimulus that activates this channel.

6 Cholesterol Effects on TRPV1 Temperature Responses

We have discussed that cholesterol has strong influences on membrane fluidity [50] which affect the localization or function of transmembrane proteins as ion channels [43] but the amount of cholesterol in membranes also modifies the sensitivity of certain receptors to specific stimuli. For example, TRPV3 is also a thermosensitive channel [51] and it was reported that TRPV3 channels are sensitized to activation by lower temperatures (below 30 °C) in cholesterol-enriched cells [52].

Effects of cholesterol on TRPV1's temperature-sensitivity have been also evaluated [23]. Whole-cell recordings from TRPV1-expressing HEK293 cells with cholesterol enhancement showed that the temperature threshold for TRPV1 activation was significantly increased, since the half-activation temperature was 50 °C in comparison to 48 °C in untreated cells. Notably, the heat response of TRPV1 was unchanged in cholesterol-depleted cells. Therefore, the temperature threshold for TRPV1 activation is partially modified only when this sterol is increased in the membrane.

Thus, it is interesting to note that two structurally-related ion channels, TRPV3 and TRPV1, show distinct responses to cholesterol concentrations in the plasma membrane. Although it is not clear why these channels exhibit different responses to cholesterol, it is not uncommon that, even closely-related ion channels, respond differently to the same molecule. For example, the energetic transitions coupled to the opening or closing of the pore of a specific ion channel are not necessarily altered in the same way as what occurs in another ion channel. Moreover, in the particular cases of TRPV1 and TRPV3, the mechanism by which cholesterol

INFORME DE LABORES 2019

modulates thermal sensitivity of TRPV3 is unknown and could very well be through effects on membrane rigidity and not through a direct a mechanism as the one described for TRPV1.

7 Conclusion

Fifty years ago, it was unimaginable to consider cholesterol as a regulator of ion channels, since this sterol was only considered as a key component of the lipid bilayer where it maintains direct interaction with phospholipids. There is no doubt that cholesterol content modifies the properties of the membranes, having a strong influence in the regulation on ion channel function.

Furthermore, this sterol can regulate the function of these integral membrane proteins in a direct and specific fashion: through the interaction with specific amino acids within the sequence of these proteins.

This chapter has described the molecular mechanisms underlying the regulation of TRPV1 function by changes of cholesterol content in the cell plasma membrane or by direct interaction between the channel and the sterol.

Since cholesterol depletion modifies TRPV1 localization in the plasma membranes from sensory neurons affecting the calcium influx [21, 22], it has been concluded that TRPV1 is confined to specialized microdomains of the membrane: lipid rafts. The discrepancies observed in some cell lines where TRPV1 channels has not been identified in these detergent resistant domains [22, 24] could be attributed to differences in the amount of cholesterol between cell types. Moreover, cholesterol depletion from cells also modulates TRPV1 ion-permeability [20], indicating that the enlargement of the TRPV1 pore is strongly dependent upon cholesterol content. This differs from the idea that cholesterol only promotes stiffness of cellular membranes, since for the case of TRPV1, cholesterol has an important role on the elasticity of its pore. In addition, we have also discussed that cholesterol enrichment causes changes in TRPV1's threshold to heat [23]. Together, these experimental demonstrations, show that TRPV1 is highly susceptible to be regulated by changes on the amount of cholesterol in the membranes where it is expressed.

We have also detailed on how cholesterol directly inhibits TRPV1 activation by capsaicin, temperature and voltage through the specific interaction of cholesterol in a CARC motif located on the S4 from TRPV1 [24] and on the different TRPV1 susceptibilities to cholesterol of different species (rat and human isoform or variants) [36]. Data from our work group and further examination of the literature, has led us to conclude that cholesterol can inhibit human TRPV1 activation by interacting with other cholesterol binding domains recently described [25].

Now, cholesterol is considered as a molecule key in regulating TRPV1 function; however, the physiological consequences of this regulation have still to be explored.

ABSTRACT

Senescent cells accumulate in various tissues and organs with aging altering surrounding tissue due to an active secretome, and at least in mice their elimination extends healthy lifespan and ameliorates several chronic diseases. Whether all cell types senesce, including post-mitotic cells, has been poorly described mainly because cellular senescence was defined as a permanent cell cycle arrest. Nevertheless, neurons with features of senescence have been described in old rodent and human brains. In this study we characterized an *in vitro* model useful to study the molecular basis of senescence of primary rat cortical cells that recapitulates senescent features described in brain aging. We found that in long-term cultures, rat primary cortical neurons displayed features of cellular senescence before glial cells did, and developed a functional senescence-associated secretory phenotype able to induce paracrine premature senescence of mouse embryonic fibroblasts but proliferation of rat glial cells. Functional autophagy seems to prevent neuronal senescence, as we observed an autophagic flux reduction in senescent neurons both *in vitro* and *in vivo*, and autophagy impairment induced cortical cell senescence while autophagy stimulation inhibited it. Our findings suggest that aging-associated dysfunctional autophagy contributes to senescence transition also in neuronal cells.

INTRODUCTION

Aging is accompanied by a wide range of symptoms that reduce health span, such as cardiovascular dysfunction, osteoporosis, neurodegeneration and cancer, among other diseases. Amelioration of those symptoms has been achieved after pharmacological interventions using a novel class of drugs termed senolytics. These compounds clear senescent cells that accumulate late in life both in normal tissues and especially in those affected by age-related pathologies [1]. Nevertheless, senescent cells are harmful only when they persist, since transient senescent cells, which are eliminated by effector immune cells, contribute to wound healing, regeneration, immunity and even morphogenesis during development [2]. Therefore, it is fundamental to understand the molecular mechanisms of senescence establishment and maintenance.

Cellular senescence is a phenotype characterized by a durable cell cycle arrest (*i.e*. cells do not respond to mitogens) and a flattened and vacuolated morphology with stress granules collection. Even though there is no single marker of senescence, some of the most common features observed are: activation of the lysosomal enzyme senescence-associated β-galactosidase (SA-β-gal); persistent DNA damage response detected by γH2AX foci; expression of tumor suppressors $p21^{CIP1/WAF1}$ (encoded by *Cdkn1a)* and/or $p16^{INK4A}$ (encoded by *Cdkn2a)*; lipofuscin accumulation [3]; and nuclear deformation associated with nuclear envelop proteins degradation [4]. The most important activity of senescent cells is the secretion of a set of molecules, known as the senescence-associated secretory phenotype (SASP) that, depending on the physiological context, can be either beneficial or harmful. In early stages senescent cells secrete cytokines that promote the migration and infiltration of effector immune cells, as well as growth factors and proteases that facilitate tissue repair and remodeling. Yet, persisting signaling contributes to chronic inflammation, a hallmark of aging and a major contributor to age-related dysfunctions. SASP molecules also have an autocrine role, fostering the senescent phenotype, and a paracrine role inducing senescence in surrounding cells [5], inflammation and tumorigenesis [6, 7].

Autophagy is a catabolic process that degrades intracellular components, like proteins and damaged organelles, including mitochondria, through lysosomes. Similar to senescence, it is induced in response to stressful stimuli, therefore both senescence and autophagy are often observed simultaneously. The interplay between autophagy and senescence requires further investigation, since autophagy has been implicated in both promoting and inhibiting cellular senescence. While autophagy inhibition promotes senescence in normal proliferating cells [8], autophagy inhibition delays oncogene-induced senescence and the synthesis of SASP components [9]. A possible explanation for the opposing role of autophagy over senescence is that it could engulf alternative targets that regulate cellular senescence in opposite manners. For example, the stability of the transcription factor GATA4, a key activator of SASP genes, is regulated by autophagy. Upon senescence induction, GATA4 escapes autophagic degradation because its interaction with p62/SQSTM1 (an autophagy cargo receptor) decreases, leading to GATA4 accumulation [10]. On the other hand, during oncogene-induced senescence, autophagy fosters the SASP through a specialized compartment known as the TOR-autophagy spatial coupling compartment (TASCC), where mTOR localizes at the surface of autolysosomes, which are surrounded by endoplasmic reticulum; a flux of recycled amino acids and metabolites released from the autolysosomes are used by mTORC1 for supporting the synthesis of SASP factors, hence facilitating senescence [11]. Therefore, selective autophagy actively suppresses cellular senescence through the degradation of GATA4, whereas autophagic degradation of other proteins (perhaps long-lived proteins), facilitates the SASP [12].

The traditional view of senescence as a specific phenomenon where a proliferation-competent cell undergoes permanent growth arrest, has limited the study of senescence of post-mitotic cells. Accordingly, the limited studies on cellular senescence in the brain have mostly focused on glial cells [13]. Nonetheless, some senescent markers have been described in several studies of both physiological aging and neurodegenerative diseases [14]. For example, cortical and Purkinje neurons show several senescence features like SA-β-gal activity, lipofuscin accumulation, γH2AX and macroH2A foci, and IL6 expression, all in a $p21^{CIP1/WAF1}$-dependent manner [15]. Interestingly, human neurons might also senesce, since there is expression of *p16/Cdkn2a* in pyramidal neurons in the prefrontal cortex from human brains of people over 77 years old [10]. We are interested in understanding the molecular basis for neuronal senescence, because we hypothesize that when senescent neurons persist in the brain, they contribute to cognitive decline by impairing synaptic function, inducing paracrine senescence and chronic inflammation.

While cellular senescence of mitotic cells is induced mainly by stressful stimuli (most of them inducing DNA damage), telomere attrition during cell division, oncogene activation or developmental cues [2], the molecular mechanisms that induce post-mitotic cells senescence are less understood. Also, whether autophagy regulates senescence in any direction in post-mitotic cells is completely unknown. Several groups have observed that neuronal cells acquire some senescent features *in vitro*, providing a very helpful system to study the molecular basis of neuronal senescence. For example, primary cortical, hippocampal and cerebellar granule neurons become SA-β-gal-positive over time [16-20]. However, these studies were limited to the detection of SA-β-gal activity, which could be misleading [21]. Recent *in vitro* studies confirmed the presence of additional senescent features, including γH2AX foci in neurons from mouse neuro-glial co-cultures maintained up to 27 days *in vitro* (D*IV*) [22]. Taken together, these reports support the notion that cultured neurons *in vitro* are capable of undergoing cellular senescence with the same features that occur *in vivo*.

For senescent neurons to contribute to chronic inflammation and paracrine senescence, they must establish a senescent phenotype including the SASP. Paracrine senescence has been demonstrated to occur in mouse embryonic fibroblast exposed to conditioned media from senescent fibroblasts [5]. In this work we developed an *in vitro* model of neuronal senescence that recapitulates *in vivo* senescence markers, and secreted molecules able to induce paracrine glial proliferation as well as premature senescence in mouse embryonic fibroblasts, pointing towards a neuronal SASP. We found that senescent cortical cells secrete C-C motif chemokine 2, also known as monocyte chemotactic protein 1 (MCP-1), a known SASP factor able to induce paracrine senescence [23]. Interestingly, we found that rat primary cortical neurons displayed features of cellular senescence before glial cells did. As reported for proliferating cells, functional autophagy, perhaps selective, seems to prevent neuronal senescence, as we observed autophagic flux impairment. Accordingly, we observed more senescent cortical cells when autophagy was impaired and less when it was stimulated. Our findings suggest that a dysfunctional autophagy contributes to senescence transition also in post-mitotic cells.

RESULTS

Primary cortical neurons acquire several senescent features after long-term culture.

To establish an *in vitro* model to study the transition of neurons from a non-dividing terminal differentiation state into senescence *in vitro*, prenatal rat cortical cells were cultured for up to 40 days *in vitro* (D*IV*). Since several reports indicate the presence of senescent glial cells in old brains [13], we considered that glial cells could become senescent and then promote paracrine neuronal senescence; hence, we allowed the proliferation of glial cells during the culture of primary cortical cells. During the first days of culture (6 D*IV*), neurons (expressing βIII-TUBULIN) represented 96.8% (SD 2.2) of the cells with very few glial cells (expressing GFAP); due to proliferation of glial cells and some loss of neurons, by 26 D*IV* there were 51% (SD 6.9) neurons and 31% (SD 11.5) glial cells; and by 40 D*IV* 73% (SD 6.9) of the surviving cells were glial. The cells expressing βIII-TUBULIN did not expressed GFAP. On average, the total number of cells along the culture remained similar (Supplementary Figure 1S). Without any further stressful stimuli, cortical cells became SA-β-gal-positive over time and accumulated lipofuscin detected by autofluorescence and by Sudan Black B staining, a lipophilic dye [24] (Figures 1A-B). SBB staining seems to be more sensitive than SA-β-gal activity. An increment in both SA-β-gal-positive and lipofuscin accumulation was also confirmed in the cortex of old rat brains (Figures 1C-E).

Since different inducers of senescence in mitotic cells converge on the activation of the tumor suppressor $p21^{CIP1/WAF1}$, and indeed $p21^{CIP1/WAF1}$ has been suggested to mediate neuronal senescence in old brains [15], we reasoned that even though post-mitotic cells already express some CDK inhibitors to exit the cell cycle, they could still need to induce its expression for a pro-senescent activity from this protein. Therefore, we analyzed its expression on neurons or glial cells at different times of culture. As shown in Figure 2, in primary culture of cortical cells incubated 26 D*IV*, neurons but not yet glial cells expressed higher levels of $p21^{CIP1/WAF1}$. The number of glial cells with elevated expression of $p21^{CIP1/WAF1}$ increased until 40 D*IV*. This observation suggests that neurons acquire senescent features before glial cells. Interestingly, at 26 D*IV* $p21^{CIP1/WAF1}$ is slightly enriched at the nuclear periphery. This could be related to the recent finding that altered nuclear export is a common hallmark of aging [25]. We confirmed $p21^{CIP1/WAF1}$ expression is induced at transcriptional level in cortical cells at 26 D*IV* by qRT-PCR (Figure 2C).

Another hallmark of senescence is a persistent DNA damage response, commonly detected by the presence of γH2AX foci. As shown in Figure 3A, neuronal cells accumulated γH2AX foci at 26 D*IV*, accompanied by ruptures of DNA detected by Comet assay (Figure 3B). Even though we are not able to distinguish neurons from glial cells with this assay, it is conceivable that the nuclei with broken DNA come from neurons, since we observed that mainly neurons had γH2AX foci; these observations suggest that neurons accumulate DNA damage leading to a persistent DNA damage response. At both 26 and 40 D*IV*, only a small proportion of GFAP expressing cells had γH2AX foci. As expected, cortical neurons from old rat brains also contained more γH2AX foci (Figure 3C).

Finally, since during oncogene-induced senescence, replicative senescence and senescence induced by DNA damaging drugs occur nuclear morphology abnormalities associated with nuclear envelope proteins loss [26], and depletion of Lamin-B1 or Lamin-A/C is sufficient to induce senescent features [4], we wondered whether also senescent post-mitotic cells, such as neurons, would manifest nuclear morphology deformations. As shown in Figure 4, indeed both *in vitro* and *in vivo* senescent neurons had irregular nuclear morphology with folds of the nuclear envelope forming intra-nuclear Lamin-A/C structures that protrude into the nucleoplasm. Very few astrocytes showed abnormal distribution of Lamin-A/C at 26 D*IV*, strengthening the

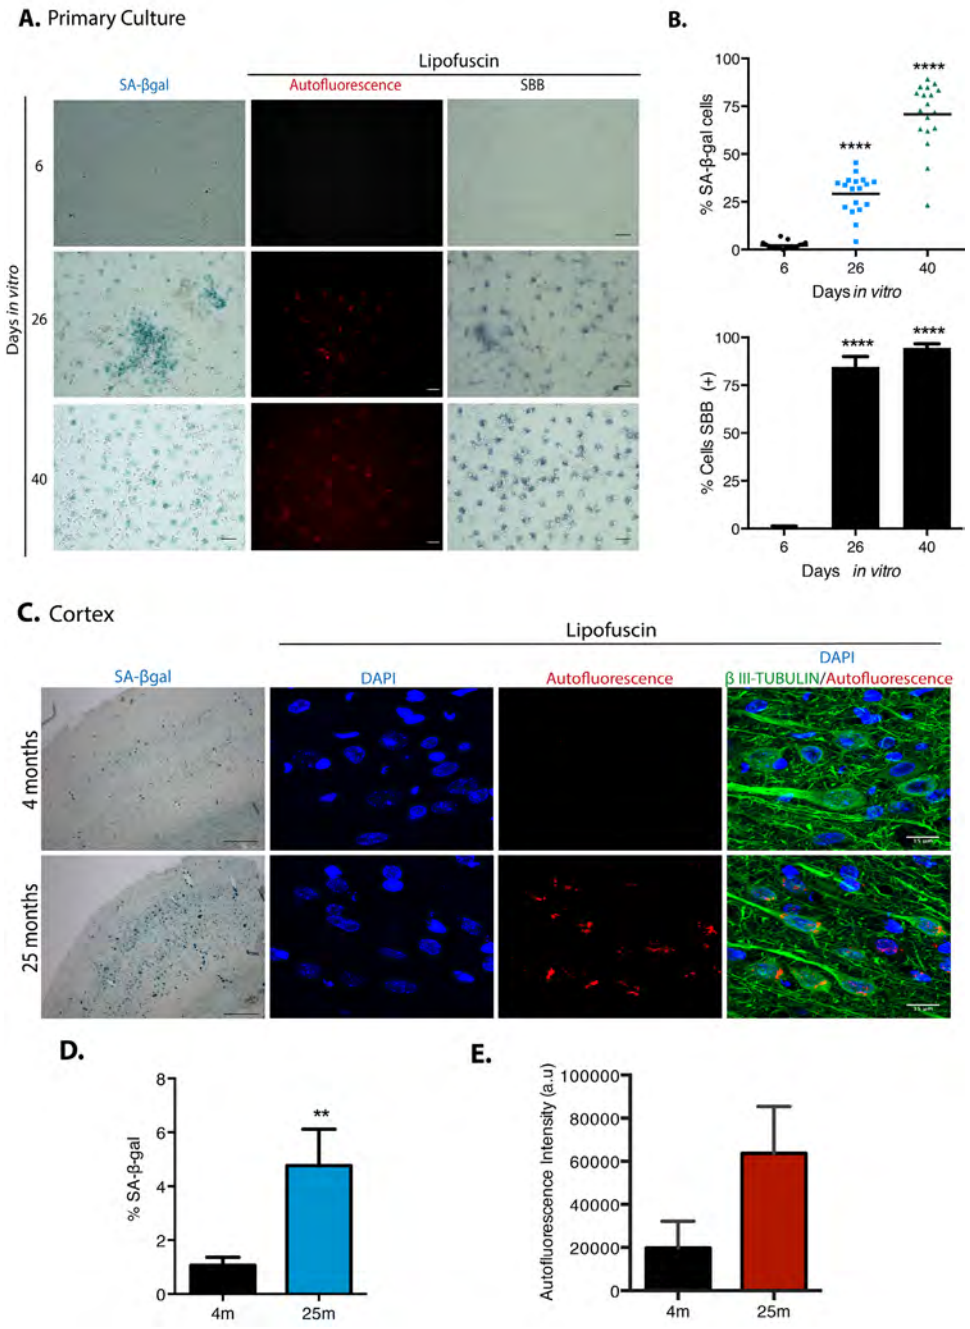

Figure 1. Cortical cells in long-term culture and in old rat brains had higher SA-β-gal activity and accumulated lipofuscin. (**A**) SA-β-gal activity or lipofuscin accumulation detected by autofluorescence or by Sudan Black B (SBB) staining were detected in primary rat cortical cells cultured for the indicated D*IV*. Notice that cortical cells have higher SA-β-gal activity and lipofuscin from 26 D*IV*. Images are representative of at least three independent experiments. Scales bar represent 100 μm. (**B**) Percentage of SA-β-gal or SBB positive cells in the cultures incubated at the indicated D*IV*. Quantification was made using NIS Elements software. The mean of three independent experiments, each done by quintupled replicas, is graphed. Bars in graphs represent SEM. Two-way RM ANOVA analysis, with Dunnett´s multiple comparison test. **** p< 0.0001 in comparison with 6 D*IV*. (**C**) Cortical neurons in old brains had higher SA-β-gal activity (scale bars represent 500 μm) and accumulated lipofuscin. Scale bar represents 15 μm. (**D**) The percentage of SA-β-gal positive area within each brain section is plot. The average of three brains per age is graphed; 15 sections from each brain were quantified. notion that neurons become senescent before glial cells in this model. Since every senescent feature, alone, is not sufficient to confirm a senescent state, we simultaneously detected SA-β-gal activity and Lamin-A/C in neurons. As shown in Figure 4B, around half of the neurons with high SA-β-gal activity at 26 D*IV* also had an aberrant nuclear morphology, supporting the notion that neurons in long-term culture acquire senescent features. The observation that some neurons with high SA-β-gal show a normal nuclear morphology, is in agreement with previous observation that SA-β-gal activity alone is not a reliable marker of senescence [21]. We propose that nuclear deformations could be a more reliable marker for neuronal senescence. Since differentiated neurons express low levels of Lamin-B1 [27], we were unable to detect loss of Lamin-B1 in senescent neurons.

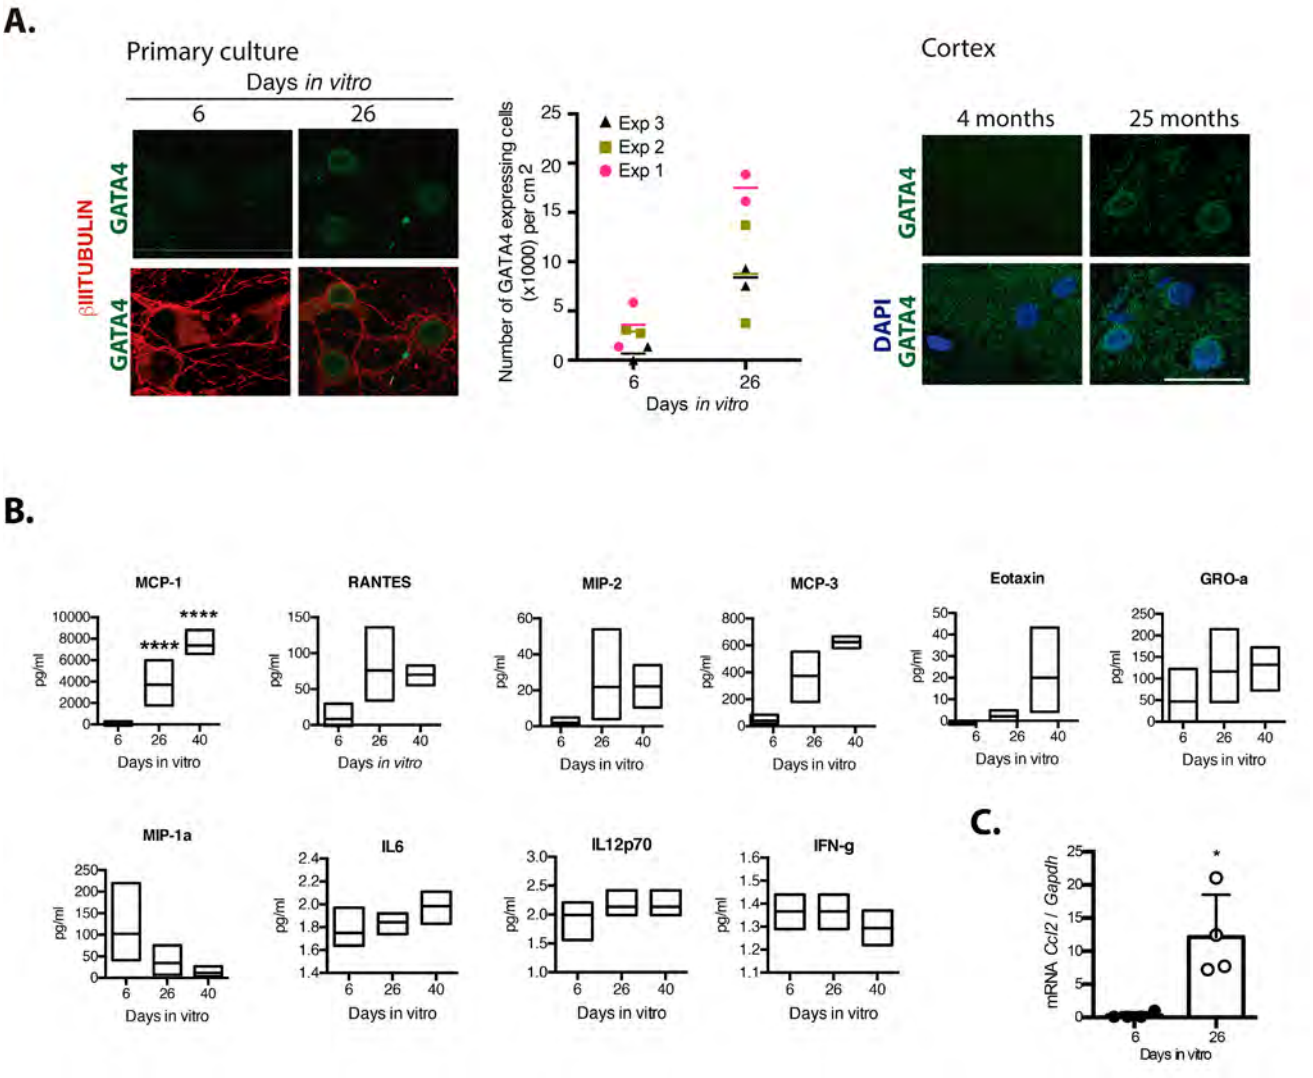

Figure 5. Senescent neurons increased the expression of GATA4 and cortical cells secreted MCP-1. (**A**) Immunofluorescence to detect GATA4 in neurons (expressing βIII-TUBULIN) in primary culture of cortical cells either incubated during the indicated days *in vitro* or in rat brains of the indicated age. Scale bars represent 25 μm. The number of cells with increased GATA4 abundance from three independent experiments, each performed in duplicate, is graphed. Bars represent SD. * p=0.0106 by unpaired t test two tailed. n=4.

Senescent cortical cells secrete molecules that induce premature paracrine senescence and glial proliferation, suggesting a neuronal SASP

We hypothesize that persistent senescent neurons, through the SASP, contribute to induce paracrine senescence and chronic inflammation in old brains. Therefore, we studied whether neurons would express GATA4, a transcription factor that promotes the expression of SASP factors [10]. As shown in Figure 5A, GATA4 accumulated in neuronal cells cultured for 26 D*IV*, as well in cortical neurons from old brains. To get an insight about the cytokines that senescent cortical cells could be secreting, we analyzed the presence of G-CSF, GM-CSF, IFNγ, IL-1α, IL-1β, IL-10, IL-12p70, IL-13, IL-17A, IL-2, IL-4, IL-5, IL-6, TNFα, EOTAXIN, GRO-α, IP-10, MCP-1, MCP-3, MIP-1α, MIP-2 and RANTES by a multiplex immunoassay. As shown in Figure 5B, MCP-1, RANTES, MIP-2, GRO-1, MCP-3 and EOTAXIN were more abundant in conditioned media from senescent cortical cultures, although only MCP-1 content showed a statistically significant difference at 26 and 40 D*IV* relative to 6 D*IV* cortical cultures; MIP-1a secretion was reduced in older cultures. To our surprise, IL6, a common SASP component, was barely detected and did not increase in conditioned media from senescent cells. Also, IL-12p70 and IFNγ secretion did not change along the time in culture and were secreted in a very small amount, at the threshold limit of detection. G-CSF, GM-CSF, IL-1α, IL-1β, IL-10, IL-13, IL-17A, IL-2, IL-4, IL-5, TNFα, GRO-α, IP-10 and MIP-1α were not detected at any time point. We further confirmed the induction of expression of *Ccl2* (gen coding for MCP-1) by qRT-PCR (Figre 5C).

Since MCP-1 has been shown to induce paracrine senescence [23], and GATA 4 is a mediator regulating MCP-1 expression during senescence induced by Lamin-A defects [28], we reasoned that senescent cortical cells could indeed acquire a functional SASP. To test this hypothesis, we analyzed whether conditioned media from senescent cortical cells could induce premature paracrine senescence (a schematic experimental design is shown in Figure 6A). To obtain conditioned media with accumulated secreted factors, the media was left for intervals of about a week in between fresh media changes over the cells, and it was collected at 6, 26 or 40 days of culture. Conditioned media was then added to young (1 D*IV*) prenatal cortical cells and after 6 D*IV* of treatment all the senescent markers described above were evaluated. Interestingly, conditioned media from cortical cells cultured for 26 D*IV* or 40 D*IV* induced abundant proliferation of glial cells (Figure 6B), suggesting that senescent cortical cells, potentially neurons, could indeed affect tissue organization. Nevertheless, we did not observe significant expression of senescent markers on young neurons (not shown). We reasoned that young neurons could be more resistant to paracrine senescence than mitotic cells; therefore, we tested whether the conditioned media from cortical cells cultured for 26 D*IV*, time at which most of the senescent cells are neurons, would induce paracrine senescence in mouse embryonic fibroblast (MEFs). Indeed, conditioned media from cortical cells cultured for 26 D*IV* induced key senescent features in MEFs, such as increased SA-β-gal activity; inhibition of proliferation (detected by Ki67 expression); DNA damage response identified by γH2AX foci; and increased expression of IL6, although this latter was not statistical different (Figure 6C). In summary, prenatal cortical cells exposed for 6 days to conditioned media from cortical cells cultured for 26 D*IV* or 40 D*IV* did not show senescent features, whereas MEFs did.

Taken together, our results confirm that neurons acquire senescent features potentially including the SASP, interestingly before glial cells. This observation suggests that senescent neurons could affect the function of surrounding cells, such as astrocytes. Intriguingly, young neurons were unresponsive to the SASP produced by senescent cortical cells, since they did not show senescent markers when exposed to the conditioned media from cortical cultures of 26 or 40 *DIV* (not shown).

Dysfunctional autophagy contributes to neuronal senescence

Abundant reports indicate that dysfunctional autophagy accompanies aging, and in the brain it causes neurodegeneration [29]. Accordingly, induction of autophagy ameliorates age-related cognition deficits [30]. Therefore, we evaluated whether dysfunctional autophagy would contribute to neuronal senescence establishment, with a similar mechanism as described for senescence transition of mitotic cells. First, we analyzed in senescent neurons whether autophagic flux is reduced, reflected by accumulation of autophagosomes and proteins associated to them like LC3 and p62/SQSTM1. As shown in Figure 7A, cortical cells at 26 D*IV*, a time point when neurons showed senescent features, had more autophagosomes detected with the specific dye CytoID® and by immunofluorescent detection of LC3. We confirmed the abundance of autophagosomes in senescent neurons by electron microscopy, labeling them with immunogold localization of LC3. As the autophagic receptor p62/SQSTM1 is degraded together with the cargo, it accumulates when the autophagic flux is interrupted. We analyzed the abundance of p62/SQSTM1 by

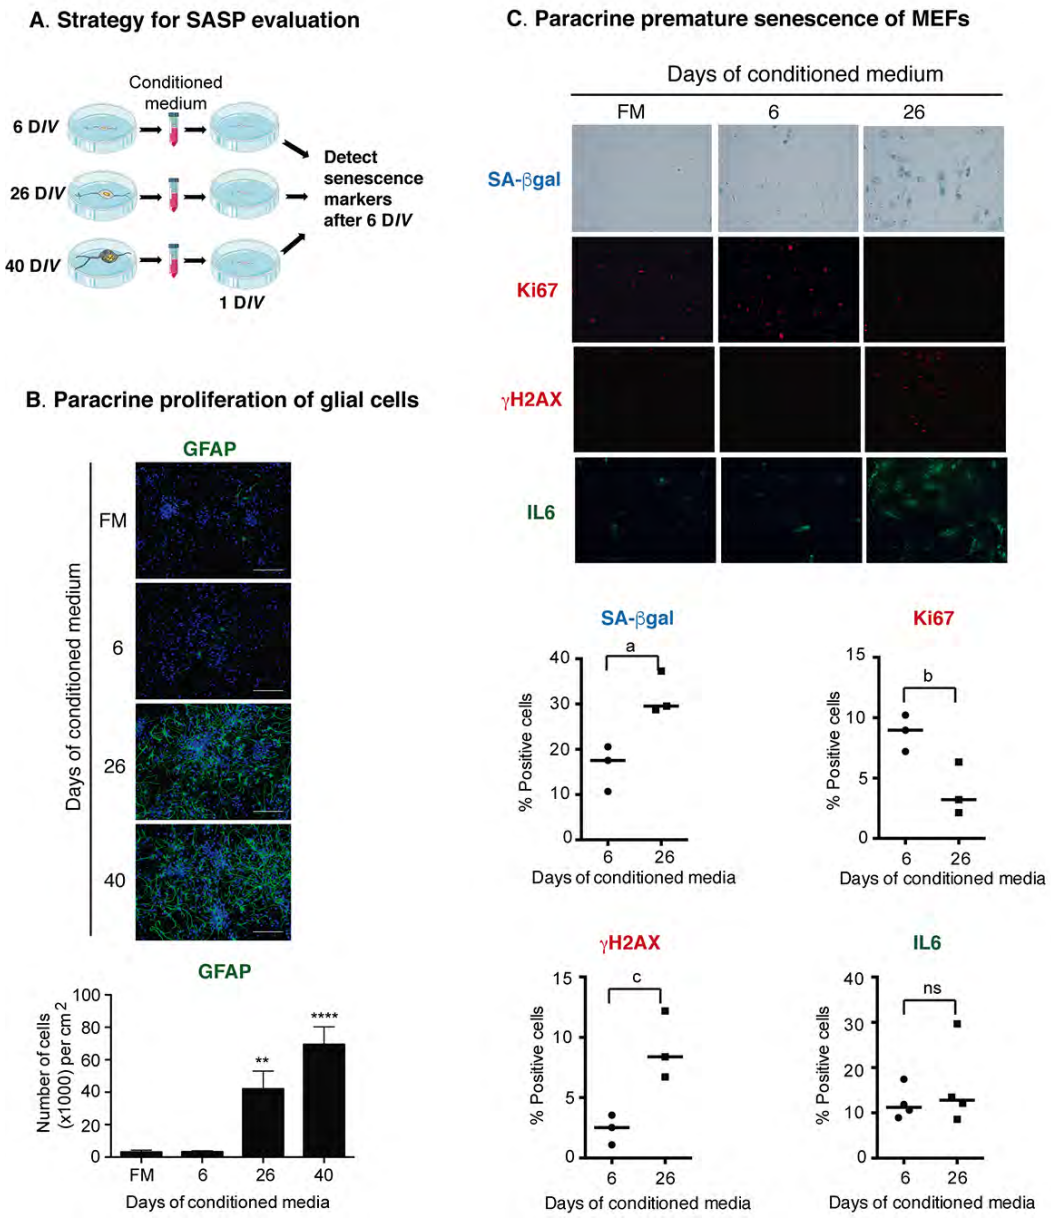

Figure 6. Senescent cortical cells develop a functional SASP. (**A**) Experimental design to evaluate the presence of secreted molecules with SASP activity from senescent cortical cells. Conditioned media was collected from cortical cells that had been incubated from 1-6 (6), 19-26 (26) or 32-40 (40) D*IV*. Either primary prenatal cortical cells or MEFs were cultured for 24 hr (1 D*IV)* before adding conditioned media; senescence markers were evaluated 6 days later. (**B**) Conditioned media from senescent cortical cells induced paracrine proliferation of glial cells in primary culture of prenatal cortical cells. Representative immunofluorescences to detect GFAP in cortical cells are shown. Cells were incubated with conditioned media collected from cortical cells that had been incubated during the indicated D*IV*. FM stands for fresh medium. Notice that conditioned media from 26 D*IV* and 40 D*IV* induced high proliferation of glial cells. Scale bars represent 500 μm. The bottom graph is a quantification of the number of GFAP expressing cells in three independent experiments, each done in duplicate. Data were analyzed by one-way ANOVA, with Dunnett´s multiple comparison test. ** p<0.01; ****p<0.0001 compared to FM. (**C**) Conditioned media from senescent cortical cells induced paracrine premature senescence in MEFs. MEFs were incubated with conditioned media collected from cortical cells that had been incubated during the indicated D*IV*. FM stands for fresh medium. Notice that senescent markers were higher in cells incubated with conditioned media from cortical cells cultured for 26 days. The bottom graphs are quantifications of the percentage of cells with blue or fluorescent signals. The signal (either blue or fluorescent) from cells incubated with 6 D*IV* conditioned media plus one standard deviation was deducted from the signal obtained from the cells treated with 26 D*IV* conditioned media. Three independent experiments, each performed in duplicate were quantified. Data were analyzed by unpaired T test. a, p=0.0175; b, p=.0.0327; c, p=0.0191.

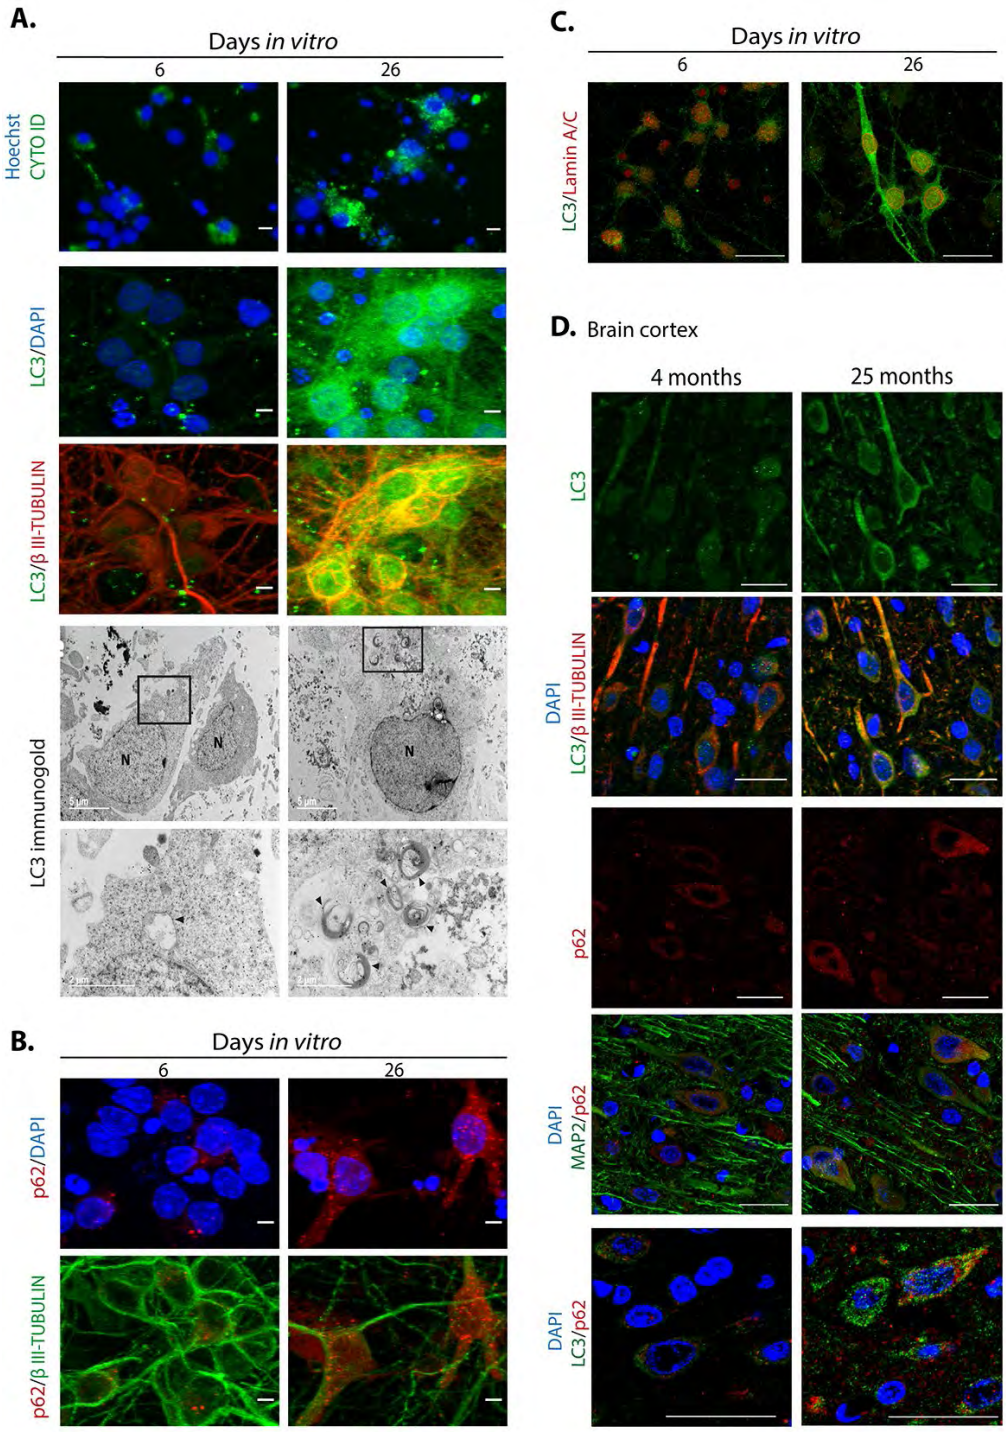

Figure 7. Autophagosomes accumulate during neuronal senescence. (**A**) Top row, autophagosomes were stained with CytoID® and nuclei with Hoechst in primary culture of cortical cells incubated during the indicated D*IV*; scale bars represent 15 μm. Middle rows, immunofluorescence to detect LC3 in neurons (expressing βIII-TUBULIN) of primary cortical cells cultivated during the indicated D*IV*. Scale bars represent 5 μm. Bottom rows, electron micrographs showing accumulation of autophagosomes in 26 D*IV* cortical cells, detected by immunogold localization of LC3 (arrow heads). Squares indicate the amplified area below. (**B**) Immunofluorescence to detect p62/SQSTM1 in cortical cells cultured during the indicated D*IV*. Nuclei were stained with DAPI. Notice that p62/SQSTM1 in neurons (expressing βIII-TUBULIN) accumulated at 26 D*IV*. Scale bars represent 5 μm. (**C**) Immunofluorescence to simultaneously detect LC3 and Lamin-A/C to observe intranuclear folds as a senescence marker, in cortical cells cultured during the indicated D*IV*. Scale bars represent 25 μm. (**D**) LC3 and p62/SQSTM1 also accumulate in cortical neurons (expressing βIII-TUBULIN or MAP2) form old rat brains. Scale bars represent 30 μm.

immunofluorescence (Figure 7B) and Western blot (Figure 8B), and we found that it was also accumulated in neurons at 26 D*IV*. To determine whether indeed senescent cells had more autophagosomes, we simultaneously detected LC3 and Lamin-A/C. As shown in Figure 7C, the same cells that had intranuclear folds of the nuclear envelop with Lamin-A/C at 26 D*IV* had LC3 accumulation (Figure 7C). Importantly, both LC3 and p62/SQSTM1 also accumulated in cortical neurons of old rat brains (Figure 7D). The accumulation of both autophagosomes and p62/SQSTM1 suggests dysfunctional lysosomes or impairment of the fusion of autophagosomes with lysosomes. We stained lysosomes with Lysotracker® and observed an accumulation of enlarged lysosomes in senescent cortical cells (Figure 8A), as it has been described in another model of neuronal senescence [21]. We confirmed altered lysosomal morphology by localizing the lysosomal protein LAMP1; we noticed that abundant p62/SQSTM1 puncta did not co-localize with LAMP1 at 26 D*IV* (Figure 8A), suggesting limited autolysosome maturation (*i.e.* reduced autophagosome-lysosome fusion), although further studies are needed to corroborate it.

p62/SQSTM1 accumulates when autophagy promotes the SASP through a compartmentalized structure coined TASCC (Tor-autophagy spatial coupling compartment),

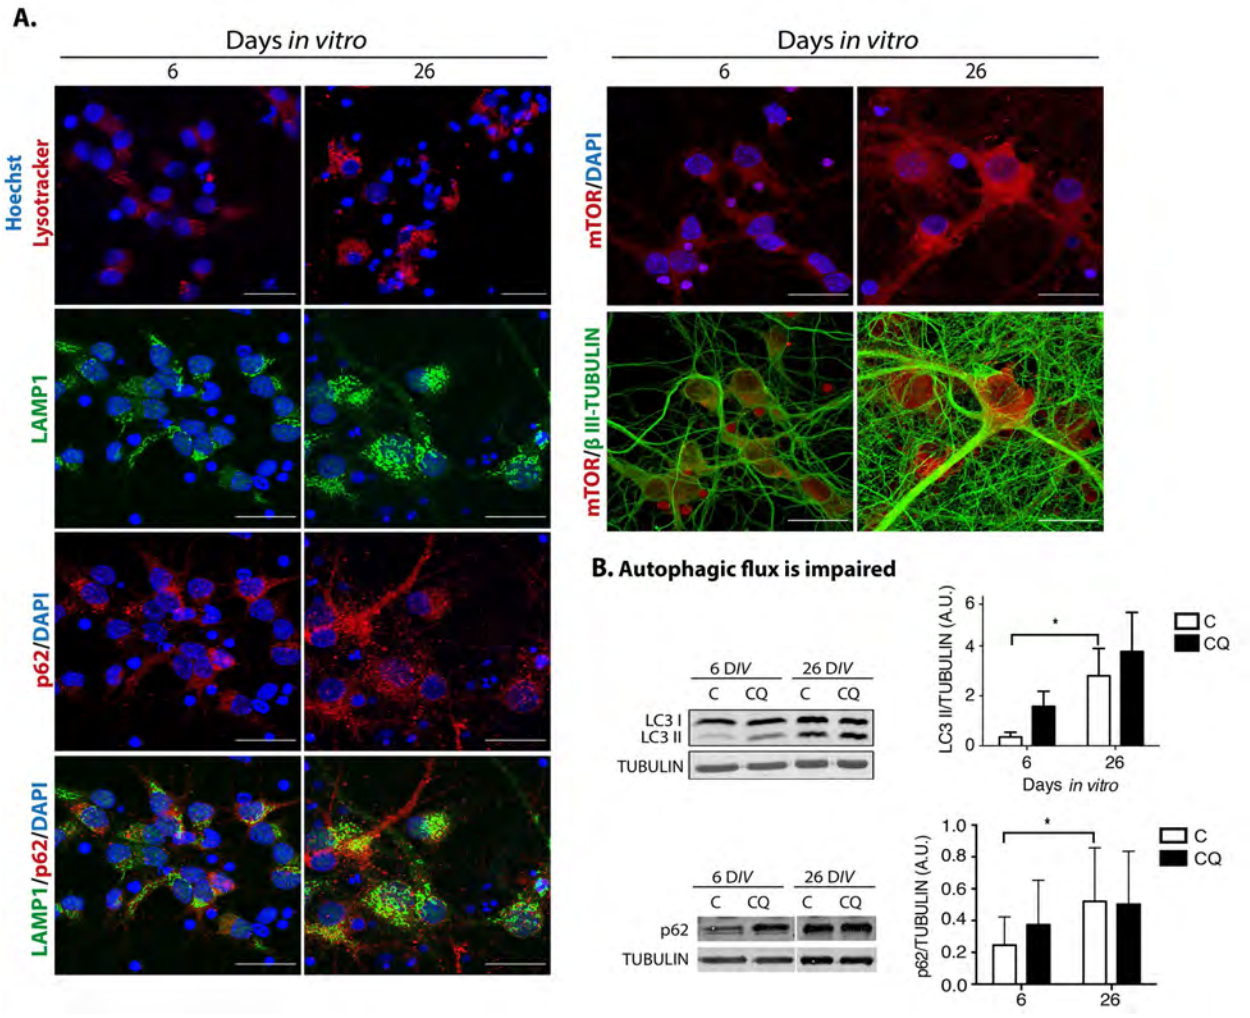

Figure 8. Dysfunctional autophagy contributes to neuronal senescence. (**A**) There was an accumulation of enlarged lysosomes and undigested p62/SQSTM1 in senescent neurons. Top row, lysosomes were detected with Lysotracker® and nuclei with Hoechst in primary culture of cortical cells incubated during the indicated D*IV*. Bottom rows, immunofluorescence to detect the indicated proteins in cortical cells cultured during 6 or 26 days. Nuclei were stained with DAPI. Notice that even though lysosomes and p62/SQSTM1 accumulated at 26 D*IV*, their intracellular distribution did not overlap. mTOR distribution did not change. Scale bars represent 25 μm. (**B**) The autophagic flux was impaired in senescent neurons. Western blot of total protein extracts from cortical cells cultured at 6 or 26 days, without (C) or with (CQ) 20 μM Chloroquine for 4 hr. Graphs represent the mean of densitometry analysis of four independent experiments. Bars represent SEM. Two-way RM ANOVA followed by Sidak´s multiple comparison test. *p<0.001.

which is where amino acids released by autolysosomes locally activate mTORC1, facilitating the synthesis of SASP proteins. The TASCC can be distinguished by the polarized co-localization of p62/SQSTM1, mTOR and LAMP2 [11]. Therefore, we analyzed whether during neuronal senescence these proteins were also distributed in a similar polarized intracellular localization (we observed LAMP1 instead of LAMP2). As can be seen in Figure 8A, neither the distribution of p62/SQSTM1 nor mTOR indicated a compartmentalized distribution. Even though lysosomes seemed to be mainly located on one side of the cells, it might reflect only the particular morphology of this type of cells, which have the cytoplasm mostly on one side of the cell. Therefore, we found no evidence of a TASCC during neuronal senescence, indicating that autophagy dysfunction, rather than function, accompanies neuronal senescence. To verify that the observed accumulation of autophagosomes was due to an impaired autophagic flux, instead of an enhanced activation of autophagy, cortical cells were incubated in the presence of Chloroquine, an agent that neutralizes lysosomes pH and impairs autophagosomes fusion with lysosomes. As shown in Figure 8B, the presence of Chloroquine did not increase the amount of LC3-II or p62/SQSTM1 accumulation at 26 D*IV*, indicating that the autophagic flux was already diminished in senescent neurons.

If a limited autophagic flux contributes to neuronal senescence, we would expect more senescent cells when autophagy is inhibited. Since basal autophagy is essential for survival, inhibition of autophagy by genetic means along the time of culture kills the neurons. Therefore, we inhibited autophagy only at distinct time windows (7 days long each) by adding Spautin-1, a molecule that indirectly induces BECN1 and PtdIns-3-kinase type 3/VPS34 (PI3KC3) degradation [31]. As shown in Figure 9B, we found that the number of cells with SA-β-gal activity increased when autophagy was inhibited during the second or third weeks of culture. When Spautin-1 was added at the fourth week of culture or later, it had no effect increasing the number of cells with SA-β-gal activity, suggesting that autophagy was already dysfunctional at this time. On the other hand, stimulating autophagy with trehalose, a disaccharide that mimics caloric restriction by preventing glucose uptake [32], reduced the number of cortical cells with SA-β-gal activity regardless of the time window of exposure, although a more noticeable protection was observed during the second and third weeks of culture. As a control to verify the function of Spautin-1 in neurons, we verified the reduction in the number of autophagosomes in cortical cells at 26 D*IV*, when we had previously observed abundant autophagosomes. We also tested that trehalose stimulates autophagy in neurons by detecting more autophagosomes in cortical cells at 6 D*IV*, which time we had observed neurons have a reduced amount of autophagosomes (Supplementary Figure 2S). To confirm that trehalose induction of autophagy indeed reduced the senescent phenotype and not just SA-β-gal activity, we repeated the experiment now immunodetecting Lamin-A/C to evaluate whether the intranuclear folds were reduced. As shown in Figure 9C, adding trehalose during one week windows statistical significantly reduced the degree of intranuclear Lamin-A/C folds. These results suggest that autophagy induction prevents senescence conversion and potentially reverts the senescent phenotype, although further experiments will be needed to address the latter.

DISCUSSION

Accumulating evidence shows the presence of senescent cells in brains from both physiologically aged subjects and with neurodegeneration [14]. In this work we have characterized an *in vitro* model useful to study the molecular basis for neuronal senescence transition and maintenance, as well as SASP components. We demonstrate that neurons, in spite of being post-mitotic cells, acquire multiple senescent features and notably they do so before glial cells. Every senescent marker we looked at in primary culture of senescent neurons was confirmed in old rat brains (25 months old), validating this *in vitro* neuronal senescence model. We demonstrated, to our knowledge for the first time, that senescent cortical cells develop a functional SASP, secreting components able to induced paracrine senescence in MEFs and glial proliferation. Since most of the senescent cells at 26 D*IV* are neurons, we suggest the existence of a neuronal SASP, although it is still possible that the few senescent astrocytes present in the culture secrete a very potent SASP. Nevertheless, a neuronal SASP is supported by other observations, such as the induction of expression of pro-inflammatory cytokines like TNF-α and CCL2 [33]. Interestingly, dopaminergic neurons with senescent phenotype due to lack of expression of SATB1, a DNA binding protein reduced in the vulnerable region of Parkinson´s Disease patients, express several SASP components, including MCP-1 [34], the cytokine we found significantly secreted by senescent cortical cells. MCP-1 is also secreted by senescent human mesenchymal stem cells and induces paracrine senescence; according to our findings, MCP-1 expression is mediated by GATA4 [28], a transcription factor we found increased in senescent cortical neurons. Further experiments are necessary to demonstrate that indeed MCP-1 secreted by senescent cortical neurons is the molecule responsible for the induction of paracrine senescence in MEFs. To our surprise, we did no detect secretions of IL6, as it is a very common SASP component and has

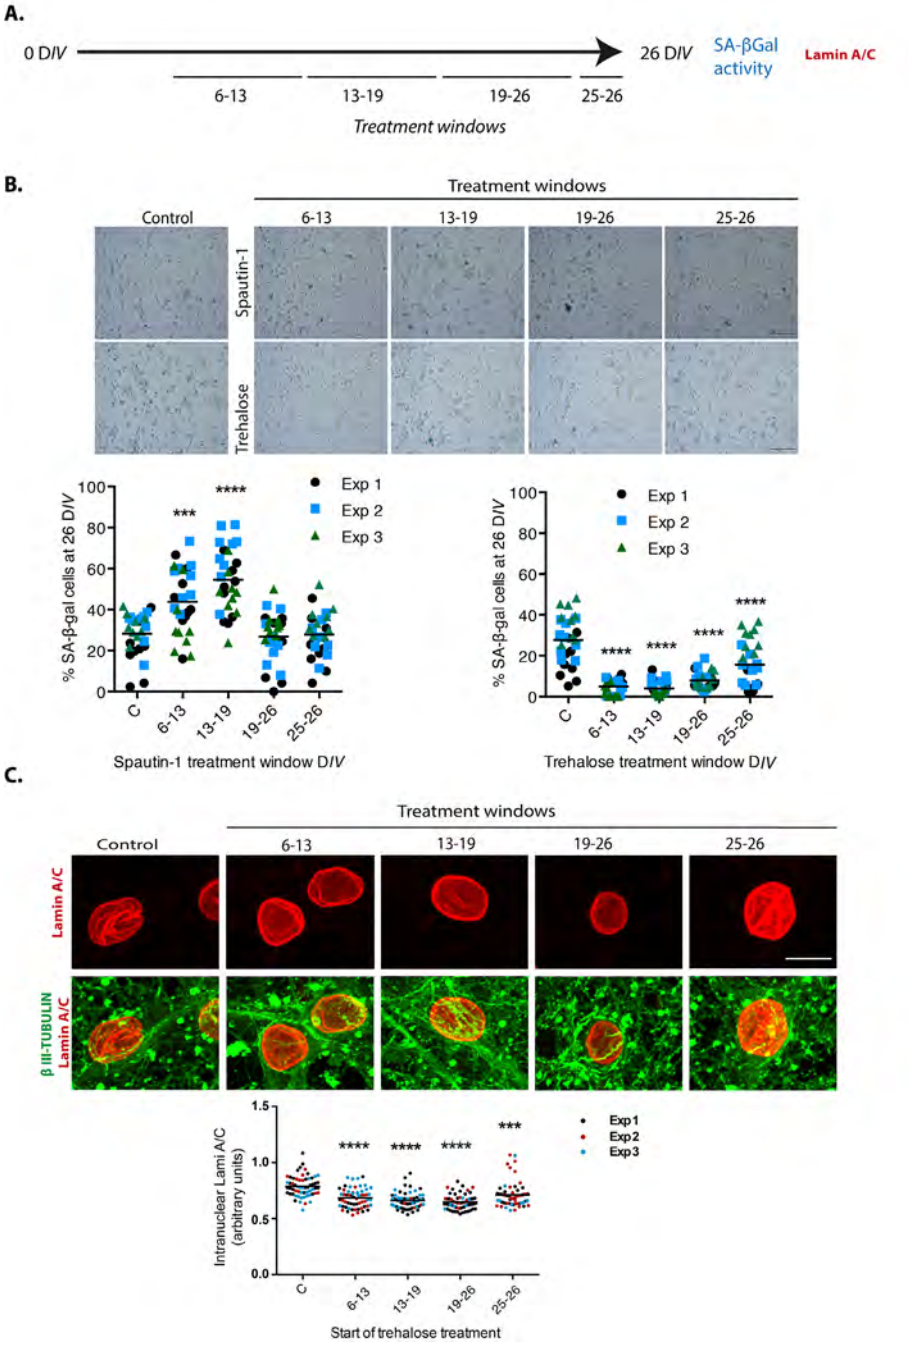

Figure 9. Autophagy modulation alters cortical cells senescence. (**A**) Experimental design. (**B**) Early inhibition of autophagy with Spautin1 increased the number of cells with SA-β-gal activity, while early induction of autophagy by adding trehalose reduced them. Spautin1 or trehalose were added during periods of several days, at the indicated time intervals in days of culture (D*IV*); after 26 D*IV* all cultures (including control with no treatment) were fixed to quantify the percentage of cells showing high SA-β-gal activity. Scale bars represent 500 μm. The bars in graphs represent the mean of each independent experiment, each done by triplicates. Three fields from each replica were scored (9 fields per experiment), each dot represent the percentage of SA-β-gal positive cells per field. Data were analyzed by two-way RM ANOVA, followed by Dunnett´s multiple comparison test. ***p<0.001 Spautin1 added during 6-13 D*IV* in comparison with control; **** p< 0.0001 Spautin1 added during 13-19 D*IV* in comparison with control, and Trehalose treatments in comparison with control. (**C**) Autophagy induction with trehalose reduced the abundance of intranuclear fold with Lamin-A/C. Trehalose were added during periods of several days, at the indicated time intervals in days of culture (D*IV*); after 26 D*IV* all cultures (including control with no treatment) were fixed to detect Lamin-A/C by immunofluorescence. Scale bar represents 5 μm. Representative images of three independent experiments are shown. At least 60 cells per treatment were quantified as described in Methods. Bars in the bottom graph represents mean. Data were analyzed by two-way RM ANOVA, followed by Dunnett´s multiple comparison test. ***p<0.001; **** p< 0.0001 with respect to control.

been found to be secreted in senescent neurons by others [22]. It is worth to note that the paracrine senescence signaling components seem to be conserved between rat and mouse, as the rat neuronal SASP was able to induce premature paracrine senescence in mouse fibroblasts (MEFs).

The finding that conditioned media from senescent cortical cells induced glial cell proliferation, suggests that persistent neuronal senescent cells could alter tissue organization. As opposed to replicative senescence, which is caused by critically short telomeres, premature senescence induced by oncogene activation initiates with hyper-proliferation, followed by a "transition phase" that signals to induce the senescent phenotype [35]. Further experiments are in progress to evaluate whether the increased proliferation of astrocytes we observed reflects a mitotic phase preceding senescence in response to the cortical SASP. Also, the finding that young neurons are resistant to undergo premature paracrine senescence in response to the SASP produced by senescent cortical cells deserves further investigation. It will be interesting to understand the molecular differences that render MEFs susceptible and prenatal cortical neurons resistant to paracrine senescence in response to the cortical SASP. Although we ought to mention that we observed in one out of six experiments an increase of young neurons with high SA-β–gal activity in response to conditioned media from senescent neurons, therefore, it is yet possible that senescent cortical cell secretes molecules able to induce neuronal paracrine senescence, but which are rather labile. We propose that persistent senescent cells in the brain would secrete molecules that induce chronic inflammation and propagate further paracrine senescence to nearby healthy cells within the brain, like astrocytes, microglia or endothelial cells, thereby spreading the senescent phenotype and thus contributing to brain aging and exacerbating neurodegeneration. In fact, chronic and low-grade inflammation (inflammaging) have been associated with neurodegeneration in aging [36, 37] and cellular senescence markers have been observed in brain tissues from Alzheimer's disease patients, such as $p16^{INK4A}$ expression, increased p38MAPK activity, and IL6 and TGFβ mRNA expression [38-41]. Actually, brain overexpression of IL6 in mice induces neurodegeneration [42]. Promising, two recent works demonstrate that eliminating senescent cells in the brain ameliorate Tau-dependent neuropathology in mice transgenic models. Bussian TJ, *et al.* did not find neurons with senescent features (looking for SA-β-gal activity and the mRNA expression of *p16*, *p19*, *p21*, *pai1* and *Il6* in an enriched population of cells expressing Cd56), and propose that senescent microglia and astrocytes induce Tau-containing neurofibrillary tangles (NFT) in neurons by an unknown mechanism [43]. Interestingly, Musi N *et al.* analyzed laser-captured microdissected cortical neurons from human brains with Alzheimer disease and compared their transcriptome signature with adjacent histopathologically normal neurons. NFT-containing neurons had a senescent gene expression profile. The same was observed in NFT-containing neurons in a Tau transgenic mouse line [44]. Therefore, it seems that all cell types in the brain are able to become senescent, but the timing of geroconversion could vary in different contexts. Since in both works senolytics ameliorated Tau-dependent neuropathology, to discover which cell type becomes senescent and how similar are senescent cells from different cell types, will be useful to design targeted therapies.

Considering that it has been widely documented that during aging autophagy becomes dysfunctional [45], that most of the interventions that improve health span and/or lifespan stimulate autophagy [46, 47], and our finding that Spautin-1 treatment increased the number of senescent cortical cells, we propose that dysfunctional autophagy during aging also contributes to cellular senescence in the brain, including neurons, which in turn contributes to synaptic dysfunction. It is fundamental, therefore, to understand the mechanisms of autophagy dysfunction with ageing in the brain. Perhaps the tubular morphology of lysosomes we observed in senescent cortical neurons interferes with lysosomes fusion with autophagosomes. Therefore, treatments that promote autolysosome maturation or prevent lysosomal dysfunction could solve or prevent the onset of neuronal senescence. Interestingly, our observation that trehalose reduced the number of senescent cortical cells suggests that the neuronal senescent phenotype is reversible. Supporting this notion, addition of resveratrol, an autophagy-inducer compound, also decreases senescent hallmarks of long-term neuroglial cocultures [22]. Further experiments are necessary to test the possible reversion of the neuronal senescent phenotype.

Having a molecular understanding of neuronal senescence, new targets for pharmacological intervention could be proposed, with potential impact to prevent or reduce both physiological brain aging and neurodegeneration.

MATERIALS AND METHODS

Animals

Wistar rats of the indicated age in each experiment were obtained from the animal house of the Institute of Cell Physiology at the National University of Mexico (UNAM) and were housed at 22 ^{0}C in 12h light/12h

dark cycle. All procedures were approved by the Internal Committee of Care and Use of Laboratory Animals of the Institute (IFC-SCO51-18). Rats had *ad libitum* access to water and food.

Cell Culture

Cortical primary cultures

Cortical primary cultures were prepared as described before [48], from Wistar rat embryos of 17 days of gestation. Cerebral cortices were isolated and dissociated by 1:1400 Trypsin-EDTA (15400054, INVITROGEN/GIBCO, Grand Island, NY, USA) digestion and trituration with a Pasteur pipette. Cells were suspended in Neurobasal medium (21103049, INVITROGEN/GIBCO, Grand Island, NY, USA) supplemented with 2% B27 (17504044, INVITROGEN/GIBCO, Grand Island, NY, USA), 200 mM GlutaMAX™ Supplement (35050061, GIBCO Life Technologies, Grand Island, NY, USA) and 0.02 mg/ml Gentamicin (15710064, INVITROGEN/GIBCO, Grand Island, NY, USA). Cells were plated at a density of 1.05 x 10^5/cm^2 in 12-well plates precoated with Poly-L-Lysine (P1524, SIGMA-ALDRICH St. Louis, MO, USA) (0.01 mg/ml). Cells were cultured up to 40 days *in vitro* (40 DIV) at 37ºC in a humidified, 5% CO_2 atmosphere. Half the medium was changed every 6 days.

Cell viability

Cell viability was estimated by staining with LIVE/DEAD viability/cytotoxicity kit (INVITROGEN/GIBCO, Grand Island, NY, USA). Alive cells were stained with Calcein, while dead cells were stained with Ethidium homodimer-1, following manufacturer´s instructions. For every experiment, only cells with healthy nuclear morphology (non apoptotic) were quantified.

MEFs culture

Mouse embryonic fibroblasts were isolated from CD1 mouse embryos at E13.5 following the standard protocol [49]. MEFs were seeded at a density of 2.6x10^3 cells/cm^2 with Dulbecco´s Modified Eagle Medium + GlutaMAX™, 10% FBS and Penicillin/Streptomycin 100 U/ml. Each experiment was performed with MEFs at cell passage 4 to avoid replicative senescence. For conditioned media experiments, one day after seeding, cells were cultured with 25% OptiMEM supplemented with GlutaMAX and 75% of conditioned media. Media and supplements were from GIBCO® Life Technologies™, Grand Island, NY, USA.

SA–β-galactosidase staining

The β-galactosidase activity was analyzed following the protocols described previously [50, 51]. Cells were fixed with 2% formaldehyde + 0.2% glutaraldehyde for 5 min, washed with PBS and stained with the staining solution containing: 20 mg/ml of X-gal (IB02260, IBI SCIENTIFIC, Peosta, IA, USA) in dimethylformamide, 0.2 M citric acid/sodium phosphate buffer pH=6, 100 mM potassium ferrocyanide, 5 M sodium chloride and 1 M magnesium chloride. Cells were incubated for 16 h at 37 °C. For colorimetric analysis, samples were observed in an inverted Nikon ECLIPSE Ti-U microscope, the number of positive cells was counted of at least 500 cells. For SA–β-galactosidase staining and immunofluorescence in the same samples, cells were stained for SA-β-gal as described above and then immunostained. Confocal detection of X-gal was performed as previously described [52].

Lipofuscin accumulation

Autofluorescence Detection

Lipofuscin auto-fluorescence was evidenced by excitation at 450-490 nm of unstained cortical cells using an inverted Nikon ECLIPSE Ti-U microscope.

Sudan Black B (SBB) staining

SBB staining was performed as described [24]. 0.7 g of SBB (199664, SIGMA-ALDRICH, St. Louis, MO, USA) were dissolved in 70% ethanol, covered with Parafilm® and thoroughly stirred overnight at room temperature. Afterwards the solution was filtered (paper filter Whatman™ 1001-110). Cells seeded on coverslips were fixed in 4% (wt/vol) formaldehyde/PBS for 30 min at room temperature and then washed three times at room temperature with PBS. Coverslips with fixed cells were incubated for 2 min in 70% ethanol. A drop of freshly prepared SBB was dropped on a clean slide. The coverslip with the cells was held facing down on the drop of SBB on the slide and was incubated for 10 seconds. The coverslip was carefully lifted and the SBB on the edges of the coverslip was wiped off manually from the back and along the edges of the coverslip with the help of an absorbent paper. The cells were then embedded into 50% ethanol for 1 min, transferred and washed with distilled water. The staining was observed under an inverted Nikon ECLIPSE Ti-U microscope and SBB staining was considered positive when cytoplasmic aggregates of blue-black granules were evident inside the cells. Three independent experiments, each done by quintupled replicas, were analyzed.

Immunofluorescence

Primary culture

Cells were fixed with 4% paraformaldehyde for 30 min, permeabilized with PBS / 0.5% Triton for 5 min, blocked with PBS/5% BSA and incubated at 4 °C with primary antibody overnight. AlexaFluor-conjugated

secondary antibodies were diluted in PBS/2%BSA (1:500, LIFE TECHNOLOGIES, Oregon, USA) and incubated for 1 h at room temperature. Nuclei were stained for 2 min with DAPI (1 μg/ml). Only cells with healthy nuclear morphology (non-apoptotic) were quantified.

Brain section

Wistar rat male brains 4 or 25 months old were isolated following IACUC guidelines. Rats were perfused transcardially with PBS, then with 4% paraformaldehyde. Brains were drop-fixed in 4% paraformaldehyde for 24h; for cryoprotection brains were immersed in PBS/30% sucrose for 24 h. Brain coronal sections (50 μm) from frontal cortex were mounted serially. The sections were permeabilized with PBS/ 0.3% Triton for 15 min, blocked with PBS/5% BSA for 1 hour at room temperature and incubated with primary antibody at 4 °C overnight in PBS/1% BSA. Next, sections were incubated with AlexaFluor-conjugated secondary antibodies (1:350, LIFE TECHNOLOGIES, Oregon, USA) in PBS / 2% BSA 1 h at room temperature; nuclei were stained with DAPI (1 μg/ml). To avoid lipofuscin autofluorescence slices were incubated with Sudan Black B.

The following primary antibodies were used: mouse anti class III β-TUBULIN (1:1000, ABCAM 14545, Cambridge, MA, USA), rabbit anti class III β-TUBULIN (1:1000, ABCAM 18207, Cambridge, MA, USA), rabbit anti- class III β-TUBULIN (1:500, BIOLEGEND, MRB435P-100, San Diego, CA, USA), rabbit anti-GFAP (1:1000, DAKO Z0334, Santa Clara, CA, USA), rat anti-GFAP (1:1000, INVITROGEN 13-0300, Camarillo, CA, USA), rabbit anti-p21 (1:25, ABCAM 7960 or 1:100 ABCAM 109199, Cambridge, MA, USA), mouse anti-γH2AX (1:500, ABCAM 26350, Cambridge, MA, USA), rabbit anti-LC3 (1:500, MBL PD014, Nagoya, Japan), mouse anti-p62 (1:300, ABCAM 56416, Cambridge, MA, USA), rabbit anti-LAMP1 (1:1000, SIGMA-ALDRICH L1418, St. Louis, MO, USA), rabbit anti-mTOR (1:200, CELL SIGNALING 2983, Beverly, MA, USA), rabbit anti-GATA4 (1:500, ABCAM 84593, Cambridge, MA, USA).

Images were acquired using a NIKON ECLIPSE Ti-U microscope or a confocal microscope Zeiss LSM 800. Images were processed using NIS Elements, Basic Research (NIKON INSTRUMENTS Inc ®, NY, USA) software, Version 3.13 or Fiji software.

Immunoelectron microscopy

Cortical cells were fixed with 3% glutaraldehyde. Following fixation, dehydration was performed in an ethanol gradient: 30-40-50-60-70-80-90-100 % ethanol at 4°C. Then, the cells were embedded in a LR White resin and polymerization was carried out at 50 °C. Ultrathin sections of 70-80 nm were cut from the polymer using an Ultracut-Recheirt-Jung and placed on nickel grids for immunogold assay.

The thin sections were washed twice for 2 min with deionized water and two times with PBS with 0.005 % Tween20. Sections were then incubated for 30 min with the blocking solution (50 mM glycine, 0.005 % Tween20, 0.01 % Triton X-100 and 0.1 % BSA in PBS) [53]. After blocking, sections were incubated with the primary antibody: rabbit anti-LC3 (1:500, MBL PD014, Nagoya, Japan). After rinsing three times in PBS with 0.005 % Tween20, the sections were incubated overnight at 4 °C with the secondary antibody: donkey anti-rabbit 25-nm gold conjugate (Electron Microscopy Science Aurion #25708). Samples were washed three times with PBS, 0.005 % Tween20 and post-fixed in 2 % glutaraldehyde in PBS for 10 min. The sections were then rinsed with distilled water twice for 5 min and contrasted with 2 % uranyl acetate, rinsed with water, dried and observed under a JEOL JEM 1200 EXII electron microscope.

Immunoblotting analysis

Cells grown in the presence or absence of 20 □M Chloroquine (C-6628 SIGMA-ALDRICH, St. Louis, MO, USA) for 4 hrs were lysed in an extraction buffer consisting of 25 mM Tris, 50 mM NaCl, 2% Igepal, 0.2% SDS and 2 mg/ml protease inhibitor 18 (Complete, Roche Molecular Diagnostics, pH 7.4). Thirty micrograms of total protein were separated by SDS-PAGE and electroblotted onto polyvinylidene fluoride (PVDF-FL) membranes (Millipore). Membranes were incubated overnight with the primary antibody at 4 °C, rabbit anti-LC3 (1:1000, MBL PD014, Nagoya, Japan), rabbit anti-p62 (1:500, CELL SIGNALING 5114S, Beverly, MA, USA), mouse anti-TUBULIN (1:10000, CELL SIGNALING 3873, Beverly, MA, USA). Following three washes with TTBS secondary antibody IRDye® 680RD goat anti-rabbit (925-68071, LI-COR) or IRDye® 800CW goat anti-mouse (925-32210, LI-COR) was applied at 1:10,000 dilution in TTBS. Membranes were scanned and analyzed using an Odyssey® IR scanner and Odyssey® Image Studio software 5.2.5.

Gene expression analysis

Total RNA was isolated using TRIzol™ reagent (Life Technologies), and cDNA was synthesized from 1 μg of RNA using the High Capacity cDNA Reverse Transcription Kit (Thermo Fisher Scientific #4368814).

The quantitative PCR (qPCR) reaction was performed with the SYBR Green mix (Kapa SYBR® Fast Universal #KK4602) in the Rotor-Gene Qthermocycler (Qiagene, Germantown, MD, USA). All reactions were performed in quadruplicate, and the expression was normalized using the glyceraldehyde-3-phosphate dehydrogenase (*Gapdh*) mRNA. The sequences of the primers used are as follows:

Cdkn1a F 5′-CCGAGAACGGTGGAACTTTGAC-3′;
Cdkn1a R 5′-GAACACGCTCCCAGACGTAGTTG-3′
Ccl2 (*Mcp-1*) F, 5′- ATGCAGTTAATGCCCCACTC;
Ccl2 (*Mcp-1*) R, 5′-TTCCTTATTGGGGTCAGCAC-3′
Gapdh F, 5′-CTCATGACCACAGTCCATGC-3′
Gapdh R, 5′-TTCAGCTCTGGGATGACCTT-3′.

Neutral Comet assay

Cells were resuspended in cold PBS at 10^3 cells/µL density. This suspension was mixed at a 1:5 ratio with 0.75% low-melting point agarose (BIO RAD Certified™ Low Melt Agarose #1613111, Hercules, California, USA) at 37°C. About 50 to 100 µL of the mix were placed on microscope slides pre-coated with 1% normal-melting point agarose (BIO RAD Certified™ PCR Agarose #1613103, Hercules, California, USA), spread with coverslips and incubated at 4° C for 2 min and 10 min more at room temperature. The coverslips were removed and slides were covered with pre-chilled lysis solution (0.03 M EDTA, 1% SDS) for 60 min at 4°C. After that, slides were washed and covered with unwinding/electrophoresis buffer (Tris 60 mM, Acetic acid 90 mM, EDTA 2.5 mM, pH 9.0) for 60 min. Electrophoresis was performed at 25 V for 20 min. Immediately, slides were rinsed and incubated for 10 min in neutralization buffer (Tris-HCl 500 mM, pH 7.5) 3 times. Finally, DNA was stained with SYBR green (SYBR™ green I Nucleic Acid Gel Stain, INVITROGEN™, Eugene, Oregon, USA) 1:10000 in PBS. For each sample 50 comet images were measured, using a Nikon ECLIPSE Ti-U fluorescence microscope. The length and area of the broken DNA were measured with NIS Elements Basic Research software (NIKON INSTRUMENTS Inc ®, NY, USA)-

SASP analysis of cortical cells

Conditioned medium was collected from neuronal cultures at 6, 26 and 40 days *in vitro* (DIV) and was frozen at -20 °C until use. Concentrations (pg/mL) of G-CSF, GM-CSF, IFN gamma, IL-1α, IL-1β, IL-10, IL-12p70, IL-13, IL-17A, IL-2, IL-4, IL-5, IL-6, TNF alpha, Eotaxin, Gro α, IP-10, MCP-1, MCP-3, MIP-1α, MIP-2 and RANTES in media conditioned by cortical cells were measured by ProcartaPlex® Multiplex Immunoassay (BIO RAD # 171K1002M). The conditioned medium was previously concentrated using centrifugal filter units Amicon Ultracel-3 kDa (Millipore # UFC800324) and a total of 50 µL of concentrated conditioned medium were examined following manufacturer's instructions. Data were obtained in a Luminex Instrument and the analytes concentration was measured calibrating with a standard curve for each cytokine provided by the manufacturer.

Cyto-ID autophagosomes detection and Lysotracker staining

The Cyto-ID (ENZO LIFE SCIENCES ENZ-51031-K200, Farmingdale, NY, USA) is an 488 nm-excitable green fluorescent reagent that specifically accumulates in autophagic vesicles. Cells were incubated in Cyto-ID (1 µl Cyto-ID/1ml cell culture medium) for 30 minutes at 37 °C, 5 % CO_2 and washed prior to analysis. Lysotracker dye (DND-99 LIFE TECHNOLOGIES, Oregon, USA) was incubated for 20 min at 37ºC. Cells were analyzed by Fluorescence Nikon ECLIPSE Ti-U microscope.

Cortical cells-derived conditioned medium collection and treatment

Conditioned medium was prepared by collecting half the medium from neuronal cultures at 6, 26 and 40 days *in vitro* (DIV) and freezing it at -20^{0}C until use. Conditioned media were diluted 3:1 with fresh medium and added to cells at 1 D*IV* in 12-well plates ($4x10^5$ cortical neurons cells/well; $1x10^4$ MEFs/well). For MEFs, to avoid adding unknown factors from serum, conditioned media were diluted with OptiMEM (GIBCO Life Technologies, Grand Island, NY, USA). Cells were incubated further for 6 days at 37°C and 5 % CO_2. At the end of incubation, the senescent markers were analyzed.

Quantification

The quantifications of cells with a particular phenotype were done using NIS Elements, Basic Research (NIKON INSTRUMENTS Inc ®, NY, USA) Version 3.13 software or Fiji software. The size of the samples analyzed is indicated in every figure legend. We counted at least 100 cells in each graph shown. To quantify data that corresponds to nuclear Lamin A/C invagination (Figure 4), we exploited the observation that internal Lamin A/C invaginations increase the signal intensity of intranuclear Lamin A/C that would otherwise be in the nuclear envelope as follows: Z-Stacked maximum intensity confocal images were utilized. Border ROIs were manually selected with the brush selection tool of FIJI, the brush size corresponded to the pixel number length closest to 500 nm, roughly

the nuclear envelope size (i.e. 101.41 μm x 101.41 μm 1024 pixels x 1024 pixels images required a brush of pixel size 5 and 1437 pixels x 1437 pixels images of the same metric size required a brush of pixel size 7). Border ROIs were selected manually including the most distal from the center of the nucleus signal of DAPI stained nuclei forming ring like ROIs. Central ROIs were selected to be exactly the internal part of the ring excluded from the border ROIs by using the clear outside function on the edit menu followed clicking on the internal part with the wand (tracing) tool of FIJI. The mean fluorescence intensity of these ROIs in Lamin A/C images was measured and the signal of the center was divided by the signal of the border so as to normalize for different Lamin A/C expression. Higher values correspond to more invagination.

Statistical Analysis.
All data were analyzed and graphed with Prism 6 (GraphPad Software Inc. La Jolla, CA, USA). Specific tests were performed according to each experimental design, and are indicated in each figure.

AUTHOR CONTRIBUTIONS

DMB carried out most of the experiments and participated in project design. EGS characterized neuronal senescence in the cortex of old rat brains; APA studied the paracrine premature senescence on MEFs; LAM and MK analyzed SASP components; GMH analyzed the double strand DNA brakes in senescent neurons; CGO performed lysotracker staining and contributed to autophagy analysis; LM contributed to experimental design and data analysis. SCO conceived the study and wrote the manuscript. All authors edited and approved the final manuscript.

ACKNOWLEDGMENTS

We are thankful to Dr. Beatriz Aguilar for her technical assistance. We acknowledge the support given by M.Sc. Ana Maria Escalante and Francisco Pérez at the IT Unit and Claudia Rivero at the Animal Facility. We are thankful to Dr. Ruth Rincón for confocal analysis assistance, to M.Sc. Rodolfo Paredes for electron microscopy imaging and to Dr. Abraham Rosas for both confocal analysis and electron microscopy imaging, all at the Imagenology Unit. Data in this work are part of the doctoral dissertation in the “Programa de Doctorado en Ciencias Bioquímicas” at the Universidad Nacional Autónoma de México (UNAM) of DMB and GMH, of the doctoral dissertation of EGS in the “Programa de Doctorado en Ciencias Biomédicas” at UNAM, and of the master dissertation in the “Programa de Maestría en Ciencias Bioquímicas” at UNAM of APA. All are recipients of fellowships from CONACyT.

CONFLICTS OF INTEREST

The authors declare no conflict of interest.

FUNDING

This project was supported by a grant from the Secretaria de Educación, Ciencia, Tecnología e Innovación de la Ciudad de México SECITI/042/2018 (INGER-DI-CRECITES-008-2018) "Red Colaborativa de Investigación Traslacional para el Envejecimiento Saludable de la Ciudad de México (RECITES)"; by CONACyT FC-921 and CB2013-220515; and by UNAM-PAPIIT IN206015-IN206518 to SCO. DMB received CONACyT doctoral fellowship 588372; GMH received CONACyT doctoral fellowship 417724; EGS received CONACyT doctoral fellowship 586932 and APA received CONACyT master fellowship 485243.

SUPPLEMENTARY MATERIAL

Supplementary Figures

Supplementary Figure 1S. Rat prenatal cortex primary culture is viable up to 40 days *in vitro* (D*IV*). (**A**) Representative immunofluorescence used to quantify neurons (βIII-TUBULIN) and glial cells (GFAP) at 6, 26 or 40 D*IV* as indicated. Nuclei were stained with DAPI. Scale bars represent 25 µm. (**B**) The percentage of neurons or glial cells along the culture is graphed. It changes along the time of culture due to both neuronal death and glial proliferation. Bars represent SEM, n=3. (**C**) Cell viability was estimated by staining with LIVE/DEAD viability/cytotoxicity kit. Alive cells were stained with Calcein, while dead cells were stained with Ethidium homodimer-1 (EthD-1). Scale bars represent 500 µm. (**D**) The total number of cells per square cm remained similar along the culture. Each dot represents the average of three wells per experiment. Bars represent the average of three independent experiments. Although there was an increment in the average number of cells at 26 D*IV*, it was not statistically significant analyzed by two-way RM ANOVA, with Dunnett´s multiple comparison test.

Supplementary Figure 2S. Spautin-1 inhibited autophagy and Trehalose induced autophagy on cortical primary cells. (**A**) Autophagosomes were stained with CytoID® to verify Spautin1 inhibition of autophagy on cortical cells cultured for 26 D*IV*, since at this time cells have abundant autophagosomes. Controls were treated with vehicle only. (**B**) Trehalose induction of autophagy was verified by adding it to cortical cells cultured for 6 D*IV*, since at this time cortical cells have only few autophagosomes. Controls were treated with vehicle only. Nuclei were stained with Hoechst. Scale bars represent 500 μm.

RNA proximity sequencing reveals the spatial organization of the transcriptome in the nucleus

Jörg Morf[1*], Steven W. Wingett[1,2], Irene Farabella[3,4], Jonathan Cairns[1,12], Mayra Furlan-Magaril[5], Luis F. Jiménez-García[6], Xin Liu[7], Frank F. Craig[7], Simon Walker[8], Anne Segonds-Pichon[2], Simon Andrews[2], Marc A. Marti-Renom[3,4,9,10] and Peter Fraser[1,11]

The global, three-dimensional organization of RNA molecules in the nucleus is difficult to determine using existing methods. Here we introduce Proximity RNA-seq, which identifies colocalization preferences for pairs or groups of nascent and fully transcribed RNAs in the nucleus. Proximity RNA-seq is based on massive-throughput RNA barcoding of subnuclear particles in water-in-oil emulsion droplets, followed by cDNA sequencing. Our results show RNAs of varying tissue-specificity of expression, speed of RNA polymerase elongation and extent of alternative splicing positioned at varying distances from nucleoli. The simultaneous detection of multiple RNAs in proximity to each other distinguishes RNA-dense from sparse compartments. Application of Proximity RNA-seq will facilitate study of the spatial organization of transcripts in the nucleus, including non-coding RNAs, and its functional relevance.

The spatial organization of nucleic acids in cell nuclei is critical for gene expression and ultimately cell physiology[1]. Different scales of the spatial organization of DNA and chromatin have been analysed; from promoter–enhancer interactions to megabase-sized topological association domains (TADs) and large-scale, higher-order folding of chromosomes into distinct compartments composed of transcriptionally active or inactive regions[2–4]. However, there is little understanding of where specific transcripts are synthesized, processed and/or sequestered in relation to nuclear landmarks. Large parts of transcriptomes have been spatially resolved in tissues[5] and single cells[6–8] with imaging techniques, but these methods do not infer colocalization or spatial associations between different RNA molecules. Pairwise probing of RNA–RNA interactions has thus far been limited to direct base-paired contacts[9] or to short-range distances between RNA ends allowing enzymatic ligations[10–13]. We therefore devised a widely applicable, massive-throughput method that determines spatial associations between pairs or groups of transcripts irrespective of the nature of their interaction to provide a functional readout of transcriptional genome activity in the nucleus.

Proximity RNA-seq uniquely barcodes RNAs in millions of subnuclear particles in parallel by a simple, rapid vortexing step combining fragmented nuclear particles with barcoded beads in a water-in-oil emulsion (Fig. 1a and Supplementary Fig. 1). Barcoded complementary DNAs are then sequenced to enable the reconstruction of proximities between chromatin-associated, nascent RNAs and non-coding RNAs in nuclei. We use Proximity RNA-seq to identify, characterize and map specific transcript families in relation to a major recognizable nuclear landmark, providing a cytological spatial map of RNAs in cells.

Results

Massive-throughput barcoding in emulsion. We first developed an on-bead PCR protocol in emulsion to uniquely barcode up to 1 billion beads individually for an experiment. We used conditions that favor the amplification of a single synthesized DNA template containing a 26-base-long random barcode on each bead in the emulsion[14,15] (Fig. 1b). The encapsulation of a single barcode with one bead can be approximated by diluting templates and beads sufficiently before emulsification. To estimate the fraction of singly barcoded beads, we first used two barcode templates of defined sequences (Supplementary Table 1) for PCR amplification on beads. Fluorescent probes were then hybridized to the amplified barcodes on beads before flow cytometry analysis and comparison with expected Poisson distributions (Fig. 1c,d). To optimize the yield of beads with individual random barcodes, we chose encapsulation conditions and template amounts according to a Poisson model that aimed at 50% barcoded beads, of which around 70% were covered with copies of a single barcode and 30% had copies of multiple barcodes. After PCR, barcode copies on beads were extended with 15 random bases to generate reverse transcription (RT) primers (Fig. 1b,e). Subnuclear particles from SH-SY5Y human neuroblastoma cells were obtained by minimal sonication to disrupt nuclei isolated from chemically crosslinked cells. After each sonication cycle, disruption of nuclei was examined by microscopy. We used ethylene glycol-bis(succinimidylsuccinate) (EGS), with a 16 Å spacer between reactive groups, in combination with formaldehyde for crosslinking, with the aim to increase the fraction of particles containing multiple RNA molecules. After sonication of nuclei, all the homogenate was encapsulated into droplets without prior centrifugation. In-droplet reverse transcription of

INFORME DE LABORES 2019

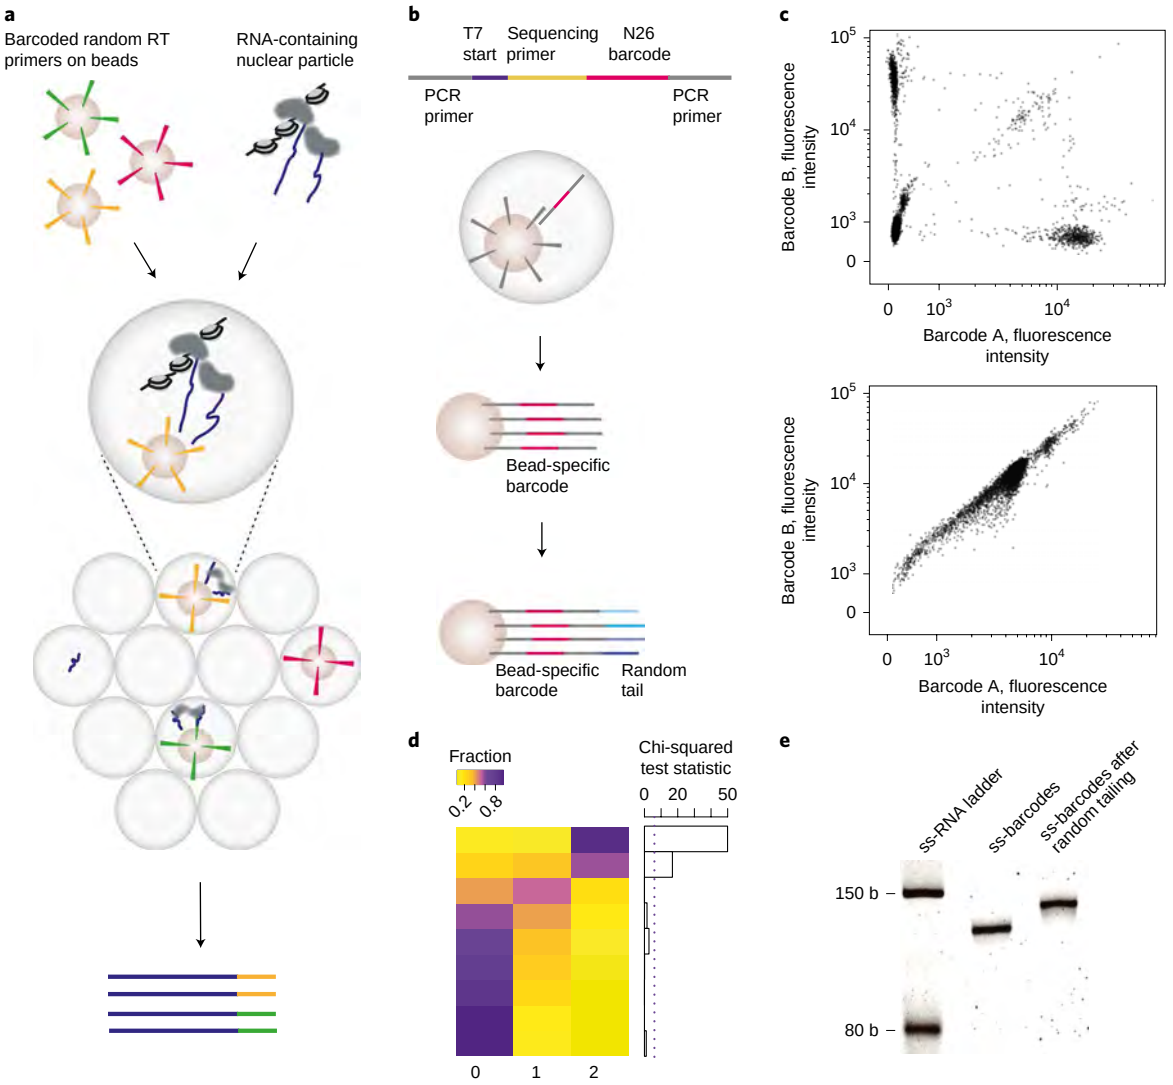

Fig. 1 | Proximity RNA-seq. a, Massive-throughput barcoding by RT of RNA-containing particles in water-in-oil droplets. **b**, Barcoding of magnetic beads with immobilized primers and diluted random DNA templates by emulsion PCR. Barcodes on beads were end-tailed with random nucleotides to subsequently serve as RT primers. **c**, To control barcoding and emulsion integrity, two barcodes of known sequence were amplified on beads in emulsion or solution prior to hybridization with complementary fluorescent probes and fluorescence-activated cell sorting (FACS) analysis to count empty, single and mixed barcoded beads. Top panel, PCR in emulsion; bottom panel, PCR in solution. Axes specify fluorescence signals of hybridized probes. **d**, Different two-barcode experiments, rows, were ordered according to increasing fractions of non-barcoded beads (yellow, low fraction; purple, high fraction). Fractions of beads containing no, one or both barcodes (columns) were compared with expected Poisson distributions (chi-squared test statistic, dashed line indicates $P = 0.05$). $n = 10{,}000$ beads per experiment were analysed. **e**, Acrylamide gel of single-stranded barcodes (ss-barcodes) before (lane 2) and after (lane 3) the addition of 15 random nucleotides. Single-stranded RNA ladder (ss-RNA ladder) was run in lane 1 ($n = 2$).

RNAs in crosslinked particles with barcoded beads followed by cDNA library amplification (Supplementary Fig. 1) resulted in a fragment length suitable for Illumina sequencing.

Proximity RNA-seq characterization and validation. Sequencing and mapping of RNAs in nuclear-enriched particles resulted in a fourfold increase in intron-to-exon read ratio compared with ribosomal RNA-depleted RNA-seq. In addition, the characteristic overrepresentation of reads at the 5′ ends in introns compared with the 3′ ends[16] demonstrated a clear enrichment for nascent transcripts (Fig. 2a,b). We trimmed three bases on either end of the barcode to account for offsets by a few bases of otherwise identical barcodes. The resulting barcode length of 20 random bases corresponds to a theoretical barcode complexity of 10^{12}, which exceeded an estimated 10^9 nascent RNA molecules in the input material. Multiple reads with the same barcode and mapping to the same transcript were dubbed a proxy read and counted as one transcript observation (Supplementary Fig. 2). Up to 25% of proxy reads were cobarcoded with proxy reads mapping to other transcripts identifying spatial RNA associations (Supplementary Fig. 3). Proximity RNA-seq benefits from sequencing into saturation to increase the number of RNAs identified on beads and cobarcoded proxy reads (Supplementary Fig. 4).

To validate spatial associations, we first analysed cobarcoding events of the abundant small RNA U3, which resides in the nucleolus together with hundreds of other small non-coding, nucleolar RNAs (snoRNAs)[17]. We found overwhelmingly significant cobarcoding of snoRNAs with U3 compared with the non-snoRNA transcriptome (Mann–Whitney U-test: $P = 4 \times 10^{-56}$; Cliff's delta effect size: 0.9; Fig. 2c). In contrast, control experiments using multi-barcoded

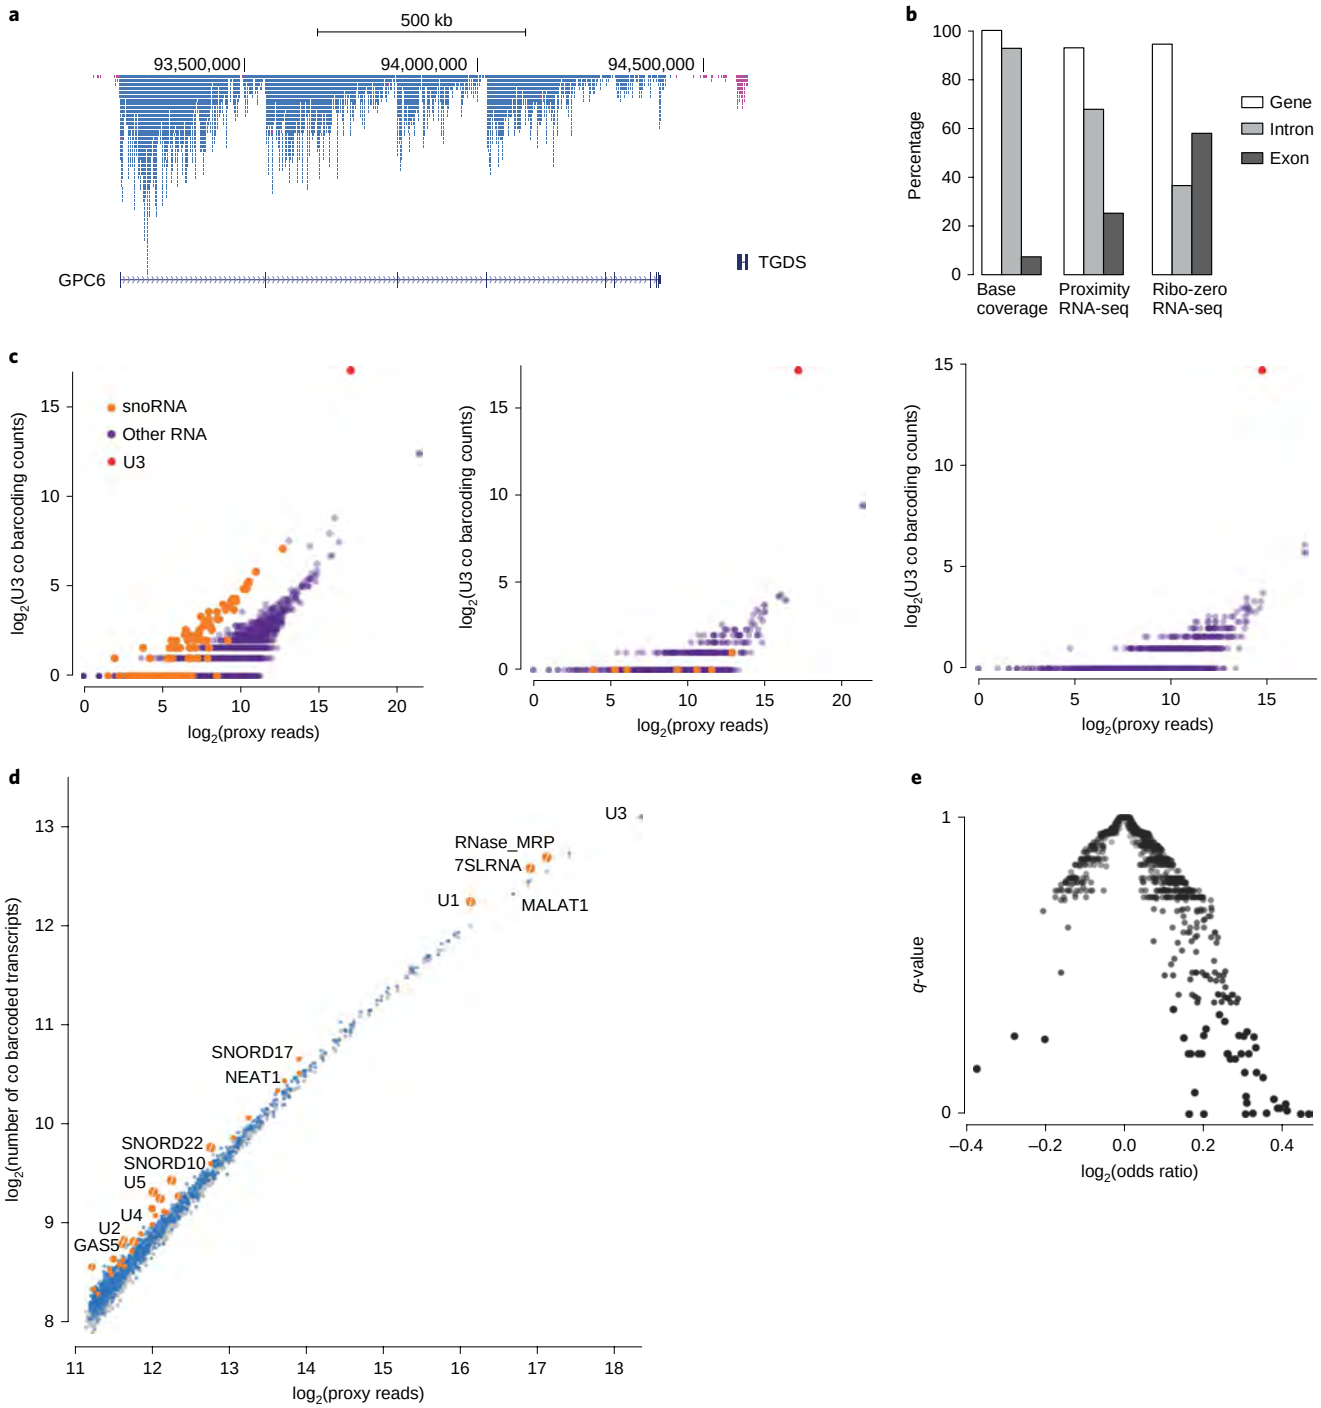

Fig. 2 | RNA cobarcoding and proximal transcriptomes. a, Proximity RNA-seq reads mapping to GPC6 (blue) and adjacent transcripts on the opposite strand (pink) illustrate both high intronic read densities and the saw-tooth read pattern along introns. **b**, Fractions in percentage of reads in transcript features. Proximity RNA-seq was compared with total RNA-seq after ribosomal depletion[39] and the base coverage of exons, introns and genes in the genome (set as 100), respectively. **c**, Counts of cobarcoding events involving U3 RNA plotted against the number of proxy reads of the other RNA. Left panel, crosslinked sample with uniquely barcoded beads; middle panel, control using crosslinked sample and randomly barcoded beads; right panel, control with purified RNA after crosslink reversal and uniquely barcoded beads. Of note, most snoRNAs are not plotted for control data, as no cobarcoding with U3 was detected. **d**, For the top 1,000 RNAs (combined data from $n = 3$ independent experiments), the number of cobarcoded transcripts was plotted against the number of proxy reads per RNA. Gray, randomized; blue, observed; orange, RNAs with high complexity of cobarcoded transcripts ($P < 0.01$); orange with white slash, $q < 0.05$ as derived in **e**. **e**, Transcripts with more complex composition of cobarcoded transcripts than expected at random were identified by Fisher's exact test, two-sided, and FDR adjustment (x axis, odds ratio with positive values indicating high complexity of cobarcoded transcripts).

beads produced by PCR amplification in a droplet-free solution showed essentially no cobarcoding between U3 and snoRNAs. Similarly, using crosslink-reversed and purified RNA and uniquely barcoded beads also showed no cobarcoding between U3 and snoRNAs. We next compared the crosslink-reversed control, the standard crosslinked condition used throughout the manuscript and a

INFORME DE LABORES 2019

prolonged crosslinked sample to assess the effects of sample preparation on particle encapsulation, RNA read counts and nuclear proximities. Global correlation in transcript abundance as measured by Proximity RNA-seq between standard crosslinked and crosslink-reversed samples (Spearman's rank correlation coefficient: 0.8) was found to be similarly high to that between replicates of crosslinked samples (Supplementary Fig. 3). Equal transcript abundances in both datasets suggested unbiased encapsulation of crosslinked RNA particles into droplets. As exemplified by U3 (Fig. 2c), the crosslink-reversed sample lacked information on RNA proximities, and global correlation in pairwise transcript cobarcoding between crosslinked and crosslink-reversed samples was poor (Spearman's rank correlation coefficient: 0.29). We then compared the sample with prolonged fixation with the standard sample preparation. The same number of sonication cycles was used for both samples to disrupt nuclei. We found that the fraction of ribosomal RNA reads increased from 43% in standard conditions to 87% with prolonged crosslinking. Of note, nuclei contribute less than the cytoplasm to a total of around 90% rRNA in whole cells[18,19]. Intronic reads decreased from 74% to 47% and exonic reads increased from 18% to 47% with prolonged crosslinking compared with standard conditions (Supplementary Fig. 5). We conclude that prolonged crosslinking copurified larger amounts of cytoplasmic RNA compared with standard crosslinking, which hampers the analysis of nuclear RNA organization. Nuclear particle preparation is therefore likely a trade-off between a high crosslinking efficiency, to increase cobarcoding of transcripts at the cost of cytoplasmic RNA contamination, and aiming for a cleaner preparation of nuclei with less crosslinking and less frequent cobarcoding of transcripts. Using our standard sample preparation in SH-SY5Y cells, high intron and modest rRNA contents suggested that the conditions were suitable to probe nuclear RNA proximities. Furthermore, correlations in pairwise transcript cobarcoding between different standard crosslinked replicates ranged between 0.71 and 0.83 (Spearman's rank correlation coefficient, Supplementary Fig. 3). These results demonstrate that our method reproducibly detects RNAs present in individual subnuclear particles. However, we cannot rule out the possibility that other conditions may be more suitable.

To calculate the significance of spatial associations between transcripts while taking their vastly different abundances into account, we randomized pairings of proxy reads and their barcodes 100,000 times to obtain simulated cobarcoding counts for pairs of transcripts (see Methods, Supplementary Fig. 3). Observed cobarcoded pairwise RNA proximities were compared with simulated counts to determine statistical significance (Supplementary Tables 2,3). These analyses verified known contacts between 18S and 28S rRNAs, MALAT1 and U1 (ref. [20]) and between spliceosomal RNAs, respectively ($q < 0.002$). To further test the analysis pipeline, we performed Proximity RNA-seq using a mixture of particles from different species. To a standard input of human particles equivalent to 50 ng RNA we added the same amount of fruit fly particles to obtain a conservative estimate of false positive RNA proximities. We first selected barcode groups with exactly two transcripts and found that 20% of all two-transcript barcode groups consisted of a fly and a human transcript (Supplementary Fig. 6). We then compared the whole dataset with randomizations and estimated the false positive rates of pairwise, inter-species RNA proximities. *P*-value cutoffs for pairwise RNA proximities at 0.01, 0.05 and 0.1 resulted in 0%, 2% and 6.4% false positive rates, respectively. This shows that Proximity RNA-seq and the analysis pipeline produce few false positives even in conditions with considerable species mixing in droplets.

Main RNA compartments and transcript positioning in nuclei. Next, we analysed the number of unique transcripts cobarcoded once or multiple times and irrespective of the significance of pairwise associations, with a given RNA molecule of the 1,000 highest expressed transcripts. We found that RNAs present at higher levels had higher cobarcoded transcript counts (Fig. 2d and Supplementary Table 4). Two factors likely underlie this trend. First, in cells, highly expressed RNAs have more opportunities to encounter other transcripts, and second, in droplets, abundant RNAs are more often cobarcoded with transcripts from distinct particles, according to the Poisson distribution of particles into droplets, thereby further increasing the number of unique cobarcoded transcripts. Notably, we identified RNAs cobarcoded with more unique transcripts than would be expected by their abundance. Such RNAs were often non-coding, rather than protein-coding, and included spliceosomal (U1, U2, U4 and U5), paraspeckle (NEAT1) and nucleolar (snoRNAs) transcripts (Fig. 2d,e). The more complex compositions of cobarcoded transcripts likely reflected transcriptome-wide functions in intron excision and exon splicing in the case of spliceosomal RNAs and supported the notion of some non-coding RNAs as spatial organizers or markers of larger RNA groups in nuclei.

In DNA contact assays, close distance on the linear genome largely increases contact strength between genomic regions. Significant but lower contact strength between regions further apart is indicative of higher-order chromatin folding. We therefore assumed that pairs of nascent RNAs, although not physically linked like DNA of the same chromosome, would show increased spatial association when the distance between their genes was small. Using randomization-derived *P* values for RNA pairs, we found higher levels of associations between transcripts encoded by genes located nearby in the linear genome than between transcripts from genes further apart or on different chromosomes (Supplementary Fig. 7). This shows that one factor that specifies spatial associations of a nascent transcript with other RNAs is linear genome proximity of the respective genes.

We then asked whether larger groups of nuclear-retained, non-coding and nascent coding transcripts preferentially associate with each other and thereby partition the nuclear transcriptome. Principal component analysis (PCA) on *P* values of pairwise associations between any RNA and the top 100 connected transcripts identified two main compartments for RNA in nuclei. Principal component 2 (PC2) separated snoRNAs as well as a set of protein-coding transcripts from the bulk of mostly protein-coding transcripts (Fig. 3a, Supplementary Table 5). We dubbed this transcript group, which is highly enriched for nucleolar transcripts, compartment I, based on the prevalent RNA polymerase I activity for rRNA synthesis within the nucleolus. Accordingly, compartment II was named after RNA polymerase II, which is predominant in the nucleoplasm (Fig. 3b). We then performed dual RNA fluorescence in situ hybridization (FISH) using U3 as a nucleolar marker and sets of 24 probes hybridizing to intronic sequences of 13 different RNAs (Fig. 3c,d). The results confirmed that nascent transcripts from compartment I are indeed preferentially synthesized in close proximity to the nucleolus, whereas nascent transcripts from compartment II are transcribed in the nucleoplasm at greater distances from the nucleolus. This validates the accuracy of Proximity RNA-seq to predict spatial distances between different transcripts and a major nuclear structure, the nucleolus, providing a 'magnetic north' reference point for genome function that is lacking in chromosome conformation capture (Hi-C) data. On average, median distances between the edge of the nearest nucleolus and transcripts of compartment I were $0.82 \pm 0.24\,\mu m$ (mean ± s.d.). Compartment II transcripts, on the other hand, were found at on average twofold increased distances from the nucleoli ($1.68 \pm 0.37\,\mu m$). Our findings suggest that the perinucleolar region, which has previously been associated with transcriptionally silent, compact chromatin[3,21], expresses a specific subgroup of RNAPII-transcribed genes.

We next analysed features of RNAs grouped into eight quantiles according to their relative nuclear position derived from PC2 values (Fig. 3b,e–g). Compartment I (quantiles 1–3) contained 370 (70%) and compartment II (quantiles 4–8) 784 protein-coding

The borders, bar and whiskers of the box plot represent the first (Q1) and third (Q3) quartiles, the median and the most extreme data points within 1.5× interquartile range from Q1 to Q3, respectively. **g**, Heatmap of Pearson residuals (yellow–magenta) from regression against PC2 quantiles (columns, PC2 quantiles 1–8: $n=1,214$, 2,017, 2,926, 3,070, 3,324, 3,884, 3,417, 3,225 exons) and bins of exon inclusion scores (rows).

transcripts (90%). We observed an accumulation of gene ontology terms, many specific to the neuronal cell type, in compartment II but few enriched terms in compartment I (Supplementary Fig. 8). Similarly, the number of transcripts with high tissue specificity[22,23] increased from compartment I to compartment II, with the exception of nucleolar quantile 1 (Fig. 3f). Consistently, genes encoding compartment II transcripts were closer in the linear genome to multi-enhancer domains crucial for cell identity (super-enhancers[24,25]) than genes whose transcripts were assigned to compartment I (Supplementary Fig. 8). Finally, alternative splicing of exons in protein-coding transcripts occurred less frequently in compartment I, as indicated by high exon inclusion[26]. In contrast, transcripts in

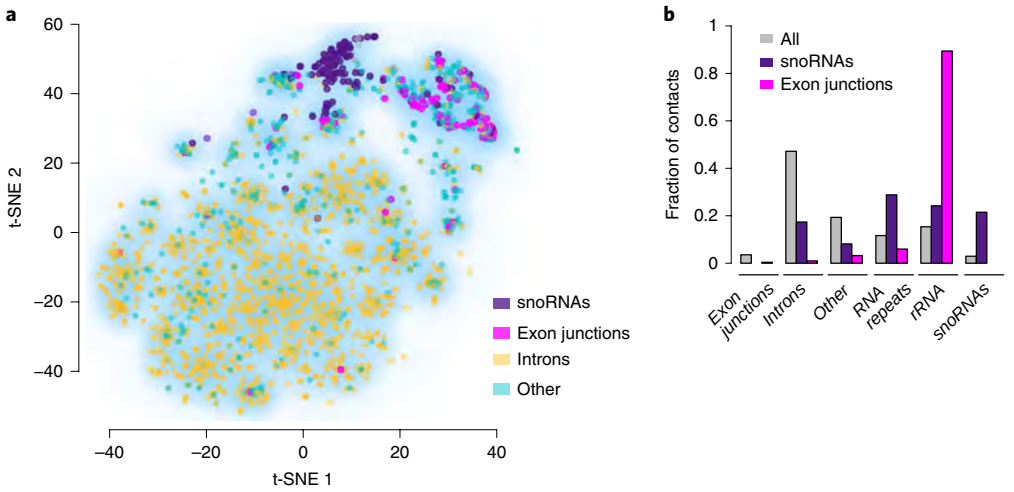

Fig. 4 | RNA proximities of nascent and processed transcripts. a, t-SNE visualization of intronic ($n=1,666$), exon junction ($n=105$) and other, ambiguous ($n=608$) RNA features based on their pairwise proximity with the top 100 connected features. Additionally, snoRNAs are colored in purple ($n=111$). **b**, Comparison of spatial RNA associations ($P\leq0.1$) between all features, snoRNAs and exon junctions with different classes of features (number of associations between features: all - exon junctions $n=1,022$, snoRNAs - exon junctions $n=0$, between pairs of exon junctions $n=4$, all - introns: $n=13,596$, snoRNAs - introns $n=147$, exon junctions - introns $n=10$, all - other $n=5,571$, snoRNAs - other $n=69$, exon junctions - other $n=33$, all - RNA repeats: $n=3,360$, snoRNAs - RNA repeats $n=244$, exon junctions - RNA repeats $n=61$, all - rRNA $n=4,426$, snoRNAs - rRNA $n=205$, exon junctions - rRNA $n=914$, all - snoRNAs $n=849$, between pairs of snoRNAs $n=182$, exon junctions - snoRNAs $n=0$).

compartment II exhibited variable and often lower exon inclusion (Fig. 3g). This suggests that the nuclear transcriptome is partitioned into broadly expressed, so-called housekeeping, transcripts in the vicinity of nucleoli in compartment I and tissue-specific RNAs and transcripts that are more frequently subject to alternative splicing in compartment II.

Precursor and processed RNA localization. To distinguish different spatial sites for precursor and processed RNA, we split reads for any transcript into three groups: overlapping introns for precursors, exon junctions for mature RNAs and a group of other, ambiguous stretches of transcripts. After comparison with random simulations (Supplementary Table 6), we visualized the high-dimensional spatial RNA association data by giving each RNA a position in a two-dimensional map using t-distributed Stochastic Neighbor Embedding (t-SNE[27]) (Fig. 4a). The clustering of snoRNAs apart from the bulk of precursor transcripts recapitulated the two compartments revealed by PCA and using gene-based transcript annotations. In addition, we found exon junctions clustered together, separated from nascent RNA and nucleolar transcript clusters. Strikingly, most pairwise RNA associations involving exon junctions were formed with ribosomal RNA (89%). Unlike snoRNAs, which contact each other and rRNA in nucleoli, exon junctions showed no association with snoRNAs (Fig. 4b). These results indicate that rRNA was captured at two distinct stages and locations: during synthesis and processing with snoRNAs in nucleoli, and as functional ribosomes, likely situated at the outer nuclear envelope and copurified from the cytoplasm by crosslinking to nuclei, in complex with spliced protein-coding RNAs as represented by exon junction reads.

Compartment- and transcript-specific local RNA density. Proximity RNA-seq enables the simultaneous detection of two or more proximal transcripts. We reasoned that frequent or rare simultaneous detection of multiple proximal transcripts is characteristic of a specific RNA and the nuclear region from which crosslinked particles originate and reflects high or low local RNA density, respectively. To derive local RNA density and/or connectivity for individual transcripts, we introduced a measure describing how often a transcript was detected singly or cobarcoded with one or multiple other RNA molecules. This so-called 'valency' of a given transcript was inferred from relative enrichments or depletions (z-score) in the number of reads mapping to the transcript in barcode groups encompassing one, two and three transcripts, respectively, compared with the nuclear transcriptome average (Fig. 5a, Supplementary Fig. 9, Supplementary Table 7). After assigning valency to individual transcripts, we analysed the distribution of valency in compartments I and II. We found that transcripts in compartment I overall exhibited high valency (that is, z-scores of valency $1<0$ and z-scores of valency 2 and $3>0$), indicating the increased RNA density in nucleoli[28]. Of note, spatial regions adjacent to nucleoli contained in PC2 quantiles 2 and 3 also exhibited high valency despite much reduced numbers of snoRNAs in such regions. In contrast, low-valency transcripts prevailed in compartment II (Fig. 5b). Further, we analysed valencies of whole proximal transcriptomes (association $P\leq0.1$) specific to the abundant non-coding RNAs 7SLRNA, 7SK and nuclear speckle-resident MALAT1, respectively (Fig. 5c). We first examined transcript assignments to PC2 quantiles and found 7SLRNA enriched in proximity to compartment I transcripts (quantiles 1–3). 7SK and MALAT1 colocalization with proximal transcripts peaked near the border of or within compartment II (quantiles 4–8), respectively (Fig. 5d). We then combined transcript-specific valencies for each proximal transcriptome. All three proximal transcriptomes showed decreased valency 1 and increased valency 2 and 3 compared with the entire transcriptome, indicative of locally increased RNA density (Fig. 5e) (tests for valency 1, compared with entire transcriptome, Kolmogorov–Smirnov, two-sided: 7SL $P=5\times10^{-5}$, 7SK $P=0.001$, MALAT1 $P=3\times10^{-5}$, Cliff's delta effect size: 7SL 0.25, 7SK 0.22, MALAT1 0.21). We next asked how the valency of proximal transcriptomes is affected through associations with high-valency nucleoli and snoRNAs. Removal of snoRNAs from the analysis reduced valencies 2 and 3 and increased valency 1 of 7SLRNA (Fig. 5e) (for valency 1 with and without snoRNAs, Kolmogorov–Smirnov, two-sided: $P=0.003$, Cliff's delta effect size: −0.23). Therefore, the proximal transcriptome of 7SLRNA increased RNA density through association with nucleolar transcripts. The valency of the 7SK transcriptome showed little change upon removal of snoRNAs (for valency 1 with and without

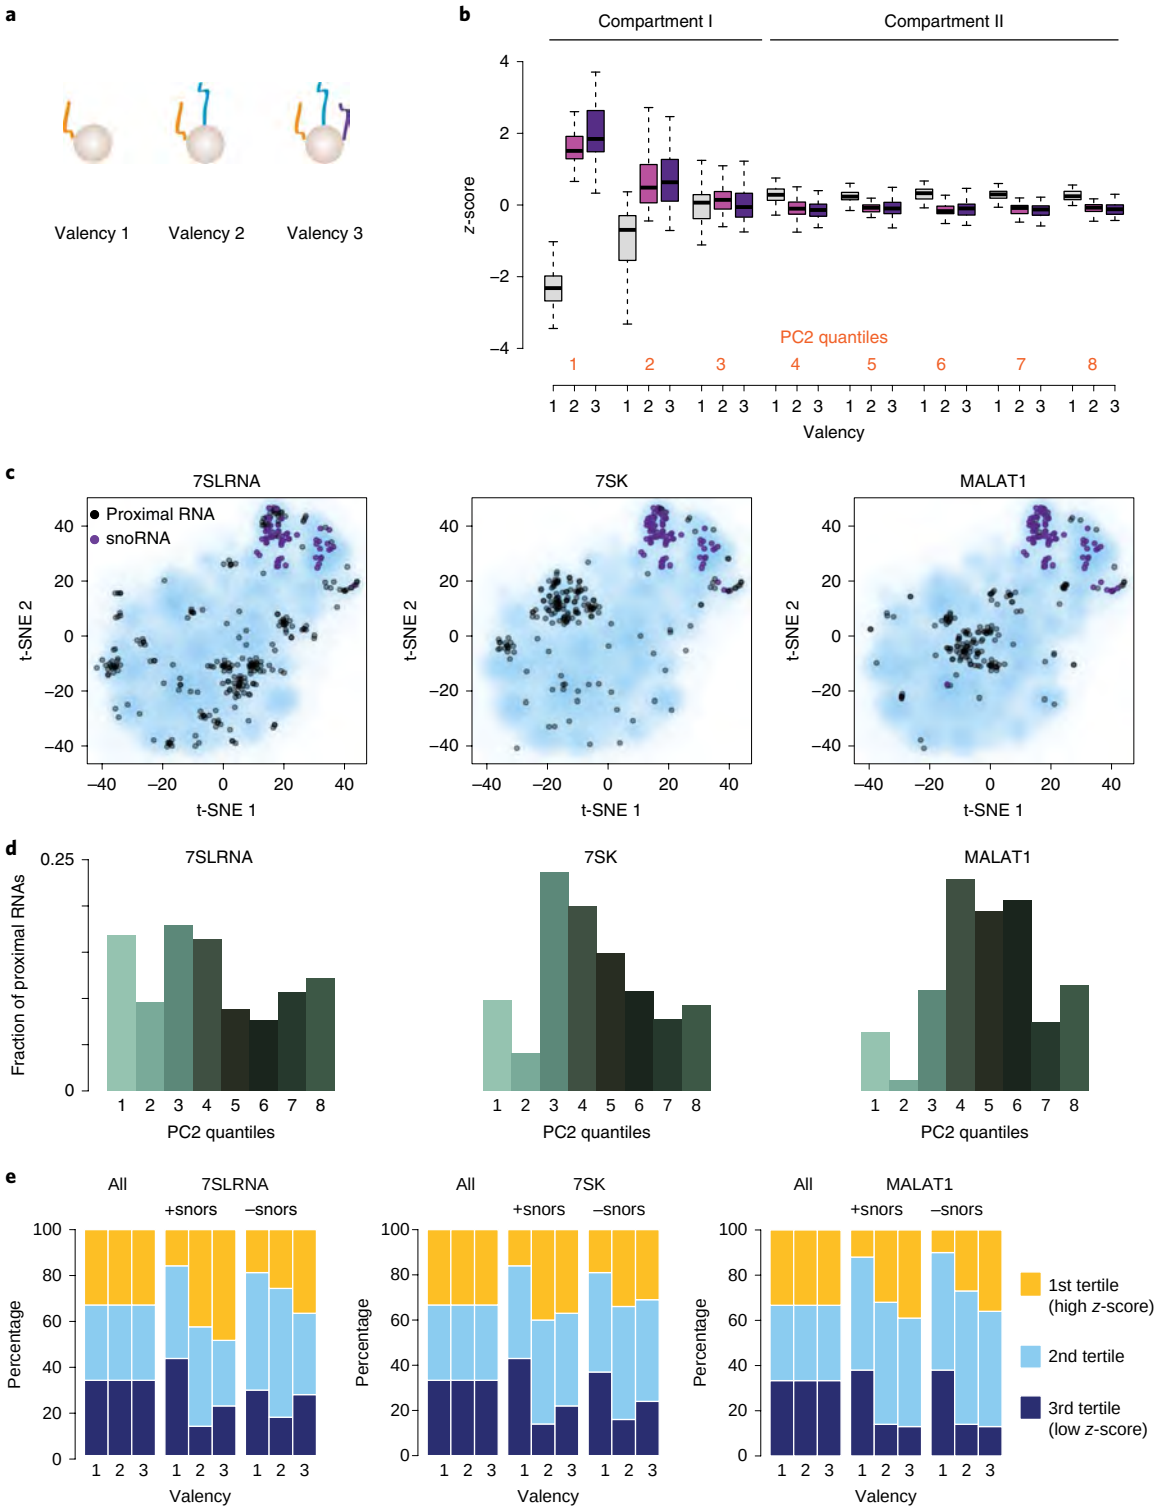

Fig. 5 | RNA valency. a, RNA valency was based on read counts of a given transcript in barcode groups with one, two or three transcripts. **b**, *z*-scores (*y* axis) of valencies (*x* axis: black numbers) along the PC2 axis (*x*: orange numbers, for PC2 quantiles 1 and 8 $n=58$, for quantiles 2–7 $n=57$ transcripts). The borders, bar and whiskers of the box plot represent the first (Q1) and third (Q3) quartiles, the median and the most extreme data points within 1.5× the interquartile range from Q1 to Q3, respectively. **c**, t-SNE visualization of transcripts (black) proximal ($P \leq 0.1$) to 7SLRNA ($n=415$), 7SK ($n=333$) and MALAT1 ($n=255$). SnoRNAs are indicated in purple. **d**, Fractions of transcripts proximal to 7SLRNA, 7SK and MALAT1, respectively, in different PC2 quantiles along the compartment I to II axis. **e**, Valency of proximal transcriptomes of 7SLRNA, 7SK, MALAT1 and of the whole transcriptome (all) before ($n=150$, 120, 103 and 2,486 transcripts, respectively) and after ($n=115$, 104, 95 and 2,411, respectively) removal of all snoRNAs from analysis (+snors, −snors). Tertiles were derived from whole-transcriptome distributions for valency 1, 2 and 3. Occurrences of transcripts proximal to 7SLRNA, 7SK and MALAT1 were counted in the tertiles and shown as percentages. For example, high valency is represented by a smaller first (yellow) and a larger third tertile (dark blue) for valency 1 and vice versa for valency 2 and 3 compared with whole-transcriptome tertiles.

Kolmogorov–Smirnov, two-sided, pairs of high-valency contacts versus pairs of low-valency contacts: $P = 0$, Cliff's delta effect size: 0.25. **d**, Density map of chromosome 14 ensemble model. **e**, Distances, median indicated as bar, between the center of mass (COM) of the B compartment and COM for high- ($n = 5$) and low-valency ($n = 8$) regions in chromosome 14, respectively (Mann–Whitney *U*-test, two-sided, $P = 0.1$). **f**, Local accessibility for a virtual object with radius of 150 nm and local contact density number within spherical volumes with radii 2,000 nm. High-valency regions in red, low-valency orange. **g**, Genome-wide intronic read density decays indicated faster transcription elongation in high- (red, $n = 20$) than low-valency (orange, $n = 50$) genomic regions (Kolmogorov–Smirnov, two-sided: $P = 0.03$, Cliff's delta effect size: 0.33). The borders, bar and whiskers of the box plot represent the first (Q1) and third (Q3) quartiles, the median and the most extreme data points within 1.5× the interquartile range from Q1 to Q3, respectively.

snoRNAs, Kolmogorov–Smirnov, two-sided: $P = 0.3$, Cliff's delta effect size: −0.13). Similarly to 7SK and in line with its architectural role in membrane-less nuclear bodies, autonomous from nucleoli, the proximal transcriptome of MALAT1 retained its valency state irrespective of snoRNAs (for valency 1 with and without snoRNAs, Kolmogorov–Smirnov, two-sided: $P = 0.9$, Cliff's delta effect size: −0.07). In conclusion, we found compartment I to be clearly distinguished from compartment II based on RNA density. Yet, the proximal transcriptome of MALAT1 was identified as a high-valency, RNA-dense body apart from compartment I, suggesting a heterogeneous RNA valency distribution throughout the relatively RNA-sparse compartment II.

RNA valency identifies dense, fast-transcribing chromatin. We next applied valency to differentiate transcriptionally active genomic subcompartments. Given that up to 80% of Proximity RNA-seq reads mapped to introns, we reasoned that Proximity RNA-seq-derived valency could be deployed to further classify transcript-encoding genome regions. We therefore performed Hi-C in SH-SY5Y cells and assigned average RNA valency scores to genomic regions. Hi-C studies have described open, transcriptionally active domains that preferentially contact other active domains in higher-order A compartments, while compact, poorly expressed domains preferentially contact each other in B compartments[2,29–31]. We found genomic A regions with high average RNA valency to be enriched in compartment I transcripts. Low-valency A regions more frequently encoded compartment II transcripts (Fig. 6a). As expected, genomic regions without assigned valency encompassed most B regions with low transcript expression (Supplementary Fig. 10) and showed very strong enrichment of chromatin contacts between

them by Hi-C (Fig. 6b). When comparing high- and low-valency genomic regions by Hi-C, we identified stronger DNA contact enrichments for pairs of high-valency compartment I regions, which resembled A to B contacts, whereas contact enrichments between low-valency regions were weaker, similar to A to A contacts (Fig. 6b,c, Kolmogorov–Smirnov, two-sided, pairs of high-valency contacts versus pairs of low-valency contacts: $P=0$, Cliff's delta effect size: 0.25). To gain further insights into distinct spatial distributions and local chromatin properties for different valency regions, we created three-dimensional (3D) models of a chromosome using Hi-C contact frequencies as spatial restraints[32]. In line with the contact enrichment profiles, high-valency domains in chromosome 14 were spatially closer to the B compartment than low-valency regions (Fig. 6d,e). Electron micrographs of nuclei likewise provided evidence for RNA-dense regions adjacent to compact chromatin (Supplementary Fig. 11)[33]. 3D model-derived estimates of local accessibility of a virtual object and of chromatin contact counts per volume suggested, furthermore, that high-valency regions were less accessible and more compact than low-valency regions (Fig. 6f, Supplementary Fig. 12). Finally, we observed increased transcription elongation rates in high-valency compared with low-valency regions (Fig. 6g, Supplementary Fig. 13) as estimated by regression of 5′ to 3′ read density within long introns measured by Proximity RNA-seq (Fig. 2a)[16,34]. This suggests that high- and low-valency territories are also distinguishable by local, apparent catalytic activities. In a reciprocal analysis in K562 haematopoietic cells we confirmed that fast-transcribing genomic regions, defined by BruDRB-seq[35], showed stronger Hi-C contact enrichments than slowly transcribed regions[36] (Supplementary Fig. 14).

Discussion

Much insight into RNA–RNA associations has so far been gained from methods using psoralen derivatives to specifically crosslink base-paired interactions. This approach has proved invaluable to map RNA secondary structure and to identify pairs of RNAs with complementary and hybridized sequence patches[9–13,37]. However, the larger 3D context of where RNA molecules are located and form contacts in cells has remained unaddressed. Proximity RNA-seq measures co-localization and positioning of RNAs in cellular 3D space at the resolution of individual transcripts, while psoralen methods identify base-paired regions within a transcript or a pair of transcripts. Dimensionality reduction of pairwise spatial RNA associations enabled us to accurately position transcripts to compartment I, encompassing the nucleolus and adjacent regions, and compartment II, the nucleoplasm and nuclear periphery, in strong agreement with 3D RNA-FISH. Previously, the detection and identification of the RNA-dense compartment I based on DNA proximity ligations has been hampered due to the low and repetitive DNA content in nucleoli. Furthermore, distances between genes distributed over the surface area of nucleoli are probably too large for ligation[3]. Measuring RNA proximities in subnuclear particles circumvents this limitation of DNA ligation assays to describe RNA-dense regions in nuclei. Ligation-free DNA proximity measurements mirror our finding of transcript compartments at the genome level[3].

Positioning of a gene to dense heterochromatin around nucleoli has been associated with gene repression[3,21]. However, the direct spatial mapping of transcriptional output here identified active RNA synthesis from specific genes at the periphery of nucleoli. Little is known about what defines the positioning of active genes and their nascent transcripts to either the nucleoplasm or nucleoli. Gene editing experiments, in which a compartment I gene, whose transcripts are close to nucleoli, replaces a gene encoding compartment II transcripts positioned further away from nucleoli, promise insights into whether DNA regions and/or the expressed transcript play roles in gene and RNA positioning.

Our in-emulsion barcoding and sequencing method enables not only the identification of pairwise spatial associations but also the simultaneous detection of more than two RNAs in proximity to each other. This allows transcripts to be characterized by valency, which can be interpreted as a local RNA density or connectivity. Transcripts can therefore be located and assigned to RNA-dense or sparse neighborhoods. For example, we mapped the proximal transcriptomes of 7SLRNA overlapping or at the border to high-valency compartment I, which explained the increased valency of the network. In contrast, the proximal transcriptome of MALAT1 in speckle bodies assigned to the often RNA-sparse compartment II showed increased valency independently of associations with nucleoli in compartment I.

The combined analysis of Hi-C chromatin contacts and RNA valency suggested that chromatin regions encoding compartment I transcripts with increased RNA valency exhibit stronger DNA contacts, reflecting proximity to the perinucleolar B compartment. These nucleic-acid-dense territories displayed faster transcription elongation compared with low-valency compartment II regions. We can only speculate that, besides genomic sequence and chromatin determinants, sequestering of certain protein factors might favor rapid transcription elongation in high-valency nuclear regions. Interestingly, transcription elongation factors have been shown to associate with chromatin in an RNA-dependent manner[38], which raises the possibility that transcripts themselves in crowded RNA-dense regions might accumulate elongation factors critical to speed up transcription and thereby sustain local high RNA valency.

The utility of Proximity RNA-seq will lie in its versatility to sequence different subcellular RNA-containing structures. Our understanding of the composition and functioning of RNA compartments beyond the nucleus, such as RNA-rich phase separations or aggregates in disease states, will benefit from the spatial RNA measurements introduced here. We envision that large-scale proximity measurements of RNA, a molecule with ubiquitous but non-random distribution throughout cells, will achieve a map of whole-cell spatial organization by means of sequencing.

Methods

Preparation of nuclear homogenates for Proximity RNA-seq. SH-SY5Y cells were cultured in high-glucose DMEM medium (Thermo Fisher Scientific) containing 10% fetal bovine serum (Hyclone) and Streptomycin, Penicillin (Thermo Fisher Scientific). At 70–80% confluency in 150 mm dishes, cells were crosslinked. Culture medium was replaced by 19.8 ml of pre-warmed 1× PBS and 0.2 ml of freshly prepared 10 mM EGS (Thermo Fisher Scientific) in dimethyl sulfoxide (DMSO) was added drop-wise for 1 mM final concentration. Cells were incubated for 10 min at 37 °C. Then, 1.4 ml of 16% formaldehyde (Agar Scientific) was added to dishes for a final concentration of 1%, and the incubation was extended for another 10 min at room temperature. The addition of 3.5 ml of 1 M glycine quenched crosslinking, and cells were scraped immediately and pelleted in a 50 ml Falcon tube at 210*g* for 5 min at 4 °C. Cell pellets were washed with 1× PBS supplemented with 125 mM glycine. A second wash with 1× PBS was carried out subsequently. Cell pellets were flash frozen in liquid nitrogen and stored at −80 °C until use.

Frozen cell pellets from single 150 mm dishes were thawed on ice in 1 ml of 20 mM Tris buffer pH 7.2, spun and resuspended in 1.5 ml of hypotonic Igepal C-630 lysis buffer (20 mM Tris, pH 7.2, 5 mM NaCl, 0.2% Igepal C-630, 2 mM EDTA, 1 mM EGTA) supplemented with 1× Complete, EDTA-free protease inhibitor cocktail (Roche Applied Science) and 0.5 units μl^{-1} SUPERase IN RNase inhibitor (Thermo Fisher Scientific). Cells were kept on ice for 30 min with occasional mixing. Nuclei were spun at 2,000 r.p.m. for 5 min in a benchtop centrifuge at room temperature, and the buffer exchanged with SDS washing buffer (20 mM Tris, pH 7.2, 5 mM NaCl, 0.3% SDS, 2 mM EDTA, 1 mM EGTA) supplemented with inhibitors as listed above. Samples were incubated for 10 min at room temperature in a thermoblock with constant mixing at 750 r.p.m. Triton X-100 was added for a final concentration of 1.7% and incubation prolonged for 10 min. Nuclei were then washed once in 10 mM Tris pH 7.2, 5 mM NaCl, 0.5 mM EDTA, 1% Triton X-100, supplemented with inhibitors as specified above, and once in the same buffer with only 0.05% Triton X-100. Nuclei were resuspended in 0.2 ml of wash buffer with 0.05% Triton X-100 and sonicated in 15 ml Falcon tubes using a bioruptor UCD-200 sonicator (Diagenode) with power set to medium for three to five cycles of 10 s on followed by 10 s off at 8 °C. After three cycles of sonication, the disruption of nuclei was inspected using Trypan blue staining and light microscopy. Sonicated nuclear homogenates were flash frozen in liquid nitrogen and stored at −80 °C until use.

Content and fragment length of RNA and DNA, respectively, were estimated after crosslink reversal and purification of nucleic acids using a spectrophotometer (NanoDrop) and agarose gel electrophoresis as follows. For DNA extraction, 20 µl of nuclear homogenate was supplemented with the following reagents to final concentrations of 50 mM Tris pH 8.0, 50 mM NaCl, 2 mM EDTA, 0.2% SDS and 5 µl of proteinase K (Roche Applied Science, 10 mg ml^{-1} stock concentration) for a total volume of 40 µl. DNA extraction mixes were first incubated for 4 h at room temperature followed by 2 h at 70 °C. Then, 2 µl of RNase A (Roche Applied Science, 10 mg ml^{-1} stock concentration) was added and samples were incubated for 1 h at 37 °C. DNA was purified by phenol/chloroform extraction and salt/isopropanol precipitation and resuspended in 10 µl of nuclease-free water (Ambion). To extract RNA, final concentrations of 100 mM sodium citrate pH 6.2, 2 mM EDTA, 0.2% SDS and 5 µl of proteinase K were added for a total volume of 40 µl. RNA extraction mixes were incubated for 4 h at room temperature followed by 1 h at 70 °C. 1 ml of Trizol LS (Thermo Fisher Scientific) was added and RNA isolated according to the manufacturer's manual and resuspended in 10 µl of water.

Barcoding of beads by emulsion PCR. For eight PCR reactions, 140 µl of MyOne streptavidin C1 magnetic beads (Thermo Fisher Scientific) was washed twice in polypropylene tubes (Treff) on a magnetic rack with high salt buffer (20 mM Tris pH 8.0, 1 M NaCl, 1 mM EDTA). After resuspension in 280 µl of high salt buffer, 48 µl of 100 µM dual-biotinylated primer R (Integrated DNA technologies) was added and beads were mixed briefly by vortexing. Binding was allowed for 20 min at room temperature with occasional vortexing. Beads were then washed twice in high salt buffer and once in TTLE buffer (10 mM Tris pH 8.0, 0.5 mM EDTA, 0.05% Triton X-100) with 0.04 µg ml^{-1} of molecular biology grade BSA (NEB). Beads were resuspended in 280 µl of TTLE buffer with 0.04 µg μl^{-1} BSA and stored for up to 2 d at 4 °C.

The aqueous phase for eight PCR reactions using AccuPrime HiFi Taq DNA polymerase and reagents (Thermo Fisher Scientific) was prepared on ice in DNA LoBind tubes (Eppendorf). To 943 µl of water were added 128 µl of 10× PCR buffer I, 32 µl of $MgSO_4$ (50 mM stock), 25 µl of dNTP mix (stock of 25 mM each dNTP, Thermo Fisher Scientific), 32 µl of Primer F (100 µM stock, Sigma) and 40 µl of 1 µM non-biotinylated primer R (Sigma). Then, 35 µl of beads carrying dual-biotinylated primer R were pipetted extensively and heated at 95 °C for 40 s before addition to the PCR mix on ice. After mixing by pipetting, 20 µl of AccuPrime HiFi Taq polymerase was added, and the mix was pipetted again. Next, 25 µl of 1 nM random barcode template was heated for 1 min at 95 °C before immediate addition to the PCR mix on ice. The mix was extensively pipetted on ice. The oil phase for one PCR reaction consisted of 480 µl of Pico-Surf 1–5% in Novec 7500 (Sphere Fluidics). To 480 µl of Pico-Surf in polypropylene tubes (Treff), 160 µl of the PCR mix was added. The water–oil phase-separated mixture was then emulsified by vortexing using a Vortex Genie 2 vortexer (Scientific Industries) on a horizontal tube holder at 4 °C for 20 min at maximum speed, and 50 µl aliquots of the emulsion were pipetted into each well of a 96-well hard-shell plate (Biorad). The PCR was carried out with a lid temperature of 100 °C. After 1 min at 94 °C, 35 cycles of 15 s at 94 °C, 30 s at 58 °C and 45 s at 68 °C were performed, followed by 5 min at 68 °C.

The 50 µl emulsion PCR reactions were pooled and spun at 2,000 r.p.m. for 1–2 min in a benchtop centrifuge or until non-emulsified oil phase appeared at the bottom. The lower oil phase was removed, three volumes of the initial aqueous phase of 5% Ficoll 400 was added, and the mixture was vortexed. Then, 350 µl of PFOH (1H,1H,2H,2H-Perfluorooctan-1-ol) was added, and after vortexing, the mixture was incubated at 37 °C for 5 min. To separate beads from the mixture, the tube was placed on a magnet and incubated at 37 °C for 5–10 min. The PFOH phase at the bottom and the aqueous upper phase, if transparent, were removed. Beads were resuspended in the remaining aqueous phase and TLE buffer (10 mM Tris pH 8.0, 0.5 mM EDTA) was added up to a total volume of around 300 µl. The PFOH extraction was repeated. Beads were then washed three to four times in TLE buffer and transferred into new tubes. Further washes as specified followed: three times in 1% SDS buffer (20 mM Tris pH 8.0, 5 mM NaCl, 1% SDS), once in TLE buffer supplemented with 1% Triton X-100, once in TTLE buffer with 0.04 µg μl^{-1} BSA. Beads from eight PCR reactions were pooled and resuspended in 50 µl of TTLE buffer with 0.04 µg μl^{-1} BSA.

Barcoding quality controls. Two-barcode quality control experiments (Fig. 1c,d) were carried out as described above except that random barcode pools were replaced with two barcode templates with defined sequences. To count barcoded beads of two-barcode experiments, fluorescently labeled probes base-pairing to barcode sequences were hybridized. Briefly, 2 µl of beads from a 50 µl batch of eight PCR reactions were mixed with 3 µl of 10× Accuprime PCR buffer I, 2 × 2 µl of the two barcode-specific probes or 1 × 2 µl of T7 probe (100 µM) and water up to 30 µl. Hybridization was carried out using the following temperature program: 2 min incubations at 94 °C and 80 °C, then from 75 °C to 61 °C a temperature decrease by 1° every 2 min, followed by 10 min at 60 °C and 2 min at 55 °C, 50 °C and 45 °C, respectively. Beads were washed once with 1% SDS buffer, once in high salt buffer, then resuspended in 1× Accuprime PCR buffer I, which was pre-warmed at 67 °C and incubated for 3 min at 67 °C. These washes were repeated two more times. After resuspension in TTLE buffer with 0.04 µg μl^{-1} BSA, beads were pipetted extensively before analysis by flow cytometry. We used a FACSAria III machine (BD Biosciences) with a 70 µm diameter nozzle and removed neutral density filter. For two-barcode experiments, fluorophores were detected with settings for PE 582/15 nm (Cy3) and APC 670/14 nm (Cy5).

To control the fraction of barcoded beads when using random template pools, we only used a Cy5-labeled DNA probe (T7 probe) hybridizing to a non-random region of the barcodes. We retained bead batches with 40–60% barcoding.

Random tailing of barcodes on beads. First, unused primers immobilized on beads were digested by an exonuclease I (NEB) treatment. One batch of beads from eight PCR reactions was resuspended in 65 µl of 10× Exo I buffer, 520 µl of water and 65 µl of exonuclease I and incubated at 37 °C for 90 min. Beads were then washed once in1% SDS buffer, once in TLE buffer with 1% Triton X-100 and once in TTLE buffer with 0.04 µg μl^{-1} BSA. To remove untemplated adenosine overhangs added by *Taq* polymerase, beads were incubated for 30 min at 20 °C in 10 µl of NEB Next End Repair Reaction Buffer, 5 µl of NEB Next End Repair Enzyme Mix (NEB) and 85 µl of water. Wash steps were repeated as outlined after exonuclease I treatment. Beads were then subjected to a T7 exonuclease treatment in 20 µl of NEB 4 buffer, 10 µl of T7 exonuclease (NEB) and 170 µl of water for 15 min at 25 °C to generate single-stranded barcodes immobilized via their dual-biotinylated 5′ ends, which are inert to exonuclease activity. The same wash steps as described above were repeated. To add random bases to barcode ends on beads, a primer with a 5′ random overhang was hybridized to the 3′ ends of barcodes and the overhang used as template to introduce 3′ random bases to barcodes. To do so, beads were resuspended in a Pfx polymerase mix (Thermo Fisher Scientific) consisting of 10 µl of 10× Platinum Pfx buffer, 84 µl of water, 3 µl of 10 mM nucleotides, 2 µl of 50 mM $MgSO_4$, 1 µl of Random tail primer (100 µM) and 1 µl of Pfx polymerase enzyme. The mix was incubated for 2 min at 94 °C, 5 min at 55 °C and 10 min at 68 °C. The wash steps as described above were repeated. The T7 exonuclease treatment to generate single-stranded barcodes was repeated as described above. Beads were resuspended in 50 µl of TTLE buffer with 0.04 µg μl^{-1} BSA and stored at −20 °C or 4 °C until use.

In-emulsion reverse transcription of RNA-containing particles and crosslink reversal. Two batches of beads, equivalent to 16 PCR reactions, were used to reverse-transcribe RNA-containing particles equivalent to 50 ng of purified RNA. The beads were resuspended in 30 µl of TTLE with 0.04 µg μl^{-1} BSA, and freshly prepared Actinomycin D (Sigma) in DMSO was added for a final concentration of 6 ng μl^{-1} to inhibit reverse transcriptase activity on DNA templates. Possible aggregates of beads were disrupted by extensive pipetting, followed by sonication using a bioruptor UCD-200 sonicator (Diagenode) with power set to medium for two cycles of 5 s on followed by 5 s off. The 160 µl of RT mixes (Thermo Fisher

INFORME DE LABORES 2019

Scientific) prepared in LoBind tubes (Eppendorf) contained 32 µl of 5× First-Strand Buffer, 8 µl of 10 mM dNTP Mix (each), 8 µl of 0.1 M dithiothreitol (DTT), 2 µl of RNase inhibitor, 0.32 µl of BSA for a final concentration of 0.04 µg µl^{-1} (NEB), 1.6 µl of $MgCl_2$ for a final concentration of 0.5 mM,16 µl of Superscript III, 2 µl of Actinomycin D, final concentration of 5 ng µl^{-1}, nuclear homogenate corresponding to 50 ng of RNA, and water. The beads were heated at 90 °C for 1 min before addition to the RT mix on ice. The emulsion was prepared with 550 µl of Pico-Surf on a vortexer as described above at 4 °C for 40 min at maximum speed, and 50 µl per well was added to a 96-well plate. A cycling temperature program was used to increase the probability of RNA priming. In a thermocycler with lid temperature at 55 °C, samples were incubated at 55 °C for 2 min, then placed on ice for 2 min, followed by 30 min at 22 °C. Then, the following cycle was repeated 60 times: 22 °C for 1 min, ramping to 50 °C with a rate of 0.5 °C s^{-1}, 50 °C for 1 min. Emulsions were broken as described earlier. Beads were resuspended in 200 µl of 20 mM Tris pH 8.0, 50 mM NaCl and incubated overnight at 65 °C. cDNA on beads was treated with 1 µl of RNase H (Thermo Fisher Scientific) and 0.5 µl of RNase A (Roche Applied Science, 10 mg ml^{-1} of stock concentration) in 5 µl of 10× RNaseH buffer l (Thermo Fisher Scientific) and 43.5 µl of water for 30 min at 37 °C. Beads were then washed once in 1% SDS buffer, once in TLE buffer with 1% Triton X-100 and once in TTLE buffer with 0.04 µg µl^{-1} BSA and resuspended in 1× TTLE buffer with 0.04 µg µl^{-1} BSA.

Proximity RNA-seq library preparation. The second Illumina sequence was introduced by PCR with a primer flanked by a poly-C stretch after G-tailing of the barcoded and immobilized cDNA. For G-tailing, beads were resuspended in 5 µl of 10× TdT buffer (NEB), 5 µl of cobalt chloride, 2.5 µl of 100 µM dGTP/ddGTP mix (95 µM dGTP (Thermo Fisher Scientific), 5 µM ddGTP (Sigma)), 5 µl of TdT enzyme (NEB, 2 units µl^{-1} final) and 32.5 µl of water and incubated for 20 min at 37 °C. Beads were washed once in 1% SDS buffer, once in TLE buffer with 1% Triton X-100, once in 10 mM Tris pH 8.0, 0.5 M NaCl, 0.5 mM EDTA, 0.05% Triton X-100 and twice in TTLE buffer with 0.04 µg µl^{-1} BSA.

Beads were resuspended in 5 µl of 10× Accuprime buffer I, 42.5 µl of water, 0.5 µl of RP1_long primer (50 µM stock), 0.5 µl of polyC12_cDNA adapter (50 µM stock) and 0.5 µl of Accuprime HiFi Taq pol (Thermo Fisher Scientific). After 1 min incubation at 94 °C, five cycles of 15 s at 94 °C, 45 s at 52 °C and 2 min 30 s at 68 °C were carried out. The beads were captured, the supernatant containing the barcoded cDNA library was transferred to a new tube and 150 µl of 20 mM Tris pH 8, 50 mM NaCl, 1 mM EDTA was added. Size selection of PCR products using AMPure XP beads (0.75× the sample volume, Beckman Coulter) was repeated twice.

To reduce non-specific amplification and PCR duplicates during library amplification with low input, an emulsion PCR was performed. The eluate from the preamplification was mixed with 20 µl of 10× Accuprime buffer I, 2 µl of RP1 long (50 µM), 2 µl of Index primer (50 µM), 1 µl of dNTPs (stock of 25 mM each dNTP, Thermo Fisher Scientific), 1 µl of $MgSO_4$ (50 mM stock), 4 µl of Accuprime HiFi Taq pol and water for a final volume of 200 µl. The mix was emulsified for 20 min with 600 µl of Pico-Surf as described above. The emulsion was transferred into wells of a 96-well plate and the following PCR program run: 94 °C for 1 min, 20–24 cycles of 15 s at 94 °C, 30 s at 52 °C and 2 min 30 s at 68 °C. After pooling the PCR reactions, the aqueous phase was recovered and DNA was size-selected in one round with 0.65× AMPure beads and a second round with 0.8× AMPure beads. The final libraries were eluted in 35 µl of TLE buffer. The concentration and fragment size distribution of libraries were determined by Bioanalyzer profiles (Agilent Technologies) and Kapa Illumina SYBR green qPCR (Kapa Biosystems) according to manufacturer's instructions.

Species-mixing control experiment. For the species-mixing experiment, 1182-4H *Drosophila melanogaster* cells were cultured in M3 medium (10% FCS) according to recommendations of the Drosophila Genomics Resource Center (DGRC). Nuclear particles were prepared as described above for human cells. Fly particles equivalent to 50 ng of purified RNA were added to the same amount of human particles before encapsulation into droplets together with barcoded beads for reverse transcription. All steps were carried out as described for libraries with human particles only.

Hi-C library generation. Hi-C libraries were generated for biological duplicates as described previously[40,41]. Briefly, after fixation in 2% formaldehyde for 10 min, nuclei from 2–10 million SH-SY5Y cells were digested with HindIII at 37 °C overnight, and DNA ends were labeled with biotin-14-dATP (Life Technologies) in a Klenow fill-in reaction and then re-ligated overnight. After treatment with proteinase K (Roche) and crosslink reversal at 65 °C for 16 h, DNA was purified and sheared to an average size of 400 base pairs (bp), following manufacturer's instructions (Covaris). The sheared DNA was end-repaired, A-tailed and size-selected using AMPure XP beads (Beckman Coulter) to isolate DNA ranging from 250 to 550 bp in size. Accessible biotin at fragment ends was removed, and internally biotinylated fragments were immobilized on MyOne Streptavidin C1 DynaBeads (Invitrogen). Paired-end adapters (Illumina) were ligated to fragment ends and Hi-C libraries were amplified by PCR.

Dual RNA-FISH. The smiFISH (single molecule inexpensive FISH) strategy adapted here has been developed by Tsanov et al[42]. The transcript-specific probes (usually 24) are unlabeled but contain a fixed sequence complementary to a fluorescently labeled detector probe (FLAP oligo, Supplementary Table 1). Transcript probe design was performed with Stellaris probe designer (www.biosearchtech.com) with the following settings: probe length 20 bases, human masking level 5, minimal spacing 2 bases. The first and/or second intron of transcripts was used for probe design. An equimolar mix of probes (100 µM) was prepared, and 2 µl of this mix and 200 pmol of the FLAP oligo were added to 50 mM Tris pH 8, 100 mM NaCl in a final volume of 20 µl. The mix was incubated at 85 °C for 1 min. To hybridize probes with FLAP oligo, the temperature was then gradually decreased at 1 °C intervals from 66 to 59 °C and the mix incubated for 1 min at each temperature. After a final incubation at 55 °C for 1 min, labeled probes were frozen. Cells were seeded on a coverglass to reach around 80% confluency the following day. Then, cells on coverglasses were washed in 1× PBS and crosslinked with 3.7% formaldehyde in 1× PBS for 10 min at room temperature followed by two 1× PBS washes. Cells were permeabilized in 1× PBS with 0.3% SDS for 10 min at room temperature followed by 1× PBS with 1% Triton X-100 for 5 min at room temperature. Subsequently, samples were washed in wash buffer (2× saline sodium citrate (Thermo Fisher Scientific), 10% deionized formamide (Ambion), 10 mM Ribonucleoside Vanadyl Complex (NEB)) for 2–5 min. Coverglasses with fixed cells were then incubated upside down on 200 µl of hybridization buffer (2× saline sodium citrate (Thermo Fisher Scientific), 10% dextran sulfate, 10% deionized formamide (Ambion), 10 mM Ribonucleoside Vanadyl Complex (NEB)) with U3 probes (100 ng) and candidate transcript probes (3 µl of mix) in a light-tight humidified chamber for 4 h at 37 °C. After in situ hybridization, samples were washed twice for 30 min in wash buffer at 37 °C. During the second wash step, 10 ng ml^{-1} of DAPI was added. Then, coverglasses with cells were washed twice in 1× PBS and mounted on microscope slides using Prolong Diamond Antifade Mountant (Thermo Fisher Scientific). Stacked images were taken with a confocal Zeiss 780 microscope (Zeiss) and 3D distances measured using the Imaris software (Bitplane).

Electron microscopy of nuclei after EDTA regressive staining. EDTA regressive staining was conducted as originally reported[33] with modifications as follows. Briefly, cell pellets were fixed in 2.5% glutaraldehyde and 4% paraformaldehyde. Samples were then dehydrated with increasing concentrations of ethanol (50%, 70%, 80%, 90%, 96%, for 10 min each and 100% ethanol three times for 10 min). Then, samples were treated three times with propylene oxide for 5 min each. Samples were embedded in epoxy resin and polymerized at 60 °C for 16 h. Thin sections of about 50 nm width were mounted on copper grids covered with formvar and treated with 3% uranyl acetate for 3 min, rinsed and then floated on 0.2 M EDTA for 18 min at room temperature. After rinsing, cells were contrasted with 0.2% lead citrate for 2 min. The grids were washed with bi-distilled water and air-dried. Imaging was done with a transmission electron microscope (Jeol JEM-1010, Peabody, MA) operating at 80 kV and a CCD (charge-coupled device) camera (CCD-300-RC, MT 1).

Filtering and mapping of barcode and cDNA reads generated by Proximity RNA-seq. Proximity RNA-seq libraries were sequenced on two to three sequencing lanes. We combined the FASTQ files, 150 bp single-end, derived from the same library into one FASTQ file.

Properly constructed sequence reads started at the 5′ end with a 26 bp random barcode, immediately followed by a fixed 20 bp sequence, which specified one of the primer sequences used to amplify barcodes on beads. The pipeline confirmed that this fixed sequence was present, allowing for a 2 bp mismatch. Reads lacking the fixed primer sequence were discarded.

Low-complexity polynucleotides, the same nucleotide 13 or more times in a 20 bp sequence, in barcodes were removed. We chose this threshold because the probability of a randomly generated 20 bp sequence containing the same nucleotide at least 13 times was less than 1 in 1,000 (it was assumed that each nucleotide occurred with equal frequency and that any combination of nucleotides was equiprobable). In addition, the software filtered out putative adapter artefacts by screening barcodes against adapter sequences used in the generation of the library.

To account for errors in barcodes introduced throughout the protocol, which could lead to an inflation of the barcode complexity of a library and reduce the number of identified spatial RNA associations, the pipeline allocated barcodes to groups of barcodes of very closely related sequences, most likely derived from the same barcode.

To create these groups, barcode sequences were extracted from all the sequenced reads. This dataset was then de-duplicated and concatenated into a single string, in which barcodes were separated from one to another by 24 unspecified bases (*N*). The produced file was in FASTA format and was subsequently converted to a Bowtie 2 FM-index (based on the Burrows–Wheeler transform). Each barcode was then mapped back to this index using Bowtie 2 in FASTA mode, reporting all alignments (-a)[43]. Barcodes either mapped uniquely to this index or mapped to multiple locations. In the latter scenario, the two locations to which the read mapped were considered members of the same barcode group. After mapping, all barcode groups sharing a common barcode were collapsed into a single barcode group comprising all the observed, slightly varying barcodes.

We noticed barcode sequences that were identical to one another but offset by a nucleotide. If artefactual, this would cause new barcodes to be generated and

potentially split otherwise cobarcoded groups of transcripts. For this reason, we trimmed barcodes by 3 bp at either end after extracting from the 150 bp sequenced read and before mapping to the virtual barcode genome, which consisted of the full 26 bp units.

Finally, to remove large, likely false positive transcript groups, we chose a conservative cutoff in which the pipeline modeled the variation in increasing barcode group size, that is, the number of cobarcoded transcripts, as a Poisson distribution. Barcode groups of a size so large that they would have been expected to occur with a probability of less than 0.001 were removed from the dataset.

For mapping cDNA sequences, the first 67 bp from the start of a read were removed (26 bp barcode, 20 bp barcode PCR primer, 15 bp random reverse transcription primer and six extra base pairs, which improved mapping efficiency); the next 50 bp were retained and mapped to the human genome using HISAT2 with default parameters[44] and known splice-sites (GRCh38.83).

Ribosomal RNA sequences in the reference human genome 38 were masked. The rRNA sequence was subsequently re-introduced into the genomic sequence as a separate chromosome (NCBI Reference Sequence: NR_046235.1).

Following mapping, exact read duplicates (reads sharing identical barcodes and mapping to the same position) were removed, but one representative copy was retained.

Custom transcriptome annotation. We used gene annotations from ENSEMBL Human Genome 38 (Ensembl 78: December 2014) as transcript units. We divided the reference annotation so that reads could be aligned unambiguously to a single feature. Since genes may overlap, we defined a hierarchy to establish how regions were classified (Supplementary Fig. 2). First, the pipeline used the ENSEMBL Human Genome 38 to retrieve gene coordinates and repeat masker to define RNA repeat regions in Human Genome 38 (http://www.repeatmasker.org). Opposing strands were treated separately with respect to overlapping genes, but regions of overlap between genes on the same strand were excluded. An exception to that rule was when genes were contained entirely within a surrounding gene. In such instances, the area of overlap was assigned to the inner gene. This was particularly important, since many genes, such as snoRNAs, are often located entirely within larger genes. Reads mapping to either strand of a RNA repeat region in the genome were assigned to single representations of 5S, HY1, HY3, HY4, HY5, U1, U2, U3, U4, U5, U6, U7, U8, U13, U14, U17, BC200, transfer RNA (all t-RNAs were collapsed into one feature), 7SLRNA and 7SK.

For gene features, only uniquely mapping reads were kept. The pipeline allowed multi-mapping as long as the best possible alignment corresponded to a predefined repeat region. Reads not mapping to any feature were discarded.

The pipeline grouped features into RNA particles or transcript groups based on the barcode read sequences. Multiple reads with the same barcode and mapping to the same transcript were counted as one observation, which we named a proxy read, due to the ambiguity of the multiple reads originating from a single RNA molecule or from several copies of the same transcript.

Monte Carlo simulation to identify preferential pairwise RNA contacts. We created a Monte Carlo simulation to identify preferential spatial associations or contacts between pairs of transcripts. The simulation took as input: (1) the number of transcript groups or RNA particles observed, which equals the number of unique barcodes in a dataset, (2) the barcode group size of each of those particles and (3) the frequency with which each transcript was observed in the dataset (number of proxy reads). The simulation first constructed frequency distributions for barcode group size and transcript abundance. Then, virtual RNA particles were created in silico by selecting a random value from the barcode group size distribution and then randomly selecting different transcripts from the transcript abundance distribution to fill up the barcode group. Again, the simulation allowed any combination of transcripts within a barcode group except combinations with multiple observations of the same transcript. On the occasion when a transcript was selected that was already present in the particle, the selection of the new transcript was rejected and instead added to a priority pool. Transcripts inside the priority pool were randomly picked for the generation of the following virtual RNA particle.

Following random particle generation, the cobarcoded pairwise RNA contacts were counted. In total, 100,000 simulations were performed, and the number of simulations in which a pairwise RNA contact occurred at least as many times as in the observed data was recorded. This gave a *P* value for the probability that an observed RNA–RNA contact in the real data could have occurred with that frequency by chance. One of the simulated randomized datasets was also passed to the Monte Carlo simulation to undergo 100,000 simulations. We intended that this would give us a measure of the variation between random datasets (but still retain comparable barcode group size and transcript abundance distributions to those of the observed datasets). There were now two groups of Monte Carlo simulations: the first the result of performing 100,000 simulations on the observed dataset (group 1) and the second the result of performing 100,000 simulations on one of the randomized datasets (group 2) of group 1.

Each *P* value assigned to an observed contact after comparison with group 1 was then added to a local distribution of 500 *P* values from the group 2 simulations. The local distributions were chosen to most closely match the RNA–RNA contact being examined in terms of the observed and simulated counts. Each distribution was modeled as a normal distribution to assign a probability of a given contact falling within that distribution. Consequently, for infrequent contacts the selected distributions generally exhibited high variability, whereas for frequent contacts the variability was lower, so the new *P* values calculated took this change in variability into account. These new, local-background-corrected *P* values obtained from the normal distribution, referred to simply as *P* values throughout the manuscript, were used when filtering spatial RNA associations and for principal component and t-SNE analyses. Furthermore, background-corrected *P* values were adjusted using Benjamini–Hochberg multiple testing correction.

Nascent versus processed transcriptome analysis. We categorized the Binary Alignment Map (BAM) format reads mapped by HISAT2 into one of three categories: 'Exon Junction', 'Nascent' or 'Other'. To achieve this, we defined regions in human genome assembly 38.78 as unambiguously intronic: that is, notated as an intron but never also notated as an exon in the case of overlapping isoforms or genes. After determining the genomic positions of these sequences, we identified BAM reads in which both ends overlapped an unambiguous intron sequence, and analysis of the Compact Idiosyncratic Gapped Alignment Report (CIGAR) string showed that the read was not split by HISAT2 during mapping. These were considered nascent reads. In contrast, we defined exon junction reads as those that that were split by HISAT2 during mapping and neither of the split read sequences overlapped with a predefined unambiguous intron region. All reads classified neither as exon junction nor as nascent were labeled as other.

Poisson distribution in bead barcoding. Bead barcoding, and in general the integrity of emulsions generated as described earlier, was controlled by applying a Poisson model to two-barcode PCR assay data (see section "Barcoding quality controls"). Specifically, flow cytometry analysis of barcoded beads was used to count the number of beads without barcodes, beads with both barcodes and beads with signal from only one of the two barcodes. However, beads for which we detected only one type of barcode could originate from PCR reactions with initially a single or multiple copies of one of the barcode templates. Similarly, beads with both barcode types could originate from more than two templates. We estimated the number of initial barcodes per droplet as follows. Let X and Y be the hidden number of initial barcode templates of each type on a bead. We assumed that $X \approx \text{Poisson}(\lambda_X)$ and $Y \approx \text{Poisson}(\lambda_Y)$, with X and Y independent. For each bead, we observe $I_X = I(X > 0)$ and $I_Y = I(Y > 0)$—that is, binary indicators of whether each Poisson variable is greater than zero. It can be shown that the maximum likelihood estimate of λ_X is $-\log(1 - \text{mean}(I_X))$, with a similar result for λ_Y. From this information, we estimated the number of beads with unique barcodes, which is $P(X+Y=1) = (\lambda_X + \lambda_Y)\exp(-\lambda_X - \lambda_Y)$ (since $X + Y \approx \text{Poisson}(\lambda_X + \lambda_Y)$). Similarly, the number of beads with multiple barcodes is $P(X+Y>1) = 1 - P(X<2) = 1 - (1 + \lambda_X + \lambda_Y)\exp(-(\lambda_X + \lambda_Y))$. Hence, we estimated the ratio of single-to-multiple barcodes as $P(X+Y=1)/P(X+Y>1)$. This assumption can be verified with the chi-squared test of independence—we used two degrees of freedom, since the total number of beads is not fixed and two parameters are estimated from the data.

Mapping statistics. We compared the percentage of reads mapping to genes, exons and introns (Ensembl 78: December 2014) from Proximity RNA-seq and ribosomal RNA-depleted total RNA library from SH-SY5Y cells[39] (SRX1007599) with the percentage of base coverage of the same features. Genes were set as 100.

U3 RNA proximities and experimental controls. The number of cobarcoding events was plotted against the number of proxy reads for each transcript. A Mann–Whitney *U*-test was performed on the log ratios ($\log_2$(cobarcoding counts) − $\log_2$(proxy reads)) for snoRNAs and non-snoRNAs.

Number of cobarcoded transcripts of top 1,000 RNAs. We restricted the analysis to the top 1,000 transcripts (based on the number of proxy reads in the observed dataset). For each of these transcripts, the number of unique, cobarcoded transcripts was counted irrespective of how many times a given pair of transcripts was observed together. The number of unique, cobarcoded transcripts was plotted against the number of proxy reads for the corresponding transcript of the top 1,000 list. Using the top 1,000 transcripts from the observed dataset, unique cobarcoded transcripts were retrieved from random simulations as well. Fisher's exact tests were performed for each transcript on 2 by 2 tables, which included the number of contacted, that is, cobarcoded, transcripts and the number of transcripts that were not cobarcoded of the top 1,000 transcriptome for the observed and the randomized data. The top 1,000 proximal transcriptome was defined as the union between observed and simulated datasets of all transcripts contacted at least once by any top 1,000 RNA. *P* values were false discovery rate (FDR)-adjusted to control for multiple testing.

RNA proximities and genomic distance. Monte Carlo simulation-derived $-\log_{10}$ *P* values, capped at 10, were plotted for RNA association pairs with more than three observations and after filtering out RNA repeats with multiple gene loci against genomic distance between the RNA-encoding genes.

INFORME DE LABORES 2019

Principal component analysis on pairwise RNA contacts. We performed PCA on a matrix of $-\log_{10} P$ values within each cell from pairwise spatial RNA associations. The top 100 connected transcripts were used as input variables (columns) and all transcripts as observations (rows). Including more transcripts as input variables resulted in failure of PCA due to violation of the normality assumption. Furthermore, we only used pairwise spatial RNA associations with more than three observations and a P value cutoff ≤ 0.1 as derived by the Monte Carlo simulations. We removed transcripts with only one reported pairing with another transcript and associations that involved mitochondrial ribosomal RNA. We restricted $-\log_{10} P$ values to a plateau at 5 and then subtracted the matrix mean from cells before performing PCA (R: princomp, using the correlation matrix). Transcripts were assigned to eight quantiles based on PC2.

Analysis of PC2 quantiles. Transcripts contained within the eight PC2 quantiles were assigned to RNA classifications retrieved from HGNC (HUGO gene nomenclature committee, http://www.genenames.org/).

We analysed enrichments of biological processes from gene ontology for transcripts in PC 2 quantiles using ToppCluster[45] (https://toppcluster.cchmc.org/). A P value cutoff ≤ 0.05 and Bonferroni correction were selected. Furthermore, limits of transcript number n (minimum and maximum number of transcripts allowed for an annotation) were set to $5 \leq n \leq 1{,}500$. Identified terms of biological processes were clustered for visualization in Supplementary Fig. 8 based on semantic grouping using the R package GOSemSim[46].

Tissue specificity of transcripts in PC2 quantiles based on Tau scores, where 0 means broadly expressed and 1 is specific, was retrieved from Kryuchkova-Mostacci and Robinson-Rechavi[23]. The expression data are based on RNA-seq measurements of 27 human tissues[22].

Exon inclusion scores, a measure for how often an exon is included in the mature transcript molecule, were used to estimate alternative splicing of transcripts in PC2 quantiles. For exons of known mRNA isoforms (excluding non-coding RNAs) as defined by the UCSC Genome Browser (GRCh37/hg19) scores were obtained from the HEXEvent database[26] (http://hexevent.mmg.uci.edu/). Furthermore, the exon inclusion scale from 0 to 1 was divided into eight equal interval groups. Thus, each exon had an assigned exon inclusion group and also a PC2 quantile. To identify overrepresented or underrepresented combinations of exon inclusion group and PC2 quantile, we used a Poisson generalized linear model (GLM). We counted the number of transcripts with each combination. This count was regressed against a linear combination of exon-inclusion-group-specific and PC2-quantile-specific parameters via a logarithmic link function. The Pearson residuals from this regression model were plotted in a heatmap.

t-SNE using introns, exon junctions and other features of transcripts or gene-based annotations. The same matrix as for PCA with $-\log_{10} P$ values within each cell from pairwise spatial RNA associations was used for t-SNE. The top 100 connected transcripts were used as input variables (columns) and all transcripts as observations (rows). Again, we only used pairwise spatial RNA associations with more than three observations and a P value cutoff ≤ 0.1 as derived by the Monte Carlo simulations. We removed transcripts with only one reported pairing with another transcript and associations that involved mitochondrial rRNA. We restricted $-\log_{10} P$ values to a plateau at 5 and then subtracted the matrix mean from cells before performing t-SNE (Rtsne package: seed 96, perplexity = 50, theta = 0.2). Similarly, for gene-based annotations the PCA matrix was used for t-SNE visualization (seed 96, perplexity = 46, theta = 0.1).

Assignment of valency to transcripts. Proxy reads for each transcript were counted in barcode groups of different size (named valencies). We then selected transcripts with the sum of valency 1, 2 and 3 (1: an observation of a single transcript, 2: two different transcripts detected with one barcode, 3: three different transcripts detected with one barcode) greater than 10 proxy reads. For each transcript, counts in valency 1, 2 and 3 were divided by the sum of all three valencies of that given transcript. Subsequently, the transcriptome-wide distributions of the three valencies were separately transformed into z-scores. Transcripts were then assigned to high- and low-valency classes, respectively. High-valency transcripts were defined based on z-scores of valency 1 <0 and a mean of valency 2 and 3 z-scores >0. Low-valency transcripts had z-scores of valency 1 >0 and a mean of valency 2 and 3 z-scores <0. Furthermore, only transcripts reproducibly assigned to high- and low-valency classes in Proximity RNA-seq triplicates were retained and used for further analysis. To analyse the valency of a group of transcripts proximal to a specific RNA, the mean valency z-scores were used.

Hi-C data processing. Sequencing data generated by Hi-C of two biological replicates were processed using HiCUP, which includes mapping to the reference genome, di-tag filtering and removal of artefacts[47].

Each chromosome contact matrix was normalized using TADbit[32]. Briefly, low-quality bins (those presenting low contacts numbers) were removed and ICE normalization[48]—also known as 'vanilla' normalization[36]—was performed using the default settings.

Identification of subnuclear genomic compartments. To segment the genome into A and B regions, the normalized Hi-C matrices at 100 kb resolution were transformed into correlation matrices using the Pearson product-moment correlation. The first component of a PCA (PC1) on each of these matrices was used as a quantitative measure of compartmentalization, and gene expression values (rpkm) from Proximity RNA-seq data were used to assign negative and positive PC1 categories to the correct compartments. If necessary, the sign of the PC1 (which is randomly assigned) was inverted so that positive PC1 values corresponded to A compartment regions and vice versa for the B compartment.

Integrative 3D chromosome modeling with TADbit. To assess the potential of the Hi-C data for modeling, we computed the MMP score (0.6) of the matrix and the predicted accuracy of the models, named distance Spearman correlation coefficient (0.5), using the MMP score as implemented in TADbit[32,49]. The MMP score is based on the matrix size, the contribution of significant eigenvectors in the matrix, and the skewness and kurtosis of the z-scores distribution of the matrix.

The normalized interaction matrix of chromosome 14 was used for modeling at a resolution of 100 kb. The short chromosome arm and the centromere were omitted due to the poor quality of the contact information. TADbit generates 3D models using a restraint-based modeling approach, where the experimental frequencies of interaction are transformed into a set of spatial restraints. The size of each particle in the models was defined by the relationship 0.01 nm bp^{-1} assuming the canonical 30 nm fibre[50]. Using a grid search approach, TADbit identified empirically the three optimal parameters to be used for modeling: (1) maximal distance between two non-interacting particles (maxdist set as 1,600 nm); (2) a lower-bound cutoff to define particles that do not interact frequently (lowfreq set as −1.6); and (3) an upper-bound cutoff to define particles that do interact frequently (upfreq set as 0.0). Once the three optimal parameters are defined, TADbit sets the type of restraints between each pair of particles considering an inverse relationship between the frequencies of interactions of the contact map and the corresponding spatial distances. Two consecutive particles were spatially restrained by a harmonic oscillator with an equilibrium distance that corresponds to the sum of their radii. Non-consecutive particles with contact frequencies above the upper-bound cutoff were restrained by a harmonic oscillator at an equilibrium distance, while those below the lower-bound cutoff were maintained further than an equilibrium distance by a lower-bound harmonic oscillator. To identify 3D models that best satisfy all the imposed restraints, the optimization procedure was then performed using a Monte Carlo simulated annealing sampling protocol as implemented in TADbit. A total of 5,000 models were generated and only the 1,000 that best satisfied the input restraints were used for further analysis. The contact map obtained from the final 1,000 models ensemble resulted in a Pearson correlation of 0.72 with the input Hi-C interaction matrix, which is indicative of good model accuracy[49].

Clustering was performed on the models ensemble to assess its structural similarity using a pairwise rigid-body superposition that minimizes the root mean squared deviation (r.m.s.d.) between the superimposed conformations, as implemented in TADbit.

Structural analysis of the 3D chromosome model. Using TADbit, a set of descriptive measures were calculated to analyse the structural properties of each particle in the ensemble model: (1) accessibility, measuring how accessible a particle is from an external object of radius of 150 nm; (2) density, measuring the local compactness of the chromatin fibre; (3) contact density, counting the number of particles within a given spatial distance (2× particle size) from a specified particle; and (4) walking angle, measuring the angle formed by a particle and its two immediate neighbor particles. Using these descriptive measurements, we calculate local proprieties of the ensemble model. We define local accessibility of a particle as the mean accessibility value of a given particle over all N models in the ensemble. Similarly, we define local contact density of a particle as the mean contact density of a given particle over all N models in the ensemble; this is used as a proxy for local packing density.

A density map is generated for each cluster in the ensemble using the *molmap* command in Chimera[51]. The density map is represented by intensities at points i (ρ_i) on a cubic grid with a grid space of resolution in kb divided a factor of 3. Each structure is defined by its beads coordinate in Cartesian space and a mass corresponding to 1 bead unit.

The density ρ_i is defined with a Gaussian function as:

$$\rho_i = \sum_N \frac{Z_N}{(\sigma\sqrt{2\pi})^3} e^{-\frac{(x-x_n)^2+(y-y_n)^2+(z-z_n)^2}{2\sigma^2}}$$

x, y and z are the Cartesian coordinates of particle N, Z_N is the mass and σ is set equal to the resolution in kb (100). Density maps for specific compartments or regions are generated accordingly.

The distances between the centers of mass (COMs) of different density map regions were calculated to analyse the relative positioning of high- and low-valency regions with respect to the B compartment. Analysis was performed with Chimera[51].

Hi-C contact enrichments between genomic valency segments. We computed contact enrichments between all PCA-derived Hi-C regions (A and B regions,

INFORME DE LABORES 2019

excluding chromosome X) using a statistical model based on a binomial test to estimate the significance of contacts as implemented in SeqMonk (https://www.bioinformatics.babraham.ac.uk/projects/seqmonk/). Contacts with P values ≤ 0.05 and at least five observations were reported. High- and low-valency transcripts (see method paragraph on valency) were scored as 1 and −1, respectively, and for every A, B genomic region the mean score of valency transcripts overlapping the region was calculated. We selected regions with at least three transcripts with assigned valency for further analysis. Low-valency regions were defined based on scores smaller than or equal to the median of all region valency scores; high-valency regions had bigger scores than the median. Regions that did not overlap with any valency transcript were classified as no-valency regions. Empirical cumulative distribution functions and means of $\log_2$ observed/expected contacts (contact enrichment) were plotted for groups of contact pairs as indicated (Fig. 6c).

Regression of intronic read density decay. We implemented a linear regression analysis to estimate the read decrease along introns into the SeqMonk suite (https://www.bioinformatics.babraham.ac.uk/projects/seqmonk/). Briefly, Proximity RNA-seq, pool of p2, p5, p8 and p7 libraries, was used as a 1D RNA-seq dataset after read de-duplication based on genomic position and ignoring RNA particle-specific barcodes. We only considered introns of at least 30 kb in length. Reads were binned into 500 bp windows for linear regression. Regressions were only reported if the slope was negative and the P value did not exceed 0.05. All slope values were reported multiplied by a factor of 1,000,000. For genomic intervals overlapped by multiple intron isoforms, the mean slope of all isoforms was used. Genomic regions with two or more valency transcripts and three or more introns with estimated elongation rates were included in the analysis.

Statistics. Proximity RNA-seq libraries were generated from multiple independent SH-SY5Y cell cultures. The frequency with which pairwise RNA cobarcoding occurred at least as many times in simulations as in observed data generated P values for RNA–RNA proximities. P values were then background-corrected based on local distributions of observed and simulated RNA–RNA proximity counts modeled as normal distributions.

In follow-up analyses exact sample sizes and statistical tests, all two-sided, are noted.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

Proximity RNA-seq and Hi-C raw sequencing data are available on Gene Expression Omnibus accession: GSE129732.

Code availability

Code for Hi-C and Proximity RNA-seq analysis is available on github: https://github.com/3DGenomes/TADbit and https://github.com/StevenWingett/CloseCall, respectively.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistical parameters

When statistical analyses are reported, confirm that the following items are present in the relevant location (e.g. figure legend, table legend, main text, or Methods section).

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒	An indication of whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☐	☒	A description of all covariates tested
☐	☒	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistics including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☐	☒	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated
☐	☒	Clearly defined error bars *State explicitly what error bars represent (e.g. SD, SE, CI)*

Software and code

Policy information about availability of computer code

Data collection	Read sequences were acquired using Illumina instrumentation and software. For dual RNA-FISH, probe design was performed with Stellaris probe designer (www.biosearchtech.com), 3D FISH distances were measured using the Imaris software (Bitplane).
Data analysis	All software and code used in this study has been described in published literature (Bowtie v2.2.6, HICUP v0.5.8, Bowtie v2.3.2, Hisat2 v2.1.0, SeqMonk v1.35.0, R v3.1.3, ToppCluster) or are custom made and available on github, https://github.com/3DGenomes/TADbit and https://github.com/StevenWingett/CloseCall.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

Proximity RNA-seq and Hi-C sequencing data are available on Gene Expression Omnibus (GEO) accession: GSE129732.

Field-specific reporting

Please select the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/authors/policies/ReportingSummary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	Proximity RNA-seq with identical experimental parameters was performed using 3 biological replicates. Results were pooled for subsequent analysis. Hi-C experiments were performed in duplicates and reads pooled for further analysis.
Data exclusions	No data was excluded.
Replication	All attempts to replicate data were successful.
Randomization	No randomization was required for this study since no comparisons were made between samples/experimental groups.
Blinding	No blinding was required for this study since no comparisons were made between samples/experimental groups.

Coronary Artery Disease Risk-Associated *Plpp3* Gene and Its Product Lipid Phosphate Phosphatase 3 Regulate Experimental Atherosclerosis

Paul A. Mueller, Liping Yang, Margo Ubele, Guogen Mao, Jason Brandon, Julia Vandra, Timothy C. Nichols, Diana Escalante-Alcalde, Andrew J. Morris, Susan S. Smyth

OBJECTIVE: Genome-wide association studies identified novel loci in *PLPP3* (phospholipid phosphatase 3) that associate with coronary artery disease risk independently of traditional risk factors. *PLPP3* encodes LPP3 (lipid phosphate phosphatase 3), a cell-surface enzyme that can regulate the availability of bioactive lysophopsholipids including lysophosphatidic acid (LPA). The protective allele of *PLPP3* increases LPP3 expression during cell exposure to oxidized lipids, however, the role of LPP3 in atherosclerosis remains unclear.

APPROACH AND RESULTS: In this study, we sought to validate LPP3 as a determinate of the development of atherosclerosis. In experimental models of atherosclerosis, LPP3 is upregulated and co-localizes with endothelial, smooth muscle cell, and CD68-positive cell markers. Global post-natal reductions in *Plpp3* expression in mice substantially increase atherosclerosis, plaque-associated LPA, and inflammation. Although LPP3 expression increases during ox-LDL (oxidized low-density lipoprotein)-induced phenotypic modulation of bone marrow-derived macrophages, myeloid *Plpp3* does not appear to regulate lesion formation. Rather, smooth muscle cell LPP3 expression is a critical regulator of atherosclerosis and LPA content in lesions. Moreover, mice with inherited deficiency in LPA receptor signaling are protected from experimental atherosclerosis.

CONCLUSIONS: Our results identify a novel lipid signaling pathway that regulates inflammation in the context of atherosclerosis and is not related to traditional risk factors. Pharmacological targeting of bioactive LPP3 substrates, including LPA, may offer an orthogonal approach to lipid-lowering drugs for mitigation of coronary artery disease risk.

VISUAL OVERVIEW: An online visual overview is available for this article.

Key Words: atherosclerosis ■ coronary artery disease ■ lipid phosphate phosphatase ■ lysophospholipids ■ lysophosphatidic acid

Downloaded from http://ahajournals.org by on October 20, 2020

Coronary artery disease (CAD) is a major component of cardiovascular disease and a leading cause of death worldwide. Due to the complexity of the disease, contributors to CAD risk can be divided into several factors, but more generally, they include both heritable and nonheritable risk factors. Genome-wide association studies identified heritable single nucleotide polymorphisms (SNPs) in *PLPP3* (phospholipid phosphatase 3), previously referred to as *PPAP2B*, as novel loci associated with risk of CAD and its complications independent of traditional risk factors.[1–3] LPP3 (lipid phosphate phosphatase 3), encoded by the gene *PLPP3*, is a cell surface enzyme that can regulate the availability and hence the signaling actions of bioactive lipids including lysophosphatidic acid (LPA). The risk-associated haplotype block is in the final intron of *PLPP3* and contains a CEBP-β (CCAAT enhancer binding protein-β) motif. The CAD risk allele disrupts transcriptional enhancer activity induced by CEBP-β binding.[4] CEBP-β binding increases transcription from the *PLPP3* promoter, and polymorphisms that disrupt this interaction are associated

Nonstandard Abbreviations and Acronyms

BMDM	bone marrow-derived macrophages
CAD	coronary artery disease
CEBPβ	CCAAT enhancer binding protein beta
LPA	lysophosphatidic acid
LPAR4	LPA receptor 4
LPP3	lipid phosphate phosphatase 3
MYH11	myosin heavy chain 11
MβCD	methyl-β-cyclodextrin
ox-LDL	oxidized low-density lipoprotein
PLPP3	phospholipid phosphatase 3
SMC	smooth muscle cell
SNPs	single nucleotide polymorphisms
Tfam	transcriptional factor A mitochondrial

with lower *PLPP3* gene expression in monocytes exposed to ox-low-density lipoprotein (oxidized LDL).[4] In addition to identifying a local expression quantitative trait loci effect in monocytes, we have demonstrated that exposure of human monocytes to ox-LDL increases LPP3 expression and activity, and that the CAD risk allele in *PLPP3* is associated with lower LPP3 expression.[4,5] Others have reported similar findings in other vascular cells.[6]

We have previously demonstrated a protective role for LPP3 and its biological target LPA in vascular injury models in a tissue-specific manner.[7–9] In fact, the loss of LPP3 in vascular smooth muscle cells exacerbates local inflammation and proliferation after carotid artery ligation that leads to increased neointimal formation likely via heightened ERK (extracellular signal–regulated kinase) activity and Rho activation.[7] We also demonstrated vascular smooth muscle cells LPP3 expression increases after injury and vascular smooth muscle cells proliferation increases with exposure to LPA.[7] In addition, endothelial, but not hematopoietic, deletion of *Plpp3* increases vascular permeability in healthy mice and enhances sensitivity after inflammation-induced vascular leak.[8] Both pharmacological and genetic inhibition of LPA production attenuates the increased vascular leak observed in this model.[8] With respect to CAD, LPP3 expression in vascular endothelial cells is critical in maintaining an anti-inflammatory phenotype and vascular barrier integrity in regions of atheroprotective blood flow.[10] In addition, LPP3 expressed in the liver of mice limits atherosclerosis progression and modulates systemic LPA levels.[11] Finally, treating mice susceptible to atherosclerosis, either through diet or peritoneal injections, with unsaturated LPA species prone to oxidation accelerates lesion formation compared with mice fed saturated LPA species.[12,13] Cumulatively these data demonstrate LPP3 harbors a protective role against injury in the vasculature and that its regulation of bioavailable LPA may be a crucial mechanism.

Highlights

- LPP3 (lipid phosphatase 3) is augmented during atherosclerosis.
- *PLPP3* (phospholipid phosphatase 3 deficiency diminishes experimental atherosclerosis.
- Deficiency of smooth muscle cell LPP3 increases atherosclerosis.

Together these observations suggest a link between polymorphisms in *PLPP3* and CAD and, specifically, that upregulation of LPP3 after injury may protect against the development and complications of CAD in humans. To functionally validate these observations, we sought to determine whether LPP3 expressed globally, or in a tissue-specific manner, influences the development of experimental atherosclerosis. Herein, we present that the loss of *Plpp3* globally or in vascular smooth muscle cells alone accelerates the progression of experimental atherosclerosis possibly in part via LPA signaling through the LPA4 (LPA receptor 4).

METHODS

The data that support the findings of this study are available from the corresponding author on reasonable request.

Animals

All procedures conformed to the recommendations of Guide for the Care and Use of Laboratory Animals[14] and were approved by the Institutional Animal Care and Use Committee. The production, initial characterization, and backcrossing of mice have previously been described.[15] To generate mice susceptible to atherosclerosis, *Plpp3fl/fl* animals (fl/fl) with or without the MX1-Cre or smooth muscle cell (SMC-22) Cre (referred to as SM22-Δ) transgene were crossed to *Ldlr*$^{-/-}$ mice (The Jackson Laboratory; Bar Harbor, ME). Littermate pups with and without the MX1 Cre transgene were treated with polyinosinic-polycytidylic acid (Sigma) between post-natal days 3 o 5 to activate the MX1 promoter (referred to as MX1-Δ). To generate *Ldlr*$^{-/-}$ mice lacking *Plpp3* in myeloid cells, lethally irradiated animals (900 rads) were reconstituted with bone marrow from fl/fl mice without or with LysM-Cre transgene (referred to as LysM-Δ). To simulate LDL receptor deficiency, mice lacking *Lpar4*[16] were backcrossed to the C57BL/6J background and then bred to generate *Lpar4*$^{Y/+}$ and *Lpar4* $^{Y/-}$ mice, which were injected with PCSK9D377Y.AAV (1×10^{11} genomic copies/mouse; provided by University of Pennsylvania, Penn Vector Core) before feeding Western diet. Mice were housed in cages with HEPA-filtered air in rooms on 12-hour light cycles, and fed Western diet (Research Diets, New Brunswick, NJ, D12079B) ad libitum for 12–20 weeks. Both male and female mice were used for the MX1 and Sm22 models of *Plpp3* ablation, and their data combined as no sex-specific differences were observed (Data not shown). Due to a lack of differences in these models, only male mice were used for the LysM bone marrow transplant model of *Plpp3* ablation. Finally, because *Lpar4* is on the X-chromosome,

Downloaded from http://ahajournals.org by on October 20, 2020

both male and female mice were used and reported separately. For procedural anesthesia, 2% isoflurane was delivered using the Harvard Apparatus Anesthetic Vaporizer. For euthanasia, mice were anesthetized with 5% isoflurane followed by cervical dislocation. This study was designed in adherence to the guidelines for experimental atherosclerosis studies as recommended in the American Heart Association statement, which includes the use of our mouse models (including proper use of sample size and use of both sexes where appropriate), quantification of atherosclerosis, characterizing plasma lipids, statistical analyses, and presentation of data.[17]

Quantification of Atherosclerosis and Immunohistochemistry

Atherosclerosis was quantified along the proximal aorta by en face technique and also by measuring lesion size at the aortic root by oil-red-O staining of tissue sections. Aortas were cleaned of the adventitia and dissected from the aortic root to the iliac bifurcation. Aortas were cut open longitudinally, exposing the intimal surface, and atherosclerosis was quantified on the intimal surface of the aorta by an en face technique and reported as proportion of total area. Aortic roots were serially sectioned (10 µm) starting ≈3 mm from the base of the aortic root as described previously.[18] Sections were stained with filtered oil red-O (0.25% in 2-propanol), counterstained with hematoxylin, and oil red-O area was quantified in sections using ImageJ software[19] and reported as lesion area.

Immunohistochemistry

Primary antibodies were LPP3,[20] smooth muscle alpha-actin (2 µg/mL; Abcam AB5694), CD68 (10 µg/mL; Abcam AB53444), PECAM1 (platelet-endothelial cell adhesion molecule-1; 5 µg/mL; BD Biosciences 553370), and podocalyxin (2 µg/mL; R&D Systems AF1556). In situ hybridization and proximity, ligation assays were performed as previously described.[21] Imaging was performed using a Nikon A1R confocal microscope with a spectral detector (Nikon, Melville, NY). For lipid measurements, aortic roots were homogenized in 0.5 mL of 0.1 mol/L HCl and extracted and GC-MS/MS performed with internal standards as described previously.[22] Using this method, S1P was undetectable in the proximal aortic tissue.

Gene Expression Analysis of Proximal Aortas

Proximal aortas were homogenized and treated with the Qiagen RNeasy Fibrous Tissue Mini Kit (Qiagen, Germantown, MD, ID:74704), and RNA (1 µg) was used for the generation of a cDNA library using MultiScribe Reverse Transcriptase (Life Technologies, Waltham, MA, 4311235). cDNA was diluted 1:10 and used in a reaction with the TaqMan Fast Universal PCR Master Mix (2×; Life Technologies, Waltham, MA, 4364103) with VIC/FAM (fluorescent reporter dye VIC specific for allele "A"/6-carboxyfluorescein FAM specific for allele "B") primers from Life Technologies designed for specific gene targets.

Plasma Analysis

Whole blood was collected into CTAD tubes supplemented with EDTA, and plasma separated by centrifugation (12 000 rpm×4 minutes). Total plasma cholesterol was measured using the Wako Diagnostics Cholesterol E Assay (Wako Diagnostics, Richmond, VA, 999-02601), and plasma triglycerides were measured using the Wako Diagnostics L-type TG M Assay with the Multi-Calibrator Lipid Standard (Wako Diagnostics, Richmond, VA, 464-01601) according to the manufacturer's protocol. Plasma lipoproteins were separated by fast-performance liquid chromatography on to a Superose 6 column (Sigma-Aldrich, St Louis, MO) and were performed on individual mouse plasma samples (N=4/genotype). Cholesterol concentration in fractions was determined by enzymatic colorimetric assay (Wako Diagnostics, Richmond, VA).

Lysophosphatidic Acid Levels.

LPA was measured in plasma and tissue by LC-MS/MS as previously described by our group.[23]

Isolation and Culture of Bone Marrow-Derived Macrophages

To isolate bone marrow cells, femur and tibia were isolated and flushed with DMEM through a 25 gauge needle. Media-cell suspension was filtered through 70 µm nylon mesh and centrifuged at 1000×*g* for 5 minutes. Cells were plated at a concentration of 1 million cells per well in DMEM Glutamax containing 10% FBS, 1% PenStrep, and 10% L929 media. Media was changed every 2 to 3 days to generate bone marrow-derived macrophages (BMDM). To isolate SMC, aorta was separated from surrounding tissue starting from the arch to the renal arteries. The aorta was digested and SMC cultured as previously described.[9] Primary human coronary artery SMC (Clonetics, Lonza, Allendale, NJ) were treated with MβCD (methyl-β-cyclodextrin) cholesterol (20 µg/mL) or vehicle for 48 hours for the generation of SMC-derived foam cells. Twelve-well transwell (Sigma, St Louis MO) plates with 8.0 µm pore size were used for migration assays.

Statistical Analysis

All data are expressed as mean±SEM unless otherwise noted. Data were classified as parametric if it passed Shapiro-Wilk normality test and Brown-Forsythe equal variance tests or nonparametric if either test failed. Statistical analysis was performed using an unpaired, 2-tailed Student *t* test unless otherwise noted. *P* value <0.05 is regarded as significant. Two-way ANOVA and the Holm-Sidak post hoc test was used when multiple comparisons were made. Statistical analysis was performed using SigmaPlot 14.0 (Systat Inc, San Jose, CA). In cases where small sample sizes were used a power analysis was performed to determine the sample size required to detect differences of 30%. The data that support the findings of this study are available from the corresponding author on reasonable request.

RESULTS

LPP3 is Dynamically Upregulated During Atherosclerosis

The association of *PLPP3* alleles with human CAD risk and their correlation with gene and LPP3 protein expression in vascular cells suggests that regulation of

Downloaded from http://ahajournals.org by on October 20, 2020

LPP3 levels could influence the development of atherosclerotic vascular disease. LPP3 expression is readily detected in human atheromas.[4] To enable a detailed histological comparison of LPP3 expression in healthy and atherosclerotic coronary arteries, we took advantage of experimental pig models in which we could compare normal coronary arteries and well-characterized coronary atherosclerosis resembling lesions in humans from normocholesterolemic or heterozygous familial hypercholesterolemic pigs, respectively.[24] Healthy porcine coronary arteries displayed relatively low levels of LPP3 expression (Figure IA in the online-only Data Supplement, left). Coronary arteries from hypercholesterolemic animals fed a high-fat diet exhibited more prominent LPP3 immunostaining that co-localized with SMC makers and that was present in other cells within the vessel wall (Figure IA in the online-only Data Supplement, right). Next, we profiled LPP3 expression in 2 different murine models of atherosclerosis and observed prominent LPP3 expression in aortic root from both *Apoe*$^{-/-}$ mice (Figure IB in the online-only Data Supplement) and in *Ldlr*$^{-/-}$ mice fed a Western diet in comparison to wild-type controls (Figure IC and ID in the online-only Data Supplement). In the atherosclerotic aortic root lesions, LPP3 expression co-localized with the endothelial markers PECAM1 (Figure IC and ID in the online-only Data Supplement) and podocalyxin (Figure IE in the online-only Data Supplement), with CD68 (Figure IF in the online-only Data Supplement), and with SMC marker SM α-actin staining (Figure IG in the online-only Data Supplement). Upregulation of LPP3 protein, which is variably glycosylated as previously reported,[25] was detected by immunoblot analysis and was restricted to the atherosclerotic-prone proximal region of the aorta but not the descending thoracic aorta (Figure IH in the online-only Data Supplement). Together, these findings confirm that LPP3 is dynamically upregulated during atherosclerosis.

Post-Natal Reduction in Plpp3 Promotes Atherosclerosis

Having established that LPP3 levels are increased in several vascular cell types in atherosclerotic arteries, we investigated the consequences of global reduction of LPP3 expression in experimental models of murine atherosclerosis. Disruption of *Plpp3* in mice results in embryonic lethality due to defects in patterning and failure of the development of the extra-embryonic vasculature.[26,27] Therefore, we used a post-natal targeting strategy to broadly reduce *Plpp3* expression. Mice carrying a previously described floxed *Plpp3* allele and Cre recombinase under the control of the *Mx1* promoter were generated on the *Ldlr*$^{-/-}$ background.[8] Control (fl/fl) and Mx1-Cre expressing neonates were treated with pI-pC, to activate *Mx1* directed recombination (MX1-Δ). Sustained reduction in LPP3 expression was confirmed by analysis of bone marrow cells from adult mice (Figure IIA in the online-only Data Supplement) with some attenuation of overall protein expression in proximal aorta (Figure IIB in the online-only Data Supplement). After consuming Western diet for 12 weeks both fl/fl and MX1-Δ mice displayed hypercholesterolemia (Figure IIC in the online-only Data Supplement) without differences in plasma lipoprotein-associated cholesterol profiles (Figure IID and IIE in the online-only Data Supplement) or plasma triglyceride levels (Figure IIF in the online-only Data Supplement). We observed no differences in complete blood counts between fl/fl and MX1-Δ mice after 12 weeks on Western diet (Figure IIIA in the online-only Data Supplement). En face examination of proximal aortas revealed a 30% higher atherosclerotic burden in the MX1-Δ mice (Figure 1A; P=0.009). Similarly, oil red-O staining of the aortic sinus revealed a similar increase in lesion area in MX1-Δ mice (Figure 1B; P=0.028). Reduced LPP3 was accompanied by a nearly 2-fold increase in CD68-positive lesion area (P<0.001; Figure 1C) and an accompanying increase in inflammatory markers ICAM (intercellular adhesion molecule; Figure 1D) and CD68 mRNA levels (P<0.05; Figure 1E) in proximal aorta of the MX1-Δ mice. Global reduction of LPP3 increased plasma LPA, with increases in both saturated and unsaturated LPA species (Figure 1F). The global loss of LPP3 also led to an ≈2-fold increase in total LPA content in the proximal aorta (Figure 1G). Together, these findings support a role for LPP3 in attenuating inflammatory responses and atherosclerotic plaque development. However, the broad activity of the MX1 promoter does not provide information about cell types contributing the observed protective effect of LPP3 against experimental atherosclerosis. Thus, we employed cell-type specific approaches to attenuate LPP3 expression.

Myeloid LPP3 May Not be a Major Regulator of Atherosclerosis

We previously reported that levels of LPP3 in human monocyte/macrophages was extremely low and substantially increased in response to atherogenic ox-LDL in a manner that is governed by CAD risk alleles.[4] However, the functional consequences of LPP3 expression in macrophages is presently unknown. We, therefore, investigated whether monocyte/macrophage expression of LPP3 regulates the extent of atherosclerosis in mice. As observed with peripheral blood monocytes from humans, *Plpp3* expression in BMDM from control (fl/fl) mice is low and increased significantly after exposure to ox-LDL but not LDL (P<0.001; Figure 2A). BMDM isolated from mice with *Lys*M-Cre driven deletion of *Plpp3* (LysM-Δ) lacked LPP3 upregulation during ox-LDL stimulated foam cell formation. To determine if LPP3 regulates ox-LDL stimulated gene expression, responses of fl/fl control and LysM-Δ cells treated

without or with ox-LDL were compared. No difference in *Cebpb* expression occurred under any condition. *Fos*, *Tfam* (transcriptional factor A mitochondrial), and *Cd36* expression were substantially upregulated in LysM-Δ as compared with fl/fl BMDM at baseline, and *Cd36* was further amplified by environmental exposure to ox-LDL (Figure 2B). Having established dynamic regulation of LPP3 in murine BMDM and effects of LPP3 deficiency on ox-LDL stimulated gene expression in these cells, the role of myeloid LPP3 in experimental atherosclerosis was investigated by performing bone marrow transplant using fl/fl and LysM-Δ bone marrow cells into lethally irradiated *Ldlr*$^{-/-}$ mice that were subsequently fed a Western diet. After 12 weeks on Western diet, animals displayed characteristic hyperlipidemia with no differences in total plasma cholesterol or plasma LPA between the groups (Figure 2C and 2D). Development of atherosclerosis was also similar, without significant differences in the extent of atherosclerotic area by en face (Figure 2E) or by aortic root analysis (Figure 2F). These results indicate that

INFORME DE LABORES 2019

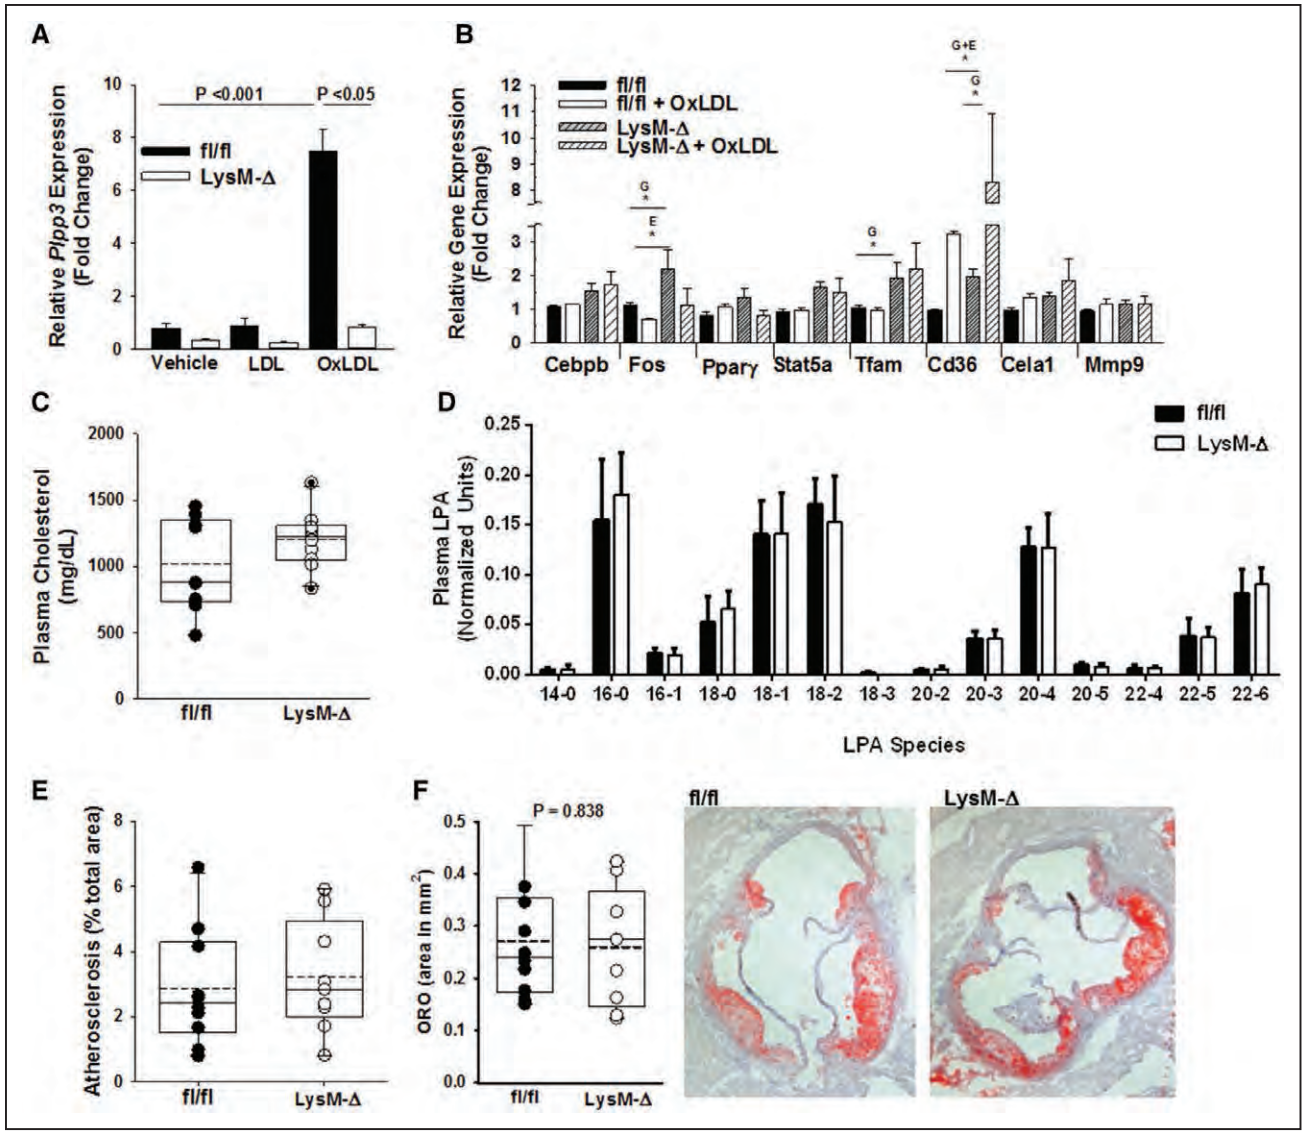

Figure 2. Myeloid deficiency of *Plpp3* does not alter atherosclerosis.
A, *Plpp3* gene expression (fold change; mean±SEM) in bone marrow-derived macrophages (BMDMs) from fl/fl and LysM-Δ mice (n=3–5 per group) treated with human LDL (low-density lipoprotein; 50 μg/mL), human ox-LDL (oxidized-LDL; 50 μg/mL) or vehicle for 18 h. Two-way ANOVA with Holm-Sidak pairwise multiple comparisons test was used to determine differences between treatment groups and genotype. **B**, Gene expression was profiled in BMDMs from fl/fl or LysM-Δ mice (n=3–5/group) exposed to vehicle or human ox-LDL. Two-way ANOVA with Holm-Sidak pairwise multiple comparisons test was used to analyze effects of genotype (*G*) and ox-LDL as an environmental stimulus for foam cell formation (*E*). **C**, Plasma cholesterol (mg/dL) in chimeric *Ldlr*$^{-/-}$ mice injected with bone marrow cells harvested from fl/fl (closed circles) or LysM-Δ (open circles) mice fed western diet for 12 wk beginning 4 wk after irradiation and reconstitution (n=10/group). **D**, Plasma lysophosphatidic acid (LPA) species quantification from fl/fl (black bars) and LysM-Δ (white bars) mice on the *Ldlr*$^{-/-}$ background after 12 wk on Western diet (n=10/group). **E**, En face analysis of atherosclerosis (% of arch area) in Wester diet fed, chimeric *Ldlr*$^{-/-}$ mice with fl/fl (closed circles) or LysM-Δ (open circles) bone marrow cells (n=10/group). **F**, Oil red-O staining of aortic sinus lesions reported as % area of aortic sinus (n=10/group). *P<0.05.

although *Plpp3* expression is dynamically regulated as macrophages assume a foam cell-like phenotype in vitro, myeloid LPP3 expression may not be a primary influencer of the development of experimental atherosclerosis.

Loss of SMC LPP3 Increases Atherosclerosis

In both murine and porcine vessels, LPP3 was prominently upregulated in cells expressing SM α-actin in atherosclerotic lesions. Our previous work established a role for LPP3 in regulating SMC responses to the bioactive lysolipid LPA, in particular, LPP3 attenuates LPA-promoted migration and RhoA and ERK activation in isolated SMC, likely due to LPP3-mediated degradation of LPA.[7] The absence of SMC LPP3 in mice promotes the development of intimal hyperplasia in normolipidemic mice, suggesting that the enzyme normally attenuates events associated with SMC migration and proliferation

Downloaded from http://ahajournals.org by on October 20, 2020

after injury.[7] Based on this evidence implicating LPP3 in SMC function, we examined the impact of loss of SMC-derived LPP3 (SM22-Δ) on the development of atherosclerosis in *Ldlr*$^{-/-}$ mice fed a Western diet. Measurement of LPP3 expression in primary cultures of SMC from fl/fl and SM22-Δ *Ldlr*$^{-/-}$ aortas confirmed efficiency of the knock-down strategy (Figure 3A). After 12 weeks on Western diet, no differences in plasma cholesterol levels were observed in fl/fl and SM22-Δ mice (Figure 3B). Unlike our MX1 mediated model of reduced *Plpp3*, no change in plasma LPA levels were detected between SM22-Δ and fl/fl mice (Figure 3C). However, SMC-specific deletion of LPP3 resulted in an approximate doubling of the extent of atherosclerosis in SM22-Δ mice as compared with the fl/fl control mice measured by en face (P=0.0002; Figure 3D) and confirmed in measurements of lesion areas in the aortic sinus by oil red-O staining (P=0.012; Figure 3E). SM22-Δ mice also displayed a significant increase in CD68 lesion area compared with fl/fl controls (P=0.006; Figure 3F). We observed a 3-fold higher expression of the inflammatory marker *Il-6* (interleukin 6) in SM22-Δ proximal aorta (P<0.05; Figure 3G). In keeping with the loss of local lipid degrading activity, aortic LPA content increased ≈2-fold in the SM22-Δ tissue (P=0.011; Figure 3H).

The results of tissue-specific targeting implicate SMC-derived, but not myeloid-derived, LPP3 as an intrinsic negative regulator of the development of atherosclerosis. Our earlier work suggests that the polymorphisms in humans associated with CAD risk influence upregulation of LPP3 in foam cells derived from monocytes. In particular, the protective allele results in higher LPP3 expression in macrophage foam cells. Cultured SMCs can assume a foam cell-like phenotype on loading with cholesterol, and intimal SMCs contribute to a substantial proportion of the foam cell population in advanced murine atherosclerosis.[28–30] Based on our findings in myeloid-derived foam cells, we sought to determine whether LPP3 expression was dynamically regulated during phenotypic modulation of SMC after cholesterol uptake. Exposure of human aortic SMCs to cholesterol reduced the SMC marker *ACTA2* and increased *CD68* consistent with downregulation of SMC markers and the assumption of an inflammatory phenotype (P<0.05; Figure 4A). Additionally, SMCs exposed to cholesterol displayed a 2-fold increased expression of *PLPP3* and more than a 10-fold increase in *LPAR4* (LPA receptor 4; P<0.05; Figure 4A). Cholesterol loading also significantly reduced cell migration in response to either serum or LPA (Figure 4B). SMC isolated from fl/fl and SM22-Δ mice respond to cholesterol loading by upregulating *Plpp3*, *Cd68*, and *Lpar4* similarly to human aortic SMCs (P<0.05; Figure 4C). LPP3 deficiency attenuated upregulation of *Cd68* and *Lpar4* (Figure 4D and 4E). These findings suggest that LPP3 may influence the phenotype of SMC-derived foam cells. To determine if LPP3 expression regulated the ability of intimal SMC to assume properties of foam cells within atherosclerotic plaque, in situ hybridization and proximity ligation assays were employed to visualize in tissue sections the H3K4dime marker of the MYH11 (myosin heavy chain 11) locus that is restricted to the SMC lineage.[21] Approximately 40% of the CD68^{+} staining cells within atherosclerotic lesions of control mice displayed the H3K4dime mark, which persists in phenotypically modulated SMC (Figure 4F). No difference was observed in sections from SM22-Δ mice (Figure 4F). These results indicate that the absence of LPP3 does not fundamentally alter the phenotype transition of SMC to foam cells, as assessed by CD68 staining. Instead, LPP3 may regulate functional response of the cells to bioactive lipids, such as LPA.

LPAR4 in Involved in the Development of Atherosclerosis

Based on the findings observed in SMC, we next focused on the role LPAR4 in the development of atherosclerosis. Control or *Lpar4*-deficient mice were injected with PCSK9D377Y.AAV to lower LDLR expression and phenotypically mimic the *Ldlr*$^{-/-}$ background, and then placed on Western diet to elicit hypercholesterolemia.[31] *Lpar4* is carried on the X-chromosome in mice, so analysis of both sexes was performed. After 16 weeks on Western diet, total plasma cholesterol was similar regardless of genotype (Figure 5A), although overall lower levels were detected in female mice injected with PCSK9 (proprotein convertase subtilisin/kexin type 9) virus. Despite similar levels of hyperlipidemia after PCSK9D377Y. AAV injection, both *Lpar4*$^{-/-}$ male (P=0.019) and female (P=0.011) mice were significantly protected from the development of atherosclerosis as measured by en face analysis (Figure 5B). Oil red-O staining of aortic sinus lesions revealed female *Lpar4*$^{-/-}$ mice were significantly protected from atherosclerosis compared with wild-type mice (P=0.008), and while male *Lpar4*$^{-/-}$ mice appeared to be protected from lesion formation the difference did not reach statistical significance (P=0.05; Figure 5C). The area of CD68 staining was statistically lower in aortic sinus lesions of male (P=0.046), but not female (P=0.11), *Lpar4*$^{-/-}$ mice compared with wild-type controls (Figure 5D) with a corresponding increase in the area of SMC α-actin staining (P=0.038; Figure 5E).

DISCUSSION

Heritable variant loci in *PLPP3* that associate with lower LPP3 expression are strong predictors of CAD risk.[1] We previously reported both a local and distant expression quantitative trait loci effect in monocyte/macrophages and found that higher expression of LPP3 was a characteristic of ox-LDL-induced foam cells from individuals with the protective allele.[4] In this report, we describe
