When *C. elegans* hermaphrodites are deprived of food during the mid-L4 larval stage and throughout adulthood, they enter an alternative stage termed "adult reproductive diapause (ARD)" in which they halt reproduction and extend their lifespan. During ARD, germ cell proliferation stops; oogenesis is slowed; and the gonad shrinks progressively, which has been described as the "oogenic germline starvation response". Upon refeeding, the shrunken gonad is regenerated, and animals recover fertility and live out their remaining lifespan. Little is known about the effects of ARD on oocyte quality after ARD. Thus, the aim of this study was to determine how oocyte quality is affected after ARD by measuring brood size and embryonic lethality as a reflection of defective oocyte production. We found that ARD affects reproductive capacity. The oogenic germline starvation response protects oogenic germ cells by slowing oogenesis to prevent prolonged arrest in diakinesis. In contrast to a previous report, we found that germ cell apoptosis is not the cause of gonad shrinkage; instead, we propose that ovulation contributes to gonad shrinkage during the oogenic germline starvation response. We show that germ cell apoptosis increases and continues during ARD via *lin-35/Rb* and an unknown mechanism. Although apoptosis contributes to maintain germ cell quality during ARD, we demonstrated that apoptosis is not essential to preserve animal fertility. Finally, we show that IIS signaling inactivation partially participates in the oogenic germline starvation response.

Introduction

To ensure species continuity, animals have developed mechanisms for protecting germ cells during stressful conditions. The *C. elegans* hermaphrodite germline serves as an excellent model for studying cell biology. In *C. elegans* hermaphrodites, 2 identical U-shaped gonad arms contain germ cells (Fig 1A). Under control conditions, L4 hermaphrodites (Fig 1C and

Competing interests: The authors have declared that no competing interests exist.

1E) produce approximately 40 germ cells that give rise 160 spermatids per gonad arm, which are stored within each spermatheca. Thereafter, during the adult stage, the remaining germ cells either differentiate into oocytes or are eliminated by physiological germline apoptosis [1, 2]. Physiological apoptosis is an essential mechanism for maintaining oocyte quality during oogenesis, as it promotes the allocation of nutrients to growing oocytes [3]. The most proximal oocytes arrest in diakinesis until they are fertilized, then complete meiosis and begin embryogenesis [3, 4] (Fig 1A and 1D). During its fertile period, a hermaphrodite produces approximately 300 new organisms in 3 days by self-fertilization with very low embryonic lethality (approx. 1–2 dead embryos/animal). Then, they cease laying eggs and live for 15 more days [4].

The short, highly stereotyped reproductive cycle of *Caenorhabditis elegans* can be altered when animals are deprived of food and enter into reversible states of growth arrest or diapause, depending on the stage in which they are deprived of food [5]. Animals subjected to high temperatures, crowding or fasting during the L1-L2 stage transition develop into a well-studied alternative larval stage known as the "dauer" stage. During dauer diapause, animals seal their orifices and form a thick impermeable cuticle, allowing them to endure stress for months [6].

When mid-L4 larvae or adult hermaphrodites face starvation conditions, they enter into adult reproductive diapause (ARD), characterized by delayed reproduction and an extended lifespan [7, 8]. ARD is a not yet fully elucidated form of diapause and differs from dauer diapause since animals starved at a low population density can enter and maintain this alternate developmental stage [8]. It has been observed that when starvation begins during the late-L4 or adult stage, embryos are retained *in utero*, hatch and cause the hermaphrodite's death [7]; however, this fate can be avoided if embryo viability is inhibited [8]. During ARD, the hermaphrodites' gonad shows a remarkable change; it shrinks in size progressively and the number of germ cells decreases to a small pool of ~35 cells [7] (Fig 1B and 1F). Starvation causes subsequent halting of the cell cycle in mitotically proliferating germ cells, which remain quiescent until conditions are restored [9]. The starved hermaphrodites form a single oocyte per gonad arm and usually carry 1–2 developing embryos within the uterus. These embryos are the result of delayed ovulation and fertilization, which occur approximately every 8 h ([8] and Fig 1B and 1F).

Remarkably, gonad shrinking and delayed reproduction are reversible [7, 8]. Following refeeding, germ cells resume their cell-cycle progression and start dividing, causing gonad regeneration, which, at least morphologically under the microscope, resembles a young adult gonad that never has been starved [7–9]. Hermaphrodites recover fertility and produce progeny by self-fertilization or mating [7]. Angelo and van Gilst (2009) proposed that apoptosis plays a crucial role during ARD, since apoptosis-defective mutants subjected to starvation from the mid-L4 stage do not reduce their gonad size and are unable to recover fertility after ARD [7].

ARD extends not only the total lifespan but also the reproductive period of animals [7]. In *C. elegans*, as in many other organisms, fertility declines with age [10], and oocyte quality is greatly affected during aging [3]. Adult reproductive diapause has been proposed as an anti-aging mechanism for protecting the germline [7]. Despite the numerous unexplained aspects of this phenomenon, whether ARD protects oocyte quality and the mechanisms that control this phenomenon have not yet been determined.

In this report, we use brood size and embryonic lethality to reflect defective oocyte production to investigate the effects of ARD on oocyte quality. We found that ARD affects gametes' reproductive capacity and prevents oogenic germ cells from undergoing prolonged arrest in diakinesis. During ARD, germ cell apoptosis is very active; however, in contrast to a previous report, we found that it is not important for gonad shrinking. We observed that increased

germ cell apoptosis during ARD depends partially on *lin-35*/Rb and an unknown mechanism. We propose that ovulation causes gonad shrinking by exhausting gonad contents when a few oocytes are produced. Finally, DAF-2 inactivation causes gonad shrinking in the presence of food suggesting that it may partially participate in this pathway. Here, we describe the effects of ARD on fertility and the regulation of germ cell apoptosis under starvation conditions.

Materials and methods

Strains

C. elegans strains were maintained as described previously [11]. All strains were grown at 20˚C or the permissive temperature using *Escherichia coli* OP50 as food. The wild-type strain was N2 Bristol. For the *daf-2* experiments, 15˚C and 25˚C were used as the permissive and restrictive temperatures, respectively. For the *pha-4(zu225)* experiments, 24˚C and 15˚C were used as the permissive and restrictive temperatures, respectively. Heterozygous EU31 *skn-1(zu135)* animals segregate as Unc and WT: Unc individuals were picked for maintenance, and WT individuals laid eggs that did not hatch. For the *fog-1(q253)* experiments, 15˚C and 25˚C were used as the permissive and restrictive temperatures, respectively. *fog-1(q253)* worms were maintained at 15˚C and upshifted to 25˚C to feminize their germline. The alleles used were as follows: JK560 *fog-1(q253)*, CB4108 *fog-2(q71)*, MD701 *ced-1*::*gfp(bcIs39)*, *cep-1(gk138);ced-1*::*gfp(bcIs39)*, MT3002 *ced-3(n1286)*, RB2071 *ced-3(ok2734)*, MT1522 *ced-3(n717)*, CB1370 *daf-2(e1370)*, DR1309 *daf-16(m26);daf-2(e1370)*, MT10430 *lin-35(n745)*, GR1307 *daf-16(mgDf50)*, EU31 *skn-1(zu135)*, SM190 *pha-4(zu225)*, VC446 *alg-1(gk214)*, RB1206 *rsks-1(ok1255)*, SS712 *ife-1(bn127)*, WS2973 *gla-3(op212)*, RN083 *daf-2(e1370);ced-1*::*gfp*, and RN084 *lin-35(n745); ced-1*::*gfp*. All the strains were obtained from the *Caenorhabditis* Genetics Center (CGC).

Image acquisition

Animals were mounted with 10 μl of 0.01% tetramisole in M9 on 2% agarose pads and observed using a Nikon Eclipse E600 microscope equipped with an AxioCam MRc camera (Zeiss). Images were obtained using Axio Vision software (Zeiss) and processed with ImageJ software.

Starvation protocol

We performed the starvation protocol described by Seidel and Kimble (2011) [8]. Synchronous L1 populations were obtained by bleaching gravid hermaphrodites. The resulting embryos were washed in M9, transferred to conical tubes and incubated for 18 h at 20˚C in a gyratory rocker. Hatched L1s were collected and placed in 10 cm plates seeded with OP50 at a density of ~1,200 L1s per plate until they reached the mid-L4 stage. To initiate starvation, the animals were collected with M9 medium and washed up to 6 times until no turbidity was observed; they were then placed in 10 cm plates with or without food at a density of ~10,000 animals per plate.

Apoptosis assay

Cell corpses were counted using the MD701 *bcIs39* [*Plim-7*::*ced-1*::*gfp;lin-15(+)*] transgenic strain. After the starvation protocol, animals were placed in seeded plates as the control condition or in unseeded plates as the starvation condition. Animals were transferred daily until they ceased laying eggs and were then picked, anesthetized, mounted and visualized under an epifluorescence microscope.

Germ cell quantification

We used DAPI staining to quantify the germ cells in each gonad arm as described by Silva-García and Navarro (2013) with some modifications [12]. Animals were dissected on glass coverslips, which were then inverted and placed on a polylysine-treated slide. The samples were freeze-cracked, fixed, stained with DAPI, mounted using 10 μl of Vectashield (Vector Lab) and visualized through fluorescence microscopy.

Fertility assay

We determined the brood size and embryonic lethality, resulting from self-fertilization and mating as described by Bukhari *et al*., 2012 [13]. Single mid-L4 hermaphrodites were transferred to seeded NGM plates and maintained at 20˚C. Animals were transferred to fresh plates each day until they ceased laying eggs. For the recovery of self-fertilizing animals following starvation, single hermaphrodites that had spent 5 days under starvation were transferred to seeded NGM plates and then to fresh plates each day until they ceased laying eggs. For mating animals, either mid-L4, well-fed 6-day-old or recovered *fog-(q253)* or *fog-2(q71)* animals were individually transferred to seeded NGM plates and crossed with 4 well-fed 1-day-old wild-type males. Twenty-four hours after the transfer of hermaphrodites, the embryos that did not hatch were scored as dead embryos. Forty-eight hours after the transfer of hermaphrodites, the number of larvae was scored.

Long-term immobilization

We determined the temporal progression of germ cell corpse clearance using a method described by Kim *et al*., 2013 [14]. Briefly, animals were immobilized using 0.5 μl of a suspension of polystyrene beads (Polysciences, 2.5% by volume, 0.1 μm diameter) on 10% agarose pads. Germ cell corpses were visualized and imaged at 60X magnification until they were completely cleared.

Ovulation rate

We followed the methodology described by Huang *et al*., 2012 [15]. Animals were individually scored for the number of embryos within the uterus using Nomarski microscopy, then transferred to fresh plates with food for 4 h and finally scored for the number of embryos within the uterus and those laid on the plate. More than 30 animals were observed for each genotype. The ovulation rate per gonad arm per hour = (embryos at the end of a time interval—embryos at the beginning) / (2 x number of animals x time interval).

Statistical comparisons

The t-test or Mann-Whitney U test was used for comparisons with controls in fertility assays. For multiple comparisons in apoptosis, fertility assays and germ cell corpse clearance assays, the data were analyzed using one way ANOVA and Dunn's test for multiple comparisons.

Results

Animals that undergo ARD do not recover their full fertility because this condition affects germ cell quality

We wanted to study how fertility and germ cell quality are affected after exposing animals to ARD. Although it has been reported that wild-type animals survive up to 30 days in ARD, their self-fertility is severely impaired after 15 days of starvation [7]. Therefore, we decided to

study the effect of ARD when animals are exposed to 5 days of starvation because this period is sufficient to reduce hermaphrodite self-fertility by up to 50% [7]. To conduct our experiments, we used synchronized populations of mid-L4 larvae that were fed (control) or starved (no bacteria) for 5 days and then refed. For simplicity we will refer to starved/refed nematodes as recovered animals. We quantified the brood size of self-fertilizing recovered wild-type hermaphrodites and compared it to that of well-fed nematodes. We found that the recovered wild-type hermaphrodites produced smaller broods than those that grew under control conditions (29% of the wild-type brood size; Table 1, Fig 2A).

When we analyzed the progeny produced by the control and recovered animals by day, we observed that recovered animals produced fewer offspring during the first two days after refeeding, after which progeny production peaked at the third day and ceased at the fifth day (Fig 2B). It is likely that the delay in offspring production in recovered animals was due to the gonad regeneration process, which usually takes two days.

One explanation for the low fertility after ARD is that because the starvation experiments started at the mid-L4 larval stage (approx. 4 h after L4 molting), when spermatogenesis has not yet been completed, insufficient sperm production could occur. To discard this possibility, we quantified sperm production in starved animals once they were close to completing the L4 larval stage (approx. 8 h after L4 molting) by DAPI staining. Control wild-type animals produced an average of 105.11± 1.1 sperm (N = 36, Fig 2C) and starved wild-type animals produced a similar number of 101.89 ± 2.5 (N = 37). After 5 days of L4 larval molting, the control wild-type animals did not have any more sperm in their spermatheca, while 5-day-starved wild-type animals still harbored an average of 102.5 ± 0.68 sperm (N = 28, Fig 2C). We conclude that even during prolonged starvation sufficient sperm are produced, therefore this is not a factor that explains low progeny numbers after ARD.

We also quantified the embryonic lethality of self-fertilizing recovered hermaphrodites after ARD and found that recovered animals exhibited significantly higher embryonic lethality than control animals (3.8 ± 0.3 dead embryos/worm in recovered animals vs. 2.1 ± 0.1 dead embryos/worm in control animals, i.e., 1.8-fold; Table 1, Fig 2D).

To counteract the effect of ARD on sperm, we quantified the brood size and embryonic lethality of wild-type hermaphrodites that were exposed to ARD and later crossed with well-fed wild-type males. Under control conditions, mid-L4 wild-type hermaphrodites were crossed with 4 wild-type males overnight and then transferred daily to new Petri dishes until they ceased laying embryos. For ARD, mid-L4 wild-type animals were deprived of bacteria for 5 days, then transferred to plates with food and immediately crossed with 4 well-fed wild-type males. We observed that the fertility of recovered wild-type animals crossed with well-fed males improved considerably (81% of that in control wild-type animals) even though their brood size never reached that of the control (Fig 2E). Additionally, we did not observe significant differences in embryonic lethality between these two groups of animals (2.6 ± 0.3 dead embryos in control mated animals vs. 2.8 ± 0.6 dead embryos in recovered mated animals; Table 1, Fig 2F). Our results suggest that ARD affects fertility and embryonic survival due to defects in oogenic germ cells; however, we were not able to rule out the possibility that sperm quality is impaired under starvation conditions.

Feminized germlines are more sensitive to ARD than those of wild-type animals

To test the effect of ARD exclusively on oogenic germ cells, we used *fog-1(q253)* and *fog-2(q71)* mutant animals, which have feminized germlines. Female *fog-2(q71)* animals are unable to produce sperm and only reproduce when they are crossed with males [16]. *fog-1(q253)*

https://doi.org/10.1371/journal.pone.0218265.g002

Fig 3A) and showed higher embryonic lethality (1.7-fold; 2.4 ± 0.3 dead embryos/worm in *fog-2* control animals vs. 4 ± 0.3 dead embryos/worm in *fog-2* recovered animals; Table 1, Fig 3B).

To confirm our findings we compared the brood size and embryonic lethality of control and recovered *fog-1(q253)* mutant animals. To do so, a group of synchronized hermaphrodite *fog-1(q253)* animals were grown from L1-mid-L4 at 25˚C and then individually transferred to a plate with bacteria and 4 wild-type males overnight as a control. Another group of *fog-1 (q253)* animals was transferred to plates without bacteria and incubated for 5 days at 25˚C. On the fifth day, the animals were recovered for 24 h in a plate with bacteria and then individually transferred to plates with bacteria and crossed with 4 wild-type males overnight. Recovered *fog-1(q253)* mutant animals showed significantly fewer progeny than control animals (Fig 3A and Table 1). Additionally, recovered *fog-1(q253)* mutant animals showed higher embryonic lethality (1.7-fold; 2.5 ± 0.1 dead embryos/worm in *fog-1* control animals vs. 4.4 ± 0.2 dead embryos/worm in *fog-1* recovered animals; Table 1, Fig 3B). Our results demonstrate that ARD affects oogenic germ cells to an extent that could interfere with embryo survival long after starvation has been ended. Since we observed that the effect of ARD was stronger in feminized mutants, we conclude that some genetic backgrounds could be more sensitive than others.

Oogenic germline starvation response prevents germ cells from entering oogenesis arrest

Well-fed virgin *fog-2* mutant animals' do not produce sperm; instead, all of their germ cells develop as oocytes, and the most proximal remain arrested in diakinesis within the gonad [16]. When *fog-2* mutant animals are mated after prolonged diakinesis arrest, their fertility and embryonic viability are severely affected [3]. By the fifth day after L4 molting, well-fed wild-type hermaphrodites have exhausted their sperm supply and arrested oocytes in diakinesis can be observed in the gonad (approx. 9) (Fig 4A). During the oogenic germline starvation response in wild-type animals, oogenesis is delayed but does not seem to be arrested (at least for the first 3 days after fasting); no stacking oocytes are observed and it is possible to distinguish only one developing oocyte per gonad arm ([8] and Fig 4B). In contrast, we observed stacked oocytes in 5-day-old ARD virgin *fog-2* mutant animals (approx. 7, Fig 4D) although they exhibited fewer stacked oocytes than well-fed 5-day-old virgin *fog-2* animals (approx. 11, Fig 4C). We also observed that *fog-1(q253)* mutant animals that were starved for 5 days at the restrictive temperature showed stacked oocytes within their gonads (approx. 4, Fig 4F) although they presented fewer stacked oocytes than well-fed 5-day-old virgin *fog-1* animals (approx. 8, Fig 4E).

To continue testing whether the oogenic germline starvation response during ARD exerts a protective effect on germ cells, we compared the quality of germ cells when they were exposed to prolonged arrest in meiosis under well-fed conditions vs. ARD. We crossed well-fed 6-day-

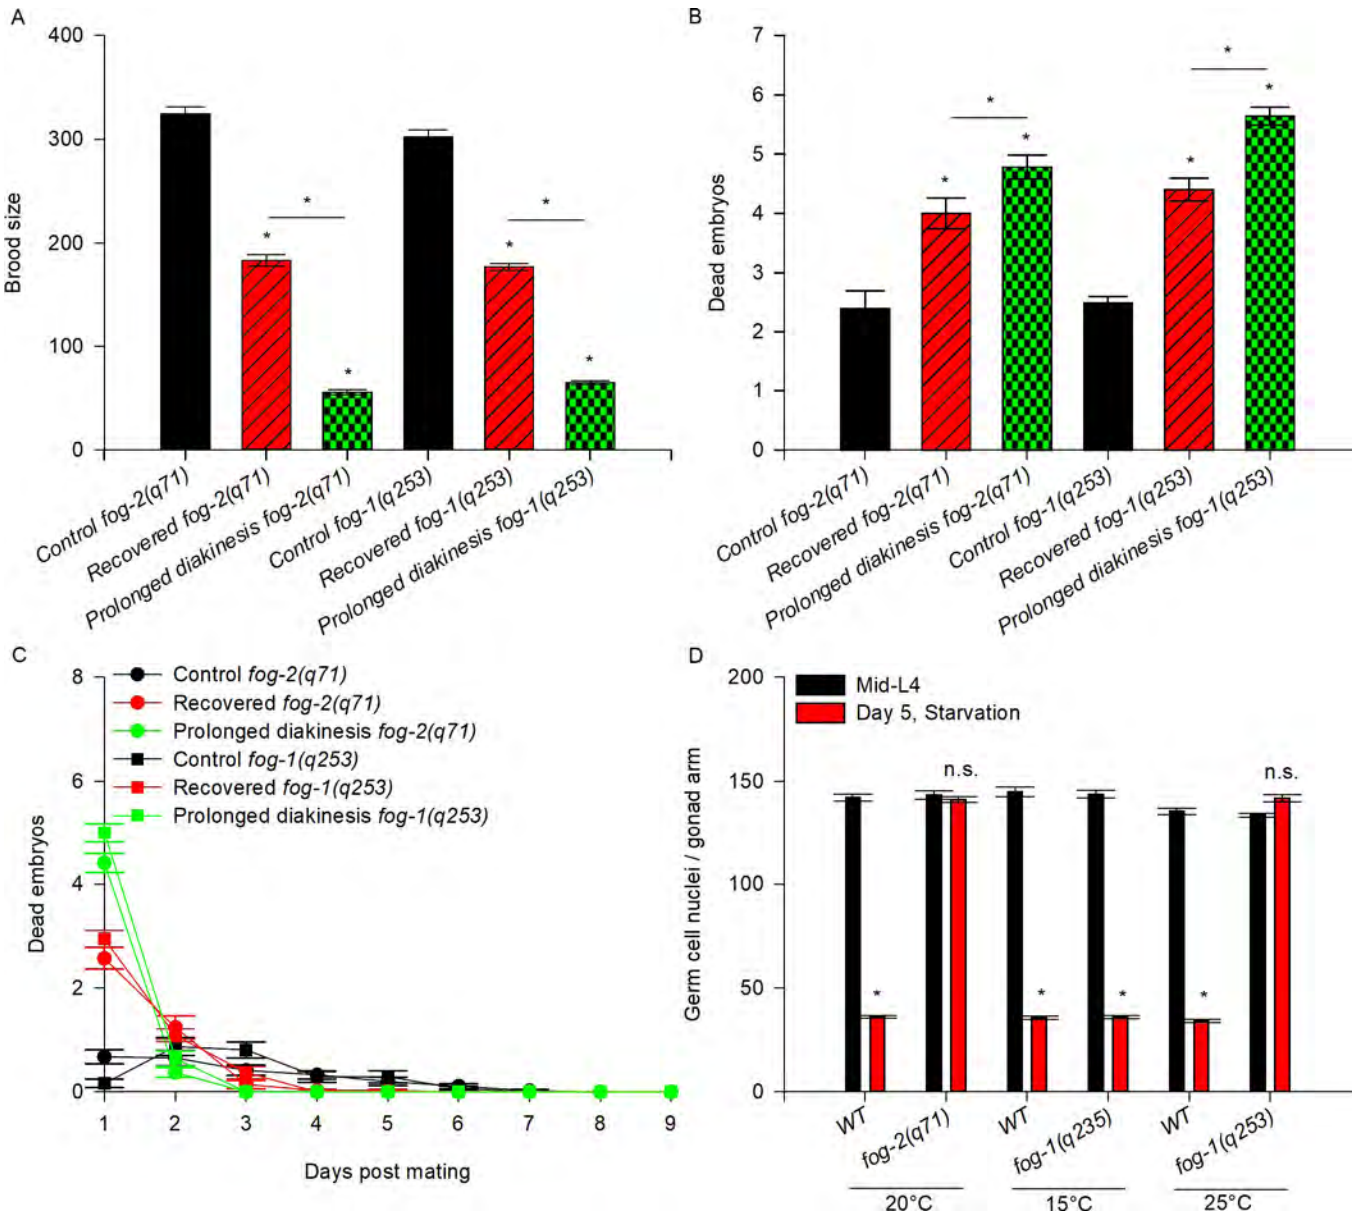

Fig 3. Germlines from feminized mutant backgrounds are more sensitive to ARD that those of wild-type animals. (A) The graph represents the brood size produced by mating virgin *fog-2(q71)* and *fog-1(q253)* mutant animals to well-fed wild-type males. Mid-L4 virgin animals from different genetic backgrounds were mated to 4 well-fed wild-type males overnight, then transferred individually to fresh plates until they ceased laying eggs (black). Mid-L4 virgin mutant animals were starved for 5 days, recovered on food for 24 h and then mated with 4 well-fed 1-day-old wild-type males overnight, after which they were transferred individually to fresh plates until they ceased laying eggs (red). Well-fed 6-day-old virgin mutant animals, which exhibited stacked oocytes arrested in prolonged diakinesis within the gonad, were mated with 4 well-fed 1-day-old wild-type males overnight and then transferred individually to fresh plates until they ceased laying eggs (green). The data represent the mean brood size (±SEM) per animal. Statistical significance was determined by one-way ANOVA on ranks, followed by Dunn's test ($P<0.05$). (B) The graph shows the number of dead embryos within the progeny produced by mating with well-fed wild-type males under control conditions (black), recovered conditions (red) and prolonged arrest in diakinesis (green). The data represent the mean number of dead embryos (±SEM) per animal. Statistical significance was determined by one-way ANOVA on ranks, followed by Dunn's test ($P<0.05$). (C) Quantification of dead embryos within the progeny produced each day by mating with wild-type males under control (black line) and recovered (red line) conditions and prolonged arrest in diakinesis (green line). Time course data are displayed as the mean (±SEM) number of dead embryos per time point. (D) Number of germ cells per gonad arm in wild-type and *fog-2 (q71)* and *fog-1(q253)* mutant animals. The graph represents the average number of germ cells scored using DAPI staining in dissected gonads during the mid-L4 stage (0) and 5 days after the mid-L4 stage under starvation conditions.

old virgin *fog-2* and *fog-1* mutant animals with well-fed wild-type males and determined their brood size and embryonic lethality, which were compared to those of *fog-2(q71)* and *fog-1 (q253)* mutant animals crossed under control and recovered conditions. We found that well-fed 6-day-old *fog-2* and *fog-1* mutant animals produced smaller broods (by 17% and 22%, respectively) than the controls and even smaller broods (by 30.5% and 36.7%, respectively) than animals recovered after 5 days of ARD (Fig 3A, Table 1).

Additionally, well-fed 6-day-old *fog-2* and *fog-1* mutant animals exhibited higher embryonic lethality than control (by 2- and 2.2-fold, respectively) and recovered animals (1.2- and 1.3-fold, respectively) (Fig 3B and Table 1). We observed that dead embryos were present mainly during the first day in well-fed 6-day-old *fog-2* and *fog-1* mutant animals (Fig 3C). Similarly, in *fog-2* and *fog-1* mutant recovered animals, the main peak of dead embryos was

The gonads of animals under control conditions or starvation were dissected, stained and scored for the number of germ cells using epifluorescence microscopy. Control animals remained on NGM plates seeded with OP50. For starvation conditions, animals were grown on food from L1 to the mid-L4 larval stage and then starved for 5 days. Animals were subsequently picked and dissected. The dissected gonads were stained with DAPI and the number of germ cells per gonad arm was scored under fluorescence microscopy.

https://doi.org/10.1371/journal.pone.0218265.t002

observed on the first day after the cross (Fig 3C). Apparently, the dead embryos were produced from the oocytes that were arrested in diakinesis for the longest period during ARD. We observed that embryonic lethality in *fog-2(q71)* and *fog-1(q253)* mutant animals was mainly caused by embryos that resulted from the fertilization of the oocytes that were already present or produced during ARD and presumably were arrested for a long period of time. We conclude that because the oogenic germline starvation response during ARD slows oocyte production, oogenic germ cells are prevented from undergoing diakinesis arrest, which preserves oocyte quality. We suggest that this could explain why feminized germline mutant animals are more sensitive to ARD than wild-type animals.

During the course of these experiments, we observed that the gonads of *fog-2* and *fog-1* animals did not shrink during ARD (Fig 4D and 4F). Our results, as well as those of other similar approaches reported previously [18], show that feminized mutant animals' gonads do not decrease in size, suggesting that ovulation is one of the causes of gonad shrinking during ARD. To verify that feminized gonads do not shrink during ARD, we quantified the germ cell number per gonad arm using DAPI staining in control animals and in animals that spent 5 days in ARD. In well-fed conditions, wild-type animals showed an increase in the number of germ cells per gonad arm from 141.9 ± 1.8 (at mid-L4) to 468.23 ± 2.0 (at the fifth day post mid-L4) (Table 2). Additionally, the number of germ cells per gonad arm decreased progressively during starvation from 141.9 ± 1.8 (at the mid-L4) to 36.0 ± 0.5 (at the fifth day post mid-L4) (Fig 3D and Table 2). We found that the number of germ cells in *fog-2* mutant animals that were starved for 5 days remained unchanged compared to the number of germ cells per gonad arm at the mid-L4 stage (143.1 ± 2.0 vs. 141.0 ± 1.5; Fig 3D and Table 2). We confirmed this result using *fog-1(q253)* mutant animals (Fig 3D and Table 2). Moreover, when *fog-1(q253)* animals were maintained at the permissive temperature (15˚C) from L1 to adulthood and subjected to ARD, their gonads were able to shrink similarly to those of the wild-type (Fig 3D and Table 2). Our results suggested that gonad shrinking during ARD is partially due to ovulation.

Germ cell apoptosis is not required to reduce gonad size during prolonged starvation

Caspase CED-3 is required for germ cell apoptosis under control and starvation conditions [19, 20]. Angelo and van Gilst, (2009) previously showed that during ARD, the gonads of *ced-3*

(n1286) mutant animals are not able to shrink and they suggested that apoptosis is required for this process [7]. However, we obtained different results. We exposed mid-L4 *ced-3* mutant animals (alleles *n1286*, *n717* or *ok2734)* to prolonged-starvation and we observed that the gonads of animals harboring all of these alleles were able to shrink during fasting (Fig 5D, 5E, 5G, 5H, 5J and 5K) similarly to those of the wild-type (Fig 5A and 5B).

To verify that the gonads of *ced-3* mutant animals shrink similarly to those of wild-type animals, we quantified the number of germ cells per gonad arm by DAPI staining from the mid-L4 stage over the next 5 days under control and starvation conditions in animals with the wild-type and *ced-3(n717)* and *(1286)* mutant alleles. We found that *ced-3* mutant animals indeed showed a progressive reduction of the germ cell number per gonad arm during starvation similar to that in wild-type animals (Fig 5M and Table 3). Moreover, the gonad size of *ced-3* mutant animals recovered when they were refed as efficiently as that of wild-type animals, as judged by Nomarski microscopy (Fig 5C, 5F, 5I and 5L) and DAPI staining (Table 3). Our data demonstrate that germ cell apoptosis is not required for gonad shrinking during prolonged starvation or gonad regeneration after fasting.

Angelo and van Gilst (2009) also reported that *ced-3(n1286)* caspase mutant animals were unable to produce progeny after 15 days of prolonged starvation and suggested that apoptosis was essential to maintain fertility after fasting [7]. We observed that neither wild-type nor *ced-3(n717 and n1286)* mutant animals produced any progeny after spending 15 days in ARD (N = 37, 39 and 42, respectively), even after they were crossed with wild-type males (N = 27, 29 and 30, respectively).

We quantified the progeny produced by well-fed and recovered *ced-3* animals (alleles *n717* and *n1286*) and compared the number to that in wild-type animals after spending 5 days in ARD. Andux and Ellis (2008) previously reported that *ced-3* mutant animals (with the *n718*, *n2439*, *n2921* alleles) produce fewer progeny and exhibit higher embryonic lethality than wild-type animals in control conditions [3]. Accordingly, we observed that the animals harboring the *ced-3* mutant alleles *n717* and *n1286* exhibited 40% fewer offspring on average than wild-type animals under control conditions (Fig 6A and Table 1). When we compared the number of progeny produced by recovered wild-type animals to that produced by recovered *ced-3* mutant animals, we observed that *ced-3* mutant animals produced 20–24% fewer progeny on average than recovered wild-type animals (Fig 6A and Table 1).

As reported by Andux and Ellis (2008), the embryonic lethality of *ced-3* mutant animals under normal conditions was higher than that of the wild-type (3.9-fold higher than the wild-type for the *ced-3(n717)* allele and 3.6-fold higher for *ced-3(n1286)*) ([3]; Fig 6B and Table 1). After ARD, *ced-3(n717)* mutant animals exhibited 1.9-fold higher embryonic lethality than recovered wild-type animals while *ced-3(n1286)* mutant animals presented 3.2-fold higher embryonic lethality than recovered wild-type animals (Fig 6B and Table 1).

To counteract the effect of ARD on sperm, we quantified the brood size and embryonic lethality of *ced-3(n717)* mutant animals exposed to ARD and subsequently crossed with well-fed wild-type males. We found that the fertility of recovered *ced-3(n717)* mutant animals crossed with well-fed males improved considerably (79% of that in the corresponding control) even though they did not reach the control brood size (Fig 6C). In control conditions, mated *ced-3(n717)* mutant animals exhibited higher embryonic lethality than mated wild-type animals (7-fold) but their embryonic lethality did not increase further after ARD (8-fold) (Fig 6D and Table 1). Our results confirmed that apoptosis is important to maintain oocyte quality under control conditions ([3] and this work). We also observed that apoptosis is important for fertility and to preserve oocyte quality during ARD; however, it is not essential, as previously claimed by Angelo and van Gilst (2009) [7].

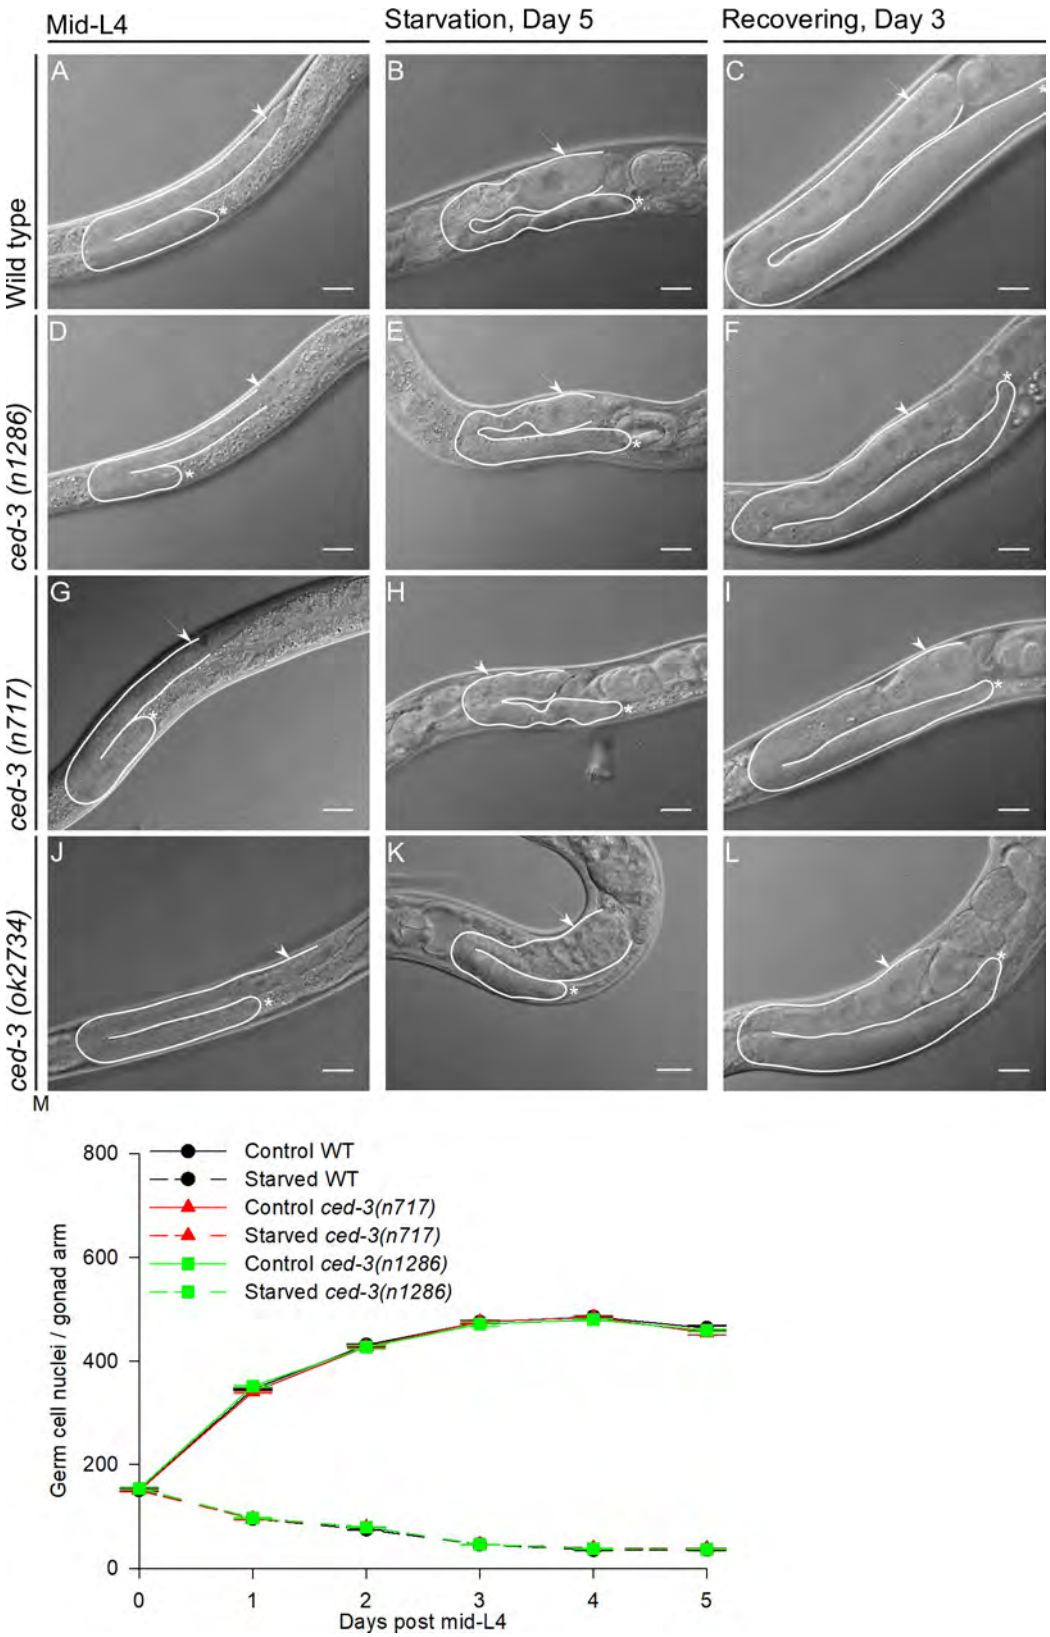

Fig 5. Apoptosis is not required to reduce gonad size during the oogenic germline starvation response. Nomarski images of gonads of mid-L4 wild-type animal and animals with the three different alleles of *ced-3* (A, D, G and J).

Nomarski images of gonads of wild-type and *ced-3* mutant animals starved for 5 days (B, E, H and K). Nomarski images of gonads of wild-type and *ced-3* animals that spent 5 days under starvation and were recovered on food for 3 days (C, F, I and L). In all images one gonad arm is outlined in white; the distal gonad is marked with an asterisk (*); the arrow points to the proximal gonad. Scale bar = 20 μm. (M) Germ cell nuclei per gonad arm scored in wild-type animals and two *ced-3* defective mutants by DAPI staining. The graph shows the average number of germ cell nuclei per gonad arm in control conditions (solid lines) and during starvation (dotted lines) ±SEM at each point.

https://doi.org/10.1371/journal.pone.0218265.g005

High germ cell apoptosis continues during ARD

We investigated germ cell apoptosis dynamics during ARD. To quantify apoptosis, we used a germ cell apoptosis reporter $P_{lim\text{-}7}$*ced-1*::*gfp*, which is expressed in the sheath cells and surrounding germ cell corpses [21]. In well-fed *ced-1*::*gfp* animals, the number of corpses per gonad arm increased with age and peaked at day 4 post-mid-L4 (16.3 ± 0.55 germ cell corpses per gonad arm), with an average of 9.65 ± 0.98 germ cell corpses per gonad over the following

The gonads of animals under control conditions, starvation and recovery were dissected, stained and scored for the number of germ cells using epifluorescence microscopy. Control animals were placed in NGM plates seeded with OP50 and transferred to fresh plates daily until they ceased laying eggs. For starvation conditions, animals were placed in NGM plates unseeded and transferred to fresh plates daily, similar to the control animals. Animals were picked and dissected. The dissected gonads were stained with DAPI, and the number of germ cells per gonad arm was scored under fluorescence microscopy. For recovery, animals that had spent 5 days in ARD were transferred to plates seeded with OP50 for 3 days. Animals were then picked and dissected.

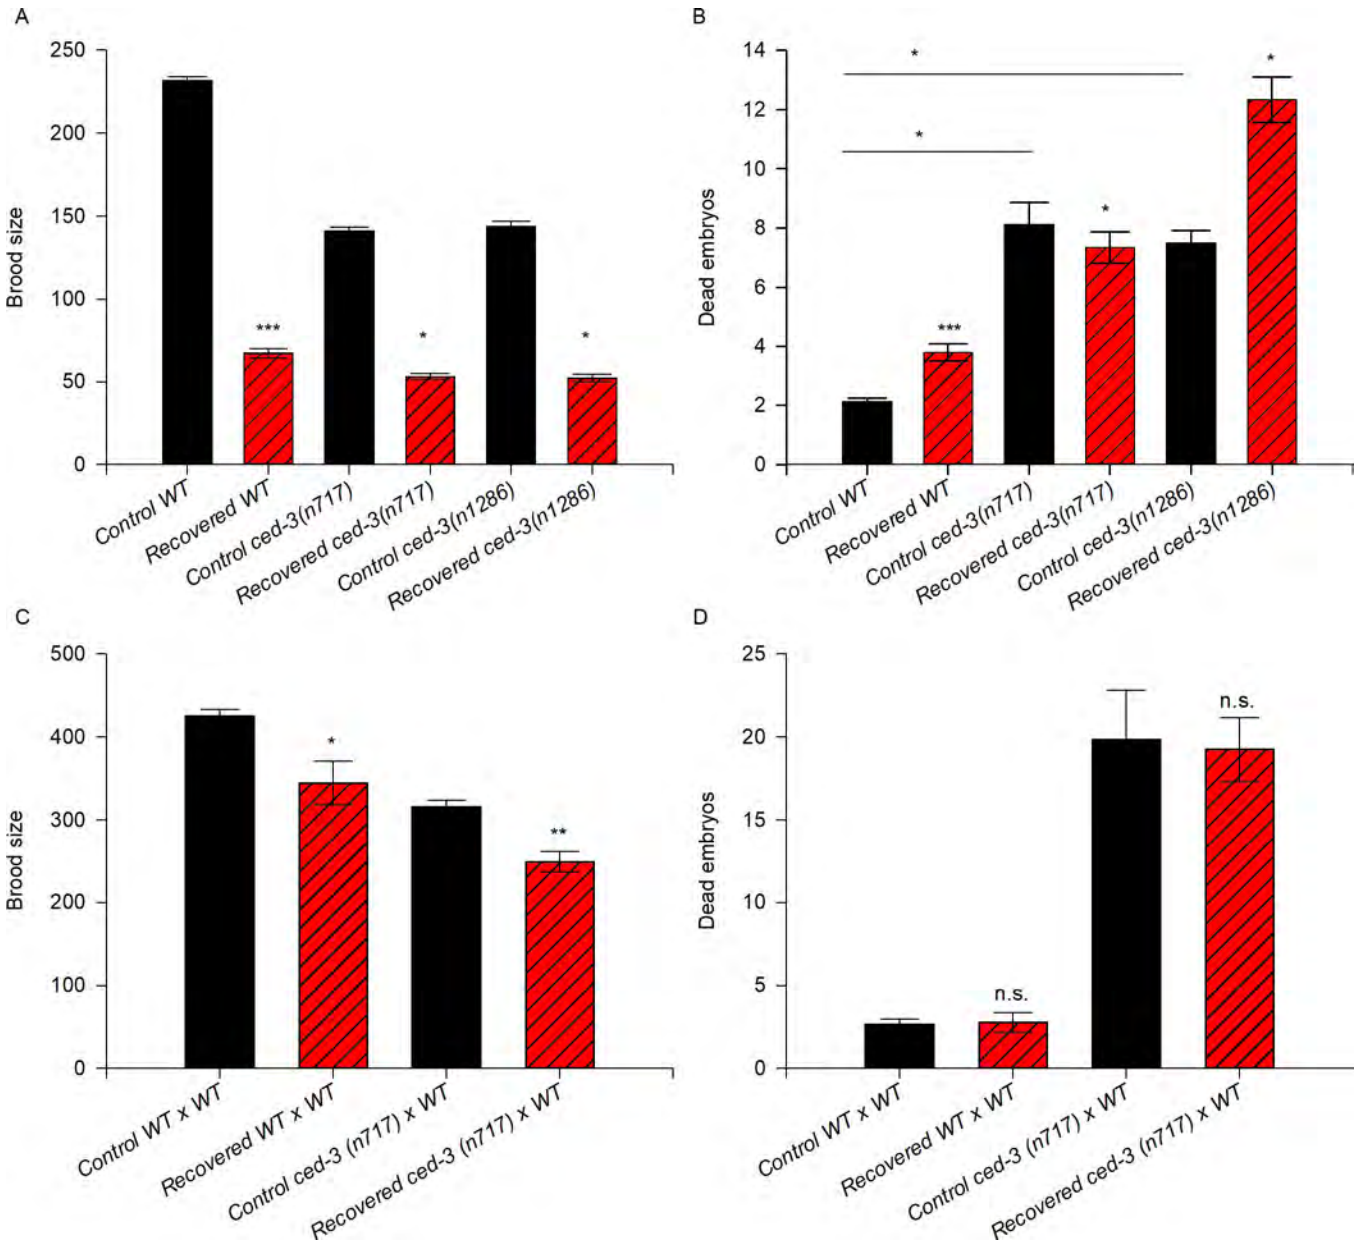

Fig 6. Apoptosis is as important to preserve oocyte quality after ARD as in control conditions but it is not essential for recovering fertility after ARD. (A) The graph represents the brood size produced by control (black) and recovered (red) wild-type and *ced-3* mutant animals. Mid-L4 hermaphrodites of the different genetic backgrounds were allowed to self-fertilize (black) or were starved for 5 days and then refed (red). The data represent the mean brood size (±SEM) per animal. Statistical significance was determined by the t-test (WT control vs. recovered) or by ANOVA on ranks and Dunn's test for multiple comparisons. (B) The number of dead embryos within the progeny of self-fertilizing wild-type and *ced-3* mutant animals under control (black) and recovered conditions (red) was calculated. The data represent the mean number of dead embryos (±SEM) per animal. Statistical significance was determined by the Mann-Whitney rank sum test ($P \leq 0.001$) (WT control vs. recovered) or by ANOVA on ranks and Dunn's test for multiple comparisons. (C) The graph represents the brood size produced by mating control (black) and recovered (red) animals of the different genetic backgrounds. Well-fed mid-L4 hermaphrodites were individually mated with 4 well-fed wild-type males overnight, then transferred individually to fresh plates until they ceased laying eggs (black). For the recovered animals, mid-L4 hermaphrodites were starved for 5 days, then recovered on food and immediately mated with 4 well-fed 1-day-old wild-type males overnight and transferred individually to fresh plates until they ceased laying eggs (red). The data represent the mean brood size (±SEM) per animal. Statistical significance was determined by the Mann-Whitney rank sum test ($P \leq 0.024$) in wild-type populations and by the Student's t-test ($P \leq 0.001$) in *ced-3(n717)* populations. (D) The number of dead embryos within the progeny produced by mating animals of the different genetic backgrounds under control (black) and recovered conditions (red) to well-fed wild-type males was calculated. Data represent the mean number of dead embryos (±SEM) per animal. Statistical significance was determined by the Mann-Whitney rank sum test.

https://doi.org/10.1371/journal.pone.0218265.g006

days (Table 4). After one day of starvation, we observed an increase of 1.6-fold in apoptosis compared to control conditions, with an average of 4.9 germ cell corpses per gonad arm over the following days (Fig 7A and Table 4).

It is remarkable that germ cell apoptosis continues and is very active during prolonged starvation particularly because germ cell proliferation stops after 30 minutes of fasting [9] and the gonad is completely shrunken after the fifth day. To quantify the proportion of germ cells that were being eliminated by apoptosis during starvation versus those that remained in the starved gonad, we determined the number of germ cells per gonad arm in dissected gonads under control and fasting conditions, using DAPI (4',6'-diamino-2-phenylindole) staining. We found that under control conditions the number of germ cells per gonad arm increased gradually with age until day 4 post-mid-L4, after which the numbers of germ cells per gonad arm were similar (approx. 534.2 germ cells/gonad arm) (Fig 7B and Table 5). During prolonged-starvation, the germ cell number decreased gradually until reaching the minimal number at day 6 post-mid-L4, then remained almost unchanged over the course of the experiments (38.1 germ cells/gonad arm on average) (Fig 7B and Table 5).

We quantified the percentage of germ cells eliminated by apoptosis (Table 4) and compared it to the number of germ cells present in the gonad (Table 5) under control conditions and during starvation. We found that under control conditions, approximately 1.91% of the total number of germ cells appeared as germ cell corpses at each time point. However, during starvation the percentage of germ cell corpses was considerably higher at each point compared to the control conditions (average of 9.27% of the total number of germ cells) (Fig 7C). Our data show that germ cell apoptosis increases up to 4.8-fold during the oogenic germline starvation response and continues under these conditions.

To test whether germ cell corpse clearance is affected during starvation, we quantified germ cell corpse engulfment in animals exposed to 1–5 days of starvation by time-lapse microscopy (see methods). We found that the timing of germ cell corpse clearance was not extended during the first 5 days of prolonged starvation compared to the control (approx. 55 minutes (prolonged starvation), similar to the control time of 58 minutes) (Fig 7D, Table 6). Our results demonstrate that the process of germ cell corpse engulfment remains active during prolonged starvation.

Germ cell apoptosis can be triggered by DNA damage or meiosis defects via CEP-1, the *C. elegans* p53 homologue [21–24]. *cep-1* mutant animals do not show increased germ cell apoptosis after DNA damage or meiosis defects. To test whether the germ cell apoptosis during prolonged starvation is regulated by DNA damage or meiosis defects, we quantified germ cell apoptosis in a *cep-1* mutant background [25]. We starved mid-L4 *ced-1*:*gfp* and *cep-1(gk138); ced-1*:*gfp* animals for 5 days and scored the number of germ cell corpses and the number of germ cell nuclei per gonad arm daily (see Methods). *ced-1*:*gfp* and *cep-1(gk138);ced-1*:*gfp* animals showed similar germ cell apoptosis levels in control and starvation conditions (Fig 8A), and the number of germ cell nuclei was progressively reduced during starvation (Fig 8C). Our results indicate that the proportion of germ cells eliminated by cell death was similar in the two genetic backgrounds (Fig 8E) suggesting that the increased germ cell apoptosis observed during ARD is not a consequence of DNA damage or defects during meiosis.

In our previous work, we found that *lin-35*/Rb is essential for inducing germ cell apoptosis during starvation [26]. Hence, we asked whether the high germ cell death triggered during ARD depended on *lin-35* and we found that it partially did. To demonstrate this, we subjected *ced-1*::*gfp* (control) and *lin-35(n745);ced-1*::*gfp* animals to 5 days of starvation beginning in the mid-L4 stage and determined germ cell apoptosis dynamics during ARD (Fig 8B). As previously reported [27], we found that *lin-35(n745);ced-1*::*gfp* mutant animals showed lower germ cell apoptosis compared to *ced-1*:*gfp* animals in well-fed conditions (Fig 8B). As previously

reported [26], we also observed that after 24h of starvation, *lin-35(n745);ced-1*::*gfp* animals do not increase their number of germ cell corpses (Fig 8B). However, it is important to remember that during prolonged starvation the number of germ cells progressively decreased (Fig 8D), which could explain why we observed lower apoptosis levels in the *lin-35* mutant background on subsequent days (Fig 8B). We calculated the proportion of germ cells eliminated by apoptosis versus the germ cell number as we did previously (Fig 7C) and observed that germ cell apoptosis increased in the *lin-35* mutant background although it never reach control levels (Fig 8F). We concluded that *lin-35* is partially responsible for germ cell apoptosis induction during ARD, but there is an unknown mechanism that also triggers germ cell apoptosis under these conditions.

The gonads of *daf-2* deficient animals shrink in the presence of food similar to the oogenic germline starvation response

In an attempt to reveal the molecular mechanisms that govern the oogenic germline starvation response, we subjected mid-L4 hermaphrodites of different genetic backgrounds to starvation for 5 days, followed by refeeding for 3 days, to test the capacity of their gonad to shrink and regenerate. We chose the gene candidates based on their known roles in the stress response or in germ cell proliferation. We tested the *C. elegans* retinoblastoma ortholog *lin-35*/Rb because it is essential for inducing apoptosis in short-term starvation [26] and partially required for inducing germ cell apoptosis in ARD (this work). We tested the *daf-16*/FoxO transcription factor due to its implication in the regulation of dauer diapause [28, 29]; the *skn-1*/NrF and *pha-4*/FoxA transcription factors due to their roles in dietary restriction and other types of stress responses [30]; the *alg-1* Argonaut ortholog due to its role in microRNAs pathway regulation and germ cell proliferation [13]; the *rsks-1* putative ribosomal protein S6 kinase, which has been implicated in resistance to starvation and, together with the eIF4E/*ife-1*, which regulates the germline cell cycle progression during development [31, 32]; the gene encoding the

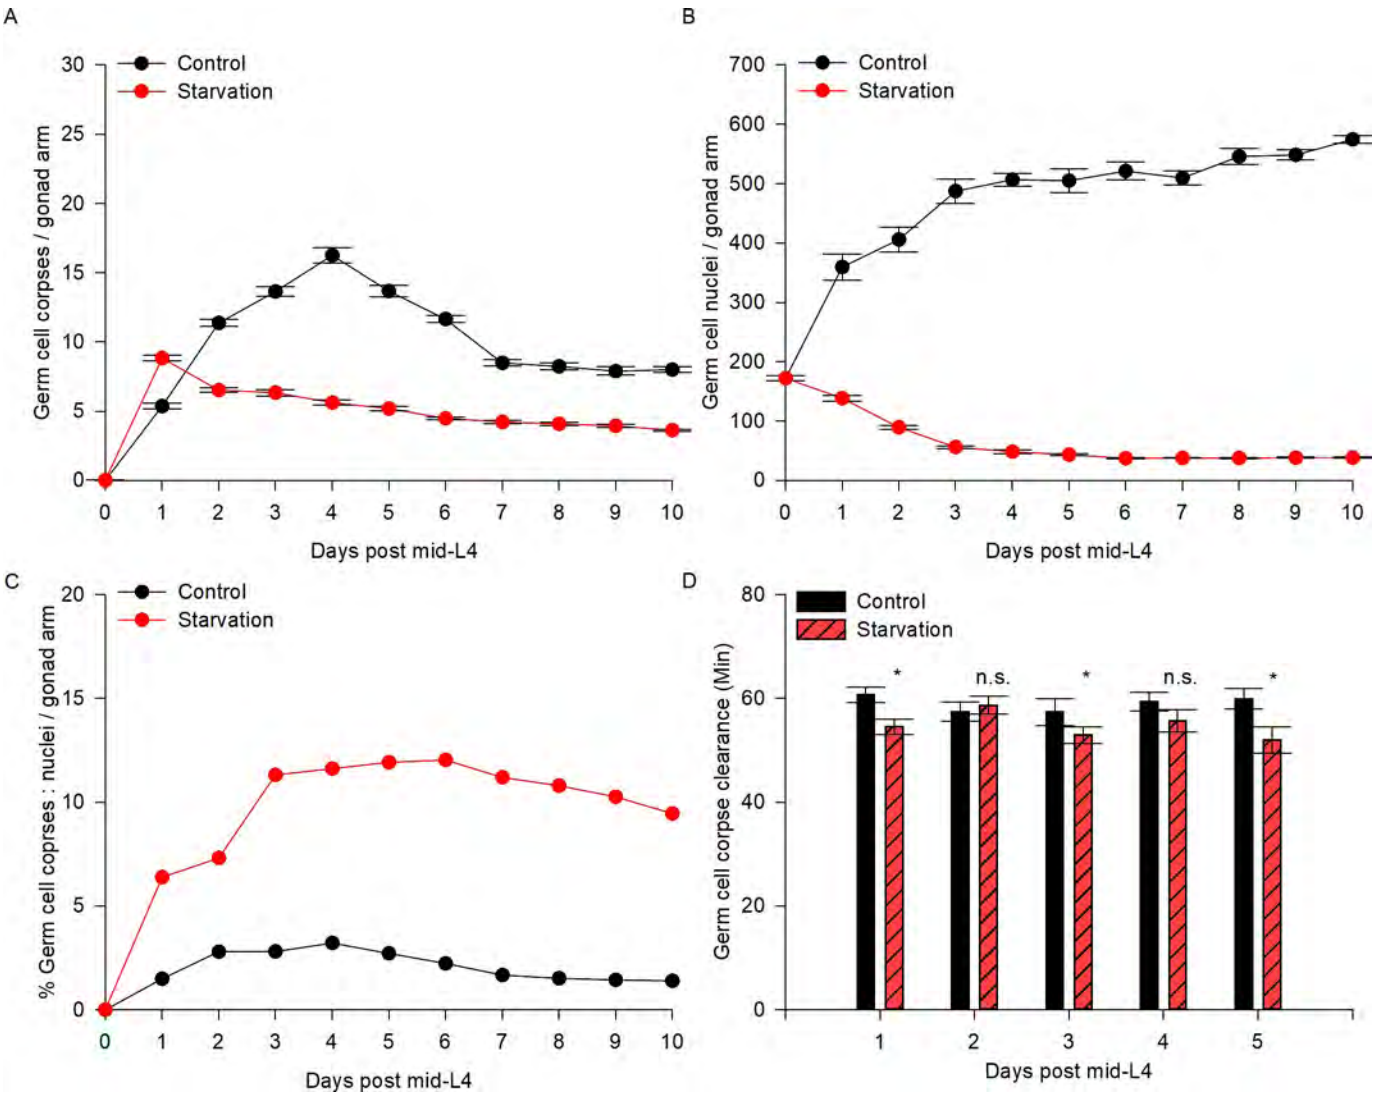

Fig 7. Germ cell apoptosis is increased and continues during ARD. (A) The *ced-1*::*gfp* transgene was used to visualize the number of germ cell corpses per gonad arm (see Materials and methods) for 10 days in control (black line) and starvation conditions (red line). The average number of germ cell corpses per gonad arm is shown with SEM. (B) DAPI staining was used to quantify the number of germ cells per gonad arm (see Materials and methods) for 10 days in control (black line) and starvation (red line) conditions. The average number of germ cells per gonad arm is shown with SEM. (C) The percentage of germ cell corpses among the total germ cells per gonad arm in fed animals (black line) and during starvation (red line) was calculated. (D) The time of germ cell corpse clearance was recorded every day after 1–5 days post-mid-L4 (see Materials and methods) in control (black bars) and starvation (red bars) conditions.

https://doi.org/10.1371/journal.pone.0218265.g007

TIS11-like zinc-finger-containing protein *gla-3* mutant, which exhibits increased germline apoptosis [33]; and the p53 *C. elegans* ortholog *cep-1*, which is required for the DNA damage response [34]. None of the tested genes were required to shrink the gonad during the oogenic germline starvation response or to regenerate upon refeeding (Table 7).

The insulin/insulin receptor signaling (IIS) pathway has been established as a link between nutrient availability and homeostasis in species ranging from worms to humans. This pathway is maintained through the activity of insulin-like molecules that bind to the insulin receptor. In *C. elegans*, more than 40 peptides related to insulin bind to the insulin receptor/DAF-2 to negatively regulate the DAF-16/FoxO transcription factor. Thus, mutations in the insulin receptor/DAF-2 promote the transcription of target genes through the activity of DAF-16/

FoxO to cope with nutrient scarcity and other types of stress [35]. This pathway regulates entry to dauer diapause, a well-studied diapause stage in *C. elegans* that occurs between larval stages L1-L2 in response to different cues, including a lack of food [36].

To test the role of *daf-2* in the oogenic germline starvation response, we used the temperature-sensitive mutant *daf-2(e1370)* [37]. Synchronous populations of wild-type or *daf-2(e1370)* animals were grown from hatching to mid-L4 at the permissive temperature (15˚C) (Fig 9A and 9D, respectively) and then transferred to the restrictive temperature (25˚C) for 5 days in the absence of food. We found that the gonads of *daf-2(e1370)* mutant animals grown at the restrictive temperature (25˚C) and starved for 5 days were able to shrink similarly to those of the wild-type animals (Fig 9E and 9B; Table 7) suggesting that *daf-2* is not required for the oogenic germline starvation response.

Table 6. Germ cell corpse clearance under control and starvation conditions.

		WT								
Days post mid-L4		**Control**			**N**	**Starvation**				**N**
0		No corpses detected			25	No corpses detected				25
1		60.7	±	1.51	9	54.6	±	1.47	*	9
2		57.4	±	1.89	9	58.7	±	1.74	n.s.	9
3		57.3	±	2.63	9	52.9	±	1.61	*	9
4		59.4	±	1.74	8	55.6	±	2.15	n.s.	8
5		59.9	±	1.97	8	52.0	±	2.50	*	8

The timing of germ cell corpse clearance under control and starvation conditions was scored using a long-term immobilization technique and Nomarski microscopy at 60x magnification. Control mid-L4 hermaphrodites were placed in NGM plates seeded with OP50, picked daily for up to 5 days and immobilized with 0.5 μl of a polystyrene bead suspension on 10% agarose pads to observe an individual germ cell corpse and determine its clearance time in minutes. For starvation conditions, mid-L4 hermaphrodites were placed in unseeded NGM plates, picked daily for up to 5 days and then immobilized with 0.5 μl of a polystyrene bead suspension on 10% agarose pads to observe an individual germ cell corpse and determine its clearance time in minutes. The Holm-Sidak test for comparisons within groups was used. n.s. = non significant

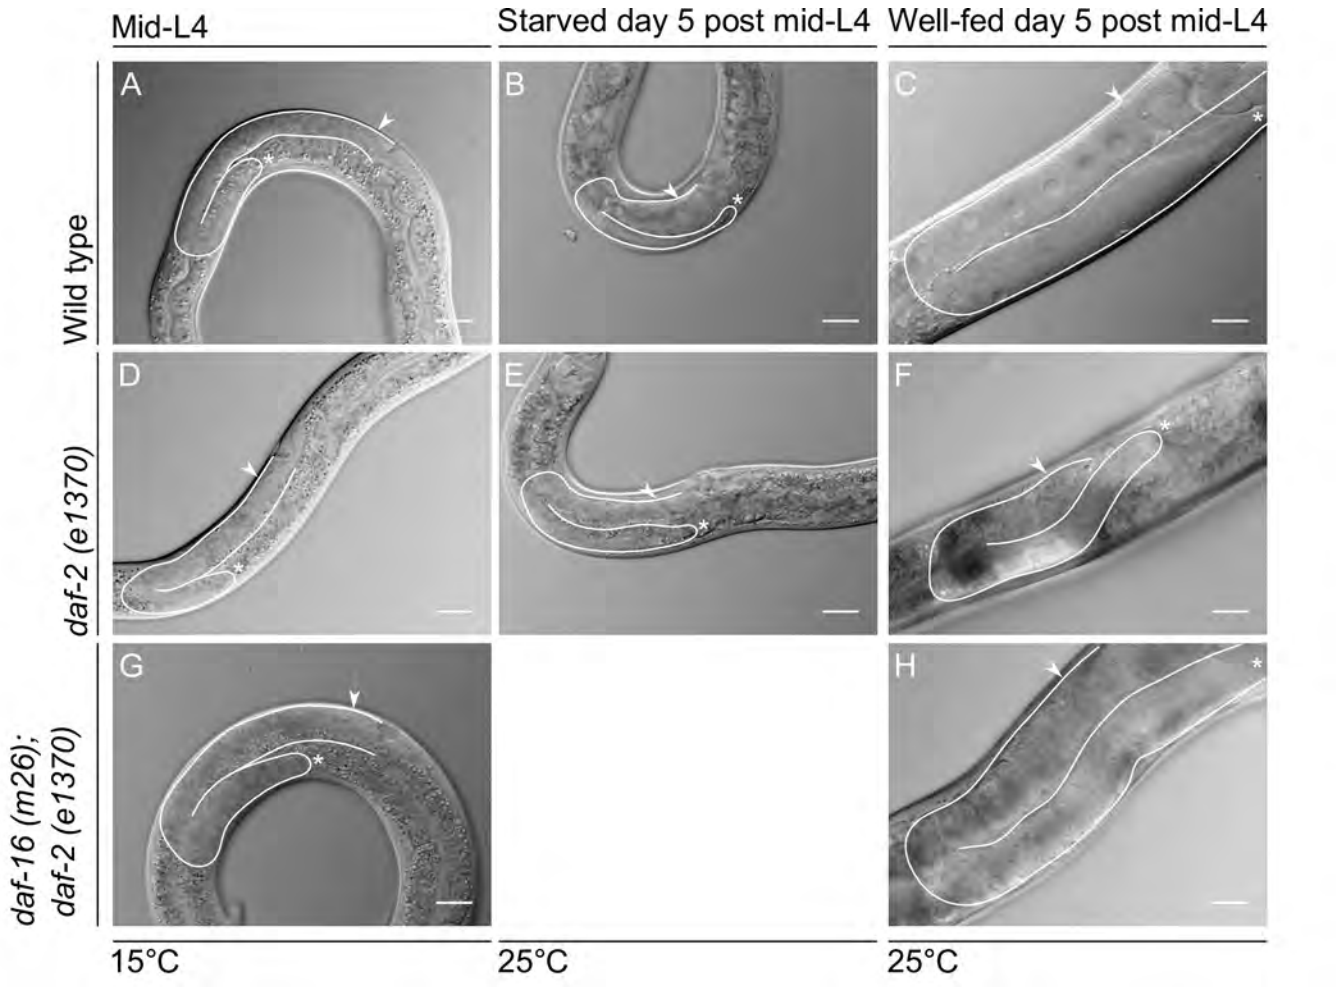
https://doi.org/10.1371/journal.pone.0218265.g008

Unexpectedly, we observed that the well-fed control mid-L4 *daf-2* mutant animals grown at the restrictive temperature for 5 days exhibited shrunken gonads in the presence of food (Fig 9F) when their gonads were compared to those of the wild-type animals (Fig 9C). We decided to quantify the germ cell number per gonad arm at the mid-L4 stage and 5 days after IIS pathway inactivation in the presence of food using *daf-2(e1370)* mutant animals and the wild-type as a control. We found that in wild-type animals, the germ cell number increased from 140.6 ± 1.2 at mid-L4 to 380.8 ± 3.4 5 days post-mid-L4. However, *daf-2(e1370)* mutant animals did not show the same increase; instead, the number of germ cell nuclei per gonad arm was reduced from 137.6 ± 1.0 at mid-L4 to 77.2 ± 1.5 5 days post-mid-L4 (Fig 9I and Table 8).



The transcription factor *daf-16/FoxO* is activated when the *daf-2* signal is absent [38]. As we previously showed, *daf-16* is not required to shrink the gonad during ARD, but we tested whether gonad shrinking induced in the absence of *daf-2* in the presence of food requires *daf-16*. To test this, *daf-16(m26);daf-2(e1370)* double mutant animals were grown from hatching to mid-L4 on food at the permissive temperature and then shifted to 25˚C for 5 days (Fig 9G and 9H). We observed that the gonads of animals lacking *daf-2* did not shrink in the presence of food when *daf-16* was not present. We quantified the germ cell number in this double mutant genetic background and found that the number of germ cells increased from 136.4 ± 0.7 at mid-L4 to 382.2 ± 2.5 5 days after IIS pathway inactivation in the presence of food (Fig 9I and Table 8). These results suggest that inactivation of *daf-2* in well-fed animals might trigger a mechanism similar to ARD that requires *daf-16*/FoxO.

Hermaphrodites from the different backgrounds were selected at the mid L4, starved for 5 days and observed daily under Nomarski microscopy to compare their gonad size to that under the oogenic germline starvation response using WT hermaphrodites as a control. At day 5, the hermaphrodites were refed for 3 days and observed daily under Nomarski microscopy to determine their gonad recovery, using WT hermaphrodites as a control.

Fig 9. Long-term IIS pathway inactivation mimics the entry to ARD in the presence of food. Mid-L4 wild-type, *daf-2(e1370)* and *daf-16(m26); daf-2(e1370)* larvae were fed until mid-L4 at 15˚C (A, D and G, respectively). Wild-type and *daf-2(e1370)* mid-L4 larvae starved for 5 days at 25˚C (B, E). Nomarski images of well-fed wild-type, *daf-2(e1370)* and *daf-16(m26); daf-2(e1370)* animals grown until mid-L4 at 15˚C, then upshifted to 25˚C for 5 days (C, F and H). In all images one gonad arm is outlined in white; the distal gonad is marked with an asterisk (*); and the arrow points to the proximal gonad. Scale bar = 20 μm. (I) Quantification of the number of germ cell nuclei per gonad arm during prolonged IIS pathway inactivation. Animals were grown from L1 to the mid-L4 stage at the permissive temperature and then upshifted to the restrictive temperature for 5 days. Dissected gonads were stained using DAPI in each condition. The graph shows the average number of germ cell nuclei per gonad arm (±SEM). (J) Ovulation rate determination during IIS pathway inactivation. Animals were grown from L1 to the mid-L4 stage at the permissive temperature and then either upshifted to the restrictive temperature or maintained in the permissive temperature for 1 day. Animals were individually picked and scored for the number of embryos *in utero*, then placed in plates for 4 h and finally scored for the number of embryos *in utero*. The ovulation rate was calculated as follows: (final number of embryos—initial number) / (2 * 4 h). The graph shows the average number of ovulations per gonad arm per hour (±SEM).

https://doi.org/10.1371/journal.pone.0218265.g009

To test whether IIS pathway inactivation could mimic entry to ARD even in the presence of food, we determined the ovulation rate in 1-day-old wild-type and *daf-2(e1370)* and *daf-16 (m26);daf-2(e1370)* mutant animals grown from L1 to mid-L4 at 15˚C that were late upshifted to 25˚C in the presence of food. It has been reported that ARD causes a delay in the ovulation rate [8]. Wild-type animals ovulate more frequently when upshifted to 25˚C (N = 30) (Fig 9J). In contrast, *daf-2(e1370)* animals showed no increase in the ovulation rate when upshifted to 25˚C (N = 33). However, *daf-16(m26);daf-2(e1370)* mutant animals continued to exhibit a slowed ovulation rate (N = 33) (Fig 9J).

Another feature of the oogenic germline starvation response is that the ovulation rate is limited by the rate of oocyte growth [8]. Starved animals almost always form only a single oocyte at a time in each gonad arm ([8], Figs 1F and 9B). However, gonads from *daf-2(e1370)* animals grown at 25˚C in the presence of food did not exhibit this phenotype (Fig 9E). We concluded that DAF-2 might participate in the oogenic germline response but that it is not the only signal that participates in this phenomenon. It is also possible that because the *daf-2* mutation results in pleiotropic phenotypes, it is not easy to study its role in the oogenic germline response.

Discussion

Angelo and van Gilst (2009) reported a novel type of adult reproductive diapause for the first time while studying reproduction when nutrients are limited. They showed that crowded populations of mid-L4 larval stage animals subjected to starvation delay their reproductive cycle and are able to live for up to 30 days without food. Furthermore, when conditions are restored, these animals resume their reproductive cycle and live out a normal lifespan. During ARD, the gonad experiences reversible germ cell loss and size reduction; when animals are returned to food, the gonad regenerates in terms of both germ cell number and size [7].

Later, Seidel and Kimble (2011) studied ARD in depth. They showed that germline shrinkage occurs in all oogenic germlines, from the mid-L4 to adult stages, and practically all shrunken gonads regenerate upon refeeding if bagging is prevented. Seidel and Kimble (2011)

Table 8. Quantification of germ cell number per gonad arm in different genetic backgrounds on food.

								5 Days post mid-L4				
	mid-L4			N	15˚C			N	25˚C			N
WT	140.6	±	1.2	37	339.0	±	2.0	35	380.8	±	3.4	20
daf-2(e1370)	137.6	±	1.0	42	337.0	±	1.4	44	77.2	±	1.5	41
daf-16(m26);daf-2(e1370)	136.4	±	0.7	43	342.3	±	1.7	43	382.2	±	2.5	22

The gonads of animals were dissected, stained and scored for the number of germ cells using epifluorescence microscopy. Animals were grown in NGM plates seeded with OP50 from hatching to mid-L4 at 15˚C and then incubated on food at 15˚C or 25˚C for 5 days. Animals were picked and dissected. The dissected gonads were stained with DAPI and the number of germ cells per gonad arm was scored under fluorescence microscopy.

https://doi.org/10.1371/journal.pone.0218265.t008

showed that embryo production continues during prolonged starvation, and it is possible to distinguish one or two viable-looking embryos within the uterus, which are a product of recent fertilizations, indicating that oocyte production and fertilization are active but considerably delayed in starved animals; however, embryo viability is severely impaired during starvation. They also showed that population density is not a prerequisite for inducing or maintaining the starvation response in starved animals and suggested that this phenomenon is not a form of diapause [8].

Despite not supporting the existence of the ARD proposed by Angelo and van Gilst (2009), Seidel and Kimble (2011) coined the term "oogenic germline starvation response" referring to the germline plasticity controlled by nutritional cues [8]. They also reported that starvation causes reversible cell-cycle quiescence in adult germline stem cells, reducing the number of M-phase cells under 30 minutes of starvation and rapidly re-establishing their number upon refeeding [9].

Our results support the following conclusions: Long-term exposure to fasting compromises the animals' reproductive capacity, and the oogenic germline starvation response prevents oogenic germ cells from undergoing prolonged arrest in diakinesis by slowing oocyte production. In contrast to Angelo and van Gilst (2009), we demonstrated that apoptosis is not the cause of gonad shrinkage during ARD and that it is not essential for fertility recovery after ARD. Instead, we propose that once germ cell proliferation stops, ovulation contributes to gonad shrinking during the oogenic germline starvation response. Germ cell apoptosis is increased during ARD and continues during prolonged starvation. Germ cell apoptosis during ARD is not induced by DNA damage or chromosome segregation errors during meiosis but is partially regulated by *lin-35*/Rb. We also found that during ARD an unknown mechanism triggers germ cell apoptosis. Finally, we suggest that inactivation of the IIS signaling pathway triggers gonad shrinking in the presence of food that might resemble the oogenic germline response.

ARD compromises fertility by affecting oogenic germ cells

In the present work, we showed that fertility is affected after ARD (Figs 2, 3 and 6). Although recovered animals exhibit restoration of fertility upon refeeding, none of the genetic backgrounds tested (N2, *fog-1*, *fog-2* and *ced-3*) produced broods that were as large as those of the controls by self-fertilization or mating. Angelo and van Gilst (2009) proposed that the fecundity of self-fertilizing animals depended on the survival of functional sperm during starvation [7]. However, we observed that, at least during the first 5 days of starvation, the sperm number remained unchanged.

Several authors have used embryonic lethality to reflect oocyte quality [3, 39]. Our results showed that animals produce more dead embryos when they use their self-sperm to fertilize oocytes after recovery from 5 days of starvation than their respective controls (Figs 2 and 6). We showed that recovered self-fertilizing hermaphrodites produce dead embryos during the entire reproductive period (Fig 2). However, recovered *fog-1(q253)* and *fog-2(q71)* females produced the majority of dead embryos during the first two days after mating (Fig 3), which suggests that the self-sperm exposed to starvation and used to fertilize oocytes in wild-type animals had been compromised. Moreover, when well-fed male sperm were provided, the oogenic germ cells produced during starvation were prone to produce dead embryos after fertilization. Our results suggest that the self-fertilizing capacity of hermaphrodites is not only compromised by the sperm number, but also by oogenic germ cell exhaustion after ARD. It is worth noting that the effects of ARD on sperm capacity remain unclear. Further studies are needed to determine the effect of ARD on sperm quality.

Oogenesis arrest is prevented by the oogenic germline starvation response

In the *C. elegans* germline, the presence of food and sperm promotes meiotic progression and oogenesis. Sperm depletion causes prolonged diakinesis arrest in the proximal gonad due to oocyte stacking, and starvation halts meiotic progression in the pachytene region [40]. In replete conditions and the presence of sperm, hermaphrodites ovulate every ~20 minutes per gonad arm, while during ARD, hermaphrodites exhibit slowed oogenesis and produce one oocyte at a time, and the next oocyte production starts once the fully grown oocyte is ovulated, which occurs approx. every ~8 h per gonad arm, regardless of the presence of sperm [8]. The oocytes that experience longer arrest in diakinesis are more likely to produce dead embryos [3]. We demonstrated that at day 5 post-mid-L4, in the presence of food, *fog-1* and *fog-2* animals actively produced and stacked as many oocytes as possible, while under starvation conditions *fog-1* and *fog-2* animals produced and stacked fewer oocytes within their gonads (Fig 4). When mated, well-fed 6-day-old *fog-1* and *fog-2* animals produced smaller broods and more dead embryos than *fog-1* and *fog-2* animals recovered from starvation, suggesting that slowing oogenesis during starvation is a beneficial mechanism for preserving the reproductive capacity and oocyte quality.

Apoptosis is important to preserve oocyte quality during ARD; however, it is not essential for fertility and gonad shrinking

In this study, we demonstrated that *ced-3* mutant animals respond to starvation by shrinking their gonads during ARD and partially recover their fertility upon refeeding (Figs 5 and 6). In contrast to Angelo and van Gilst (2009), who reported that apoptosis-deficient *ced-3(n1286)* animals subjected to 15 days of starvation did not show loss of germ cell nuclei or gonad shrinkage, and did not produce progeny after ARD [7]. In fact, we observed that wild-type animals and *ced-3* deficient mutants are unable to produce progeny after spending 15 days under starvation, either by self-fertilization or mating with well-fed wild-type males.

As previously reported [3], we observed that apoptosis-deficient mutants produced fewer offspring and exhibited higher embryonic lethality under control conditions compared to the wild-type animals. In this paper, we show that the apoptosis-deficient animals that were recovered from 5 days of starvation produced even fewer offspring and exhibited higher embryonic lethality than the wild-type animals. Our results suggest that apoptosis is important to preserve oocyte quality in control or prolonged starvation conditions.

Germ cell apoptosis continues during ARD

Our work shows that apoptosis is increased during prolonged starvation and continues to be high during ARD. Germ cell apoptosis is required during oogenesis for properly allocating resources within the gonad and ensuring oocyte quality [3, 41]. Apoptosis increases with age under control conditions and continues in later life contributing to gonad degeneration [41, 42]. We found that increased germ cell apoptosis during ARD is not triggered by *cep-1*/p53, suggesting that it is not caused by DNA damage or meiotic defects.

Furthermore, germ cell apoptosis can be triggered when animals face different types of stress [19]. Previously, we reported that one-day-old animals exposed to 6 h of starvation presented a 2-fold increase in the number of germ cell corpses, for which *lin-35*/Rb is responsible [19, 26]. Unexpectedly, we found that apoptosis seems to be induced during ARD by *lin-35*/Rb and an unknown mechanism.

Why is germ cell apoptosis elevated during ARD? Our results support the notion proposed by Andux and Ellis (2008) that germ cell death serves as a mechanism to redistribute resources

in the gonad [3]. The biological significance of this mechanism might be that it ensures oocyte production only under suitable conditions. At the mid-L4 stage when ARD entry is promoted, some germ cells have already committed to the meiotic oogenic cell fate, which is irreversible; however, completion of meiosis and development into a mature oocyte takes several hours. Thus, we think that the germ cell apoptosis observed during ARD might arise from the germ cells that escape the mitotic cell fate but, due to lack of resources, are eliminated by apoptosis.

DAF-2 inactivation causes gonad size reduction in the presence of food

We sought to investigate the molecular mechanism that governs the oogenic germline starvation response during ARD. We tested some genes involved in the regulation of dauer diapause, L1 arrest and other genes implicated in germ cell apoptosis and proliferation and demonstrated that only IIS in the mid-L4 larval stage caused a reduction in gonad size even in the presence of food (Table 8 and Fig 9). We propose that IIS pathway inactivation might trigger a response that mimics the entry into ARD in well-fed conditions, since animals show a reduced gonad size (Fig 9). Similarly, *daf-2* animals slow ovulation when they reduced their gonad size suggesting that *daf-2* might participate in ARD signaling; however, the shrunken gonads of *daf-2* animals do not form one single oocyte at a time as that of the ARD gonads, and *daf-2* is not essential for the gonad shrinking during ARD. Although our results provide some evidence of the pathway that governs the oogenic germline starvation response, further information is still needed for a better understanding of the precise molecular mechanism that controls reproduction under starvation conditions.

Acknowledgments

We thank the *Caenorhabditis* Genetics Center (CGC), which is funded by NIH Office of Research Infrastructure Programs (P40 OD010440) for kindly providing the strains used in this work. We thank WormBase release WS224 for gathering information and making it available. Neurodegenerative diseases are among the leading causes of disability and death worldwide. The disease-related socioeconomic burden is expected to increase with the steadily increasing life expectancy. In spite of decades of clinical and basic research, most strategies designed to manage degenerative brain diseases are palliative. This is not surprising as neurodegeneration progresses "silently" for decades before symptoms are noticed. Importantly, conceptual models with heuristic value used to study neurodegeneration have been constructed retrospectively, based on signs and symptoms already present in affected patients; a circumstance that may confound causes and consequences. Hence, innovative, paradigm-shifting views of the etiology of these diseases are necessary to enable their timely prevention and treatment. Here, we outline four alternative views, not mutually exclusive, on different etiological paths toward neurodegeneration. First, we propose neurodegeneration as being a secondary outcome of a primary cardiovascular cause with vascular pathology disrupting the vital homeostatic interactions between the vasculature and the brain, resulting in

cognitive impairment, dementia, and cerebrovascular events such as stroke. Second, we suggest that the persistence of senescent cells in neuronal circuits may favor, together with systemic metabolic diseases, neurodegeneration to occur. Third, we argue that neurodegeneration may start in response to altered body and brain trophic interactions established via the hardwire that connects peripheral targets with central neuronal structures or by means of extracellular vesicle (EV)-mediated communication. Lastly, we elaborate on how lifespan body dysbiosis may be linked to the origin of neurodegeneration. We highlight the existence of bacterial products that modulate the gut-brain axis causing neuroinflammation and neuronal dysfunction. As a concluding section, we end by recommending research avenues to investigate these etiological paths in the future. We think that this requires an integrated, interdisciplinary conceptual research approach based on the investigation of the multimodal aspects of physiology and pathophysiology. It involves utilizing proper conceptual models, experimental animal units, and identifying currently unused opportunities derived from human data. Overall, the proposed etiological paths and experimental recommendations will be important guidelines for future cross-discipline research to overcome the translational roadblock and to develop causative treatments for neurodegenerative diseases.

Keywords: lifespan, vascular pathology, senescence, body–brain trophism, dysbiosis

INTRODUCTION

Neurological disorders are the leading cause of disability-adjusted life-years and the second-leading cause of deaths worldwide. This burden has increased substantially over the past 25 years because of expanding population numbers and aging (GBD 2015 Neurological Disorders Collaborator Group, 2017) and will continue to grow in the coming decades due to the further increase in life expectancy.

At intermediate and advanced stages, frequently by the time a diagnosis is made, neurodegeneration has affected higher brain areas that control cognitive, sensory, and motor functions. Because the majority of cases are seen by the age of 50 or older in both men and women, many scientists think of neurodegenerative diseases as processes that reflect abnormal aging. Likewise, since neurodegeneration involves the loss of neuronal populations brain-wide, many researchers believe that neuronal death results from altered processes intrinsic to the nervous system, such as neuroinflammation, abnormal accumulation or deteriorated clearance of toxic proteins, and reduced anti-oxidative defenses.

Hence, current explicative models of neurodegenerative diseases account for signs and symptoms already seen in affected patients. In fact, the majority of these causative models have been formulated in retrospect, based on what is already present in the patient's brain. Given the nature of these models, it is difficult to identify real causes from mere consequences and epiphenomena. This is even more puzzling given that neurodegenerative diseases are life-spanning processes that start silently at least 20 to 30 years before the pathological signs and symptoms are recognized by patients and diagnosed by physicians. In addition, accumulating information suggests an extraneural origin of neurodegeneration.

Clearly, the essential premises guiding research on neurodegenerative diseases seem at least partly incorrect and somewhat misleading. This may explain why, despite researchers' best efforts, neurodegeneration is still a growing health concern and the reason why therapeutic measures are currently palliative, while preventive approaches are often ineffective (Crous-Bou et al., 2017; Hsu and Marshall, 2017; Klein and Tyrlikova, 2017).

Here, we outline four different paths as the basis for a paradigm shift toward an etiologic view on neurodegeneration: (1) the vascular origin of neurodegeneration, (2) cellular senescence as the origin of neurodegeneration, (3) body–brain trophic interactions as the origin of neurodegeneration, and (4) lifespan gut dysbiosis as the origin of neurodegeneration. We did not cover here genetic components as risk factors for neurodegeneration, a comprehensive analysis of which can be found elsewhere (Brainstorm et al., 2018). We provide concrete recommendations on how to investigate the discussed etiological paths experimentally in future studies. This work is the result of the discussions that took place during the German-Mexican Roundtable Exploring New Etiological Paths Towards Neurodegeneration in October 2018.

THE VASCULAR ORIGIN OF NEURODEGENERATION

Neurons depend on blood vessels to deliver oxygen and nutrients, for the removal of carbon dioxide and other by-products of metabolism from the brain's interstitial space, which helps to maintain the homeostasis of the cerebral microenvironment. Therefore, to function properly, it is thought that the cerebral circulation has developed adaptive mechanisms to provide the

trophic molecules and energy substrates needed for neuronal cells at different times and regions, depending on neural activity (Girouard and Iadecola, 2006).

The recognition of these mechanisms led to the concept of neurovascular coupling (Roy and Sherrington, 1890), which refers to the dynamic functional change in cerebral blood flow that occurs in response to local neuronal activity (Dirnagl, 1997; Kisler et al., 2017; Villringer, 1997). This response increases cerebral blood flow within the activated brain regions to fulfill energy demands in a process known as functional hyperemia.

The main players of these dynamic adjustments in the cerebral blood flow are neurons, glia, and vascular cells. All of them come together in a functional morphological entity termed the "neurovascular unit". This view explains why cerebrovascular diseases linked to neurodegeneration are considered as stand-alone etiopathological states (Przedborski et al., 2003; Brown et al., 2005). Vascular diseases, however, may be the forerunners of neurodegeneration. In support of this, it has been shown that shifts in blood pressure lead neurons to adjust the excitability thresholds according to brain perfusion levels, safeguarding their homeostasis. Hence, vascular diseases may occur first and then later neurodegeneration may follow, if the process of neurovascular coupling proceeds ineffectively (Moore and Cao, 2008; Kim et al., 2016).

Cerebral blood vessels originate from large cerebral arteries arising from the circle of Willis. As they find the way through the brain, large cerebral arteries divide into pial arteries and arterioles, which grow gradually deeper and form the penetrating arteries and arterioles that become progressively smaller until they turn into cerebral capillaries (Wittko-Schneider et al., 2014). The development of nerves and astrocytes originating from central and peripheral sources is closely associated with cerebral arteries, arterioles, and capillaries as demonstrated by the observation that the inhibition of angiogenesis during development is accompanied by severe developmental defects in specific regions of the central nervous system (CNS) (Hallene et al., 2006). This highlights the importance of blood vessels during brain formation.

There are different steps and mediators underlying neurovascular coupling. Briefly, neurons and interneurons are responsible for the initiation and modulation of the vascular response by the activation of NMDA and AMPA receptors, which leads to an increase of intracellular Ca^{2+} and calcium-dependent enzymes that exert effects on the endothelium, astrocytes, and pericytes. Because of their close association with synapses and microvessels, astrocytes are in charge of the neurovascular transmission of signals to the capillaries and arterioles while endothelial cells exert a retrograde propagation of vasomotor responses to regulate cerebral blood flow (Iadecola, 2017). The endothelium also regulates the vascular tone by releasing potent relaxing and contracting factors that readjust the vascular musculature and maintain a healthy homeostasis of the vascular wall.

Nitric oxide (NO), prostacyclins, endothelial-derived hyperpolarizing factor (EDHF), and endothelin have been proposed as the main vasoactive factors related to the endothelial response to neural activity. NO promotes the vasodilation of cerebral blood vessels by stimulating soluble guanylate cyclase in the vascular muscle, leading to an intracellular increase of cGMP and relaxation (Schmidt and Walter, 1994). NO is generated by three different isoforms of the enzyme NO synthase (NOS): neuronal (nNOS), inducible (iNOS), and endothelial NOS (eNOS).

In the CNS, nNOS is mainly located in neurons, astrocytes, and neuronal stem cells and has been implicated in synaptic plasticity and in the central control of blood pressure. Abnormal NO signaling is likely to contribute to a variety of neurodegenerative pathologies such as excitotoxicity following stroke, multiple sclerosis (MS), Alzheimer's disease (AD), and Parkinson's disease (PD) (Calabrese et al., 2007).

iNOS expression had initially been shown for macrophages, but it is now clear that it can be induced by cytokines in a variety of cell types in the context of inflammation (Li et al., 1991). During episodes of acute inflammation, the role of NO appears to be protective, while chronic iNOS expression is detrimental. The high levels of NO produced by activated macrophages and other cells may not only be toxic to microbes, parasites, or tumor cells, but may also harm healthy cells (Wong and Billiar, 1995).

Endothelial NOS is mostly expressed in endothelial cells, although the isozyme has been detected in certain neurons of the brain (Caviedes et al., 2017). eNOS-derived NO is a well-known physiological vasodilator and an inhibitor of platelet aggregation and adhesion, but it also inhibits leukocyte adhesion and vascular inflammation, controls vascular smooth muscle proliferation, stimulates angiogenesis, and activates endothelial progenitor cells (Forstermann and Sessa, 2012).

In addition to the production and release of NO, cyclooxygenase produces prostacyclin, which induces the relaxation of cerebral vessels by the activation of adenylate cyclase with the accumulation of cAMP and the activation of potassium channels. Similarly, in large cerebral arteries, the production of EDHF by the cytochrome P-450 monooxygenase metabolism of arachidonic acid causes relaxation by hyperpolarizing the underlying vascular muscle through the activation of potassium channels. The contribution of EDHF increases as the vessel size decreases, with a predominance of EDHF activity in resistance vessels and a compensatory upregulation of hyperpolarization in states characterized by reduced NO availability (Ozkor and Quyyumi, 2011).

Besides vasodilatory factors, under certain conditions, the cerebral endothelium produces vasoconstrictive substances such as endothelins leading to a potent and long-lasting contraction of cerebral vessels dependent on extracellular calcium and the activation of protein kinase C (Faraci and Heistad, 1998).

The alterations of any of the cellular players involved in the neurovascular unit may impair its coupling and functional hyperemia, resulting in an alteration of homeostasis leading to brain dysfunction (Iadecola, 2004).

Heart and Vascular Diseases and the Origin of Neurodegeneration

According to the World Health Organization, cardiovascular diseases (CVDs) lead to one-third of all annual deaths globally,

which is about 17.9 million total deaths (Lim et al., 2012). CVDs are disorders of the heart and blood vessels and include among others coronary heart disease, cerebrovascular disease, and rheumatic heart disease. A large number of studies have reported a strong relationship between indices of vascular pathology (such as carotid intima-media thickness, arterial stiffness, and small-artery remodeling) and cognitive impairment and neurodegeneration (Gorelick et al., 2011).

Because the factors contributing to vascular pathology are often preventable or treatable, targeting them may prove useful for preventing or delaying the onset of neurodegenerative diseases. Epidemiological studies show that treating hypertension and hyperlipidemia reduces the incidence of neurodegenerative diseases (Larsson and Markus, 2018) and slows down the rate of cognitive impairment (Deschaintre et al., 2009). Here, we will focus on the main CVDs known to promote changes in the cerebral microvasculature that lead to neurodegeneration in the long run.

Hypertension

Hypertension – or blood pressure at or beyond 130 mmHg/80 mmHg (systolic/diastolic blood pressure) according to the 2017 American College of Cardiology/American Heart Association guidelines (Whelton et al., 2018) – affects one billion people worldwide and leads to nine million deaths every year (Lim et al., 2012). In normotensive individuals, cerebrovascular autoregulation counteracts the cerebrovascular effects of the fluctuations in arterial pressure that occur during normal activities. Cerebral arteries relax when arterial pressure decreases and constrict when arterial pressure rises. The role of this vascular adjustment is the maintenance of a stable cerebral perfusion despite changes in systemic arterial pressure.

Hypertension alters cerebrovascular autoregulation (Sadoshima et al., 1983) by impairing endothelium-dependent relaxation (Faraci and Heistad, 1998). Hypertension promotes vascular hypertrophy, remodeling, and atherosclerosis in large cerebral arteries and lipohyalinosis in penetrating arterioles. These changes are damaging because they reduce the lumen of the vessel and increase vascular resistance (Dickinson, 2001). In humans, longstanding hypertension induces the deposition of collagen and fibronectin as well as elastin fragmentation, leading to an increased stiffness of the wall of large arteries (Henskens et al., 2008). Hypertension also affects neurovascular coupling as shown by a reduction in the normal increase in cerebral blood flow elicited in the posterior parietal and thalamic areas during cognitive tasks in patients with chronic untreated hypertension relative to normotensive individuals (Jennings et al., 2005).

The disruption of the adjustment mechanisms by a sustained increase in the blood pressure has been linked to different neurodegenerative diseases such as stroke (MacMahon et al., 1990). Hypertension is also considered an important modifiable risk factor for late-life cognitive decline and non-amnestic mild cognitive impairment in the mid-aged population (Knopman et al., 2001; Reitz et al., 2007). The Honolulu Asia aging study demonstrated an association between elevated levels of blood pressure in middle age and vascular dementia (Launer et al., 2000).

Atherosclerosis

Atherosclerosis, a progressive disease, characterized by the accumulation of lipids and fibrous elements in the large arteries, is a major cause of heart disease and stroke (Banerjee and Chimowitz, 2017).

The damage leading to atherosclerosis is elicited over years and is highly influenced by lifestyle. The pathogenic sequence starts with the recruitment of circulating monocytes into the intima, where they differentiate into macrophages and internalize modified lipoproteins to become foam cells (fat-laden M2 macrophages). Then, chemokines and growth factors induce the proliferation of neighboring smooth muscle cells and the synthesis of extracellular matrix components within the intimal compartment, generating a fibromuscular plaque that undergoes progressive structural remodeling resulting in the formation of a fibrous cap, overlying a lipid-rich, necrotic core accompanied by varying degrees of matrix remodeling and calcification (Lusis, 2000). If a rupture of the plaque occurs, the highly thrombogenic contents of the necrotic core are released to the lumen of the vessel, promoting atherothrombotic occlusion.

Epidemiological and post-mortem studies have shown that the atherosclerosis of the arteries that supply the brain is associated with a two- to threefold increased odds of dementia (Hofman et al., 1997; van Oijen et al., 2007; Wendell et al., 2012; Dearborn et al., 2017). Interestingly, this association is independent of the effects of cerebral infarction (Dolan et al., 2010), which can result from the atherosclerosis-induced occlusion of vessels.

Cerebral Small-Vessel Disease

Cerebral small-vessel disease comprises white matter lesions (WMLs), lacunar infarcts, and cerebral microbleeds and is a frequent neuroimaging finding (best seen on magnetic resonance images) in elderly people (de Leeuw et al., 2001).

Factors such as arterial stiffness, also related to aging and hypertension, are considered to expose the small vessels in the brain to highly pulsatile pressure and flow (Poels et al., 2012). This causes thickening of the arterial media of these vessels, which gradually narrows the lumen. In addition, atherosclerotic plaques in large arteries can encroach on the origins of smaller arteries, blocking the blood flow to areas supplied by these arteries. Subcortical white matter is particularly susceptible to such changes, as its blood supply depends on small arteries that get progressively smaller as they descend from the cortex to the deeper parts of the brain. Hypoxia ensues, causing edema, demyelination, and infarction of the white matter.

Cerebral small-vessel disease is associated with an increased risk of cognitive decline, dementia, stroke, balance disturbances, and parkinsonism (Bohnen and Albin, 2011). Individuals with an identical WML pattern present clinically heterogeneous complaints in cognitive and motor performance, ranging from no complaints to dementia and parkinsonism, which means other factors determine the cognitive or motor outcome (de Leeuw et al., 2001). Possible explanations for this heterogeneity are the lack of sensitivity of conventional magnetic resonance imaging to the early loss of microstructural integrity in the normal-appearing white matter (Scheltens et al., 1995), the disagreement on how lesions underlying small-vessel disease

are classified (Wardlaw et al., 2013), and the efficiency of compensation mechanisms that prevent further cognitive and motor deterioration (Mondadori et al., 2006).

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia affecting 1 to 2% of the general population (Andrade et al., 2014). AF is characterized by disturbances that promote ectopic firing and reentrant mechanisms that lead to impaired atrial function [for a review on the pathophysiology of AF, refer to (Andrade et al., 2014)].

AF can lead to reduced cardiac output, intermittent cerebral hypoperfusion, and transient hypertension in the cerebral capillaries (Anselmino et al., 2016). Such changes have been suggested as possible mediators of AF-related brain damage. On the other hand, AF may be a manifestation of a broader systemic illness that involves widespread inflammation and platelet activation, which can also lead to impaired cerebrovascular function (Dietzel et al., 2018).

AF is associated with increased morbidity and mortality and has long been known as one of the main risk factors for embolic stroke (Kamel et al., 2016). It is now also considered a risk factor for dementia. de Bruijn et al. (2015) analyzed the association of prevalent and incident AF with incident dementia in 6514 dementia-free patients, revealing not only a positive association between AF and the development of dementia but also that the association was strongest for younger participants with the longest duration of AF. These findings have been replicated by several studies (Nishtala et al., 2018), some of which have shown that the association between AF and dementia is independent of the occurrence of embolic stroke (Ryden et al., 2019) and the use of anticoagulants (Graves et al., 2017). Future investigation will determine if optimal treatment of AF can prevent or postpone cognitive decline and dementia.

Vascular Pathology in Neurodegenerative Diseases

The link between vascular risk factors and neurodegenerative disease is strengthened by the evidence showing that vascular and neurodegenerative pathophysiological changes often co-exist in patients with a diverse spectrum of neurodegenerative diseases. Several lines of evidence even suggest that vascular mechanisms are *directly* involved in the pathophysiology of neurodegenerative diseases.

The event that triggers the onset of a stroke, such as the rupture of an atherosclerotic plaque, the embolization of a blood clot, or the damage to a vessel and subsequent bleeding, is often preceded by vascular pathophysiological changes that accumulate over time. One of the earliest changes is endothelial dysfunction induced by oxidative stress (Roquer et al., 2009), which occurs as a result of the aforementioned cerebrovascular risk factors. Immediately after the onset of stroke, a series of overlapping pathophysiological changes occur leading to neuronal death within and beyond the initial area of damage. These include critically low blood flow, the accumulation of free oxygen radicals, the sustained or spreading depolarization of neurons, acidosis, tissue inflammation, damage to the blood–brain barrier (BBB), and regulated cell death (Mergenthaler et al., 2004).

The same vascular mechanisms that lead to acute stroke can also lead to cognitive impairment (Popa-Wagner et al., 2010). In the condition known as vascular dementia (or vascular cognitive impairment), the consequences of these pathophysiological changes are the primary cause of neurodegeneration. They include the development of multiple or strategically located infarcts, damage to the myelin sheath and axons, small cerebral hemorrhages, chronic cerebral hypoperfusion, and brain atrophy (Iadecola, 2013). Each of these represents damaged tissue, and the accumulation of damage eventually manifests as cognitive impairment (Gorelick et al., 2011).

Vascular pathology leading to white matter damage, manifesting as WML, seems to play a particularly important role in the pathogenesis of vascular dementia (Iadecola, 2013). Very often, however, both vascular and neurodegenerative changes contribute to the development of dementia, resulting in a condition known as "mixed" dementia.

The link between vascular pathology and neurodegeneration has also been thoroughly studied in AD. Vascular damage, initiated by vascular and genetic predisposing factors, precedes the accumulation of beta-amyloid (Aβ), which eventually leads to neurodegeneration in AD (Nelson et al., 2016). Neuroimaging studies support this theory, showing that reduced CBF and abnormal neurovascular coupling occurs in elderly people at the risk of AD before they show the hallmarks of the disease such as brain atrophy, cognitive impairment, or accumulation of Aβ (Smith et al., 1999; Bookheimer et al., 2000; Ruitenberg et al., 2005).

Vascular damage may facilitate neurodegeneration by altering a major route through which substances are cleared from the interstitial space of the brain parenchyma. This route is known as the glymphatic system, which facilitates the movement of fluid from perivascular (Virchow-Robin) spaces surrounding pial arterioles to the interstitium into spaces surrounding the brain's deep veins and then to the cervical lymph nodes (Jessen et al., 2015).

Vascular risk factors cause blockages in and around small arteries, which can manifest as an enlargement of the perivascular spaces (Gouw et al., 2011) that are visible on structural magnetic resonance images (Wardlaw et al., 2013). These enlarged spaces are a sign of impeded interstitial fluid flow and hence impaired clearance of substances from the brain parenchyma, and have been linked to an increased risk of dementia (Buerge et al., 2011; Ramirez et al., 2015) and stroke (Mills et al., 2007; Selvarajah et al., 2009).

Interestingly, the spatial distribution of these enlarged perivascular spaces has been linked to different underlying pathologies. A predominant distribution in the basal ganglia indicates vascular disease caused by hypertension (Selvarajah et al., 2009; Charidimou et al., 2013), while a white matter distribution is related to cerebral amyloid angiopathy (Martinez-Ramirez et al., 2013; Charidimou et al., 2014), caused by the accumulation of Aβ protein in the walls of the cerebral and meningeal vessels.

Cerebral amyloid angiopathy, which leads to intracerebral hemorrhage that aggravates the cognitive impairment (Cordonnier, 2011), is found in more than 80% of AD patients (Jellinger, 2010). Aβ itself is a potent vasoconstrictor (Thomas et al., 1996), worsening the hypoperfusion, which, if severe enough, directly injures neurons. However, even milder hypoperfusion alters protein synthesis and plays a role in neurodegeneration (Iadecola, 2004). The critical role of hypoperfusion is supported by the evidence that the induction of chronic global hypoperfusion in animal models causes memory impairment, the accumulation of Aβ, and synaptic dysfunction (Walsh et al., 2002; Koike et al., 2010; Wang et al., 2010).

Blood–brain barrier dysfunction, which involves damage to pericytes and endothelial tight junction molecules, has been observed in several neurodegenerative diseases, including AD, PD, amyotrophic lateral sclerosis (ALS), and Huntington's disease (Zlokovic, 2008; Chao et al., 2009; Duran-Vilaregut et al., 2009; Henkel et al., 2009; Kalaria, 2010; Alvarez et al., 2011). Vascular damage worsens the situation, both by leading to further BBB dysfunction and because low blood flow traps potentially neurotoxic proteins such as Aβ that pass through the leaky barrier. These proteins, which include immunoglobulins, plasmin, thrombin, and albumin, further reduce blood flow and cause vasogenic brain edema, oxidative stress, and axonal demyelination (Chen and Strickland, 1997; Mhatre et al., 2004; Farrall and Wardlaw, 2009; Chen et al., 2010). In patients, this BBB dysfunction is detectable using neuroimaging and the analysis of the biomarkers of neurodegenerative diseases in the cerebrospinal fluid (Olsson et al., 2016; Sweeney et al., 2018).

The presence and severity of vascular damage occurring at the cellular and molecular level, affect the clinical course of neurodegenerative diseases. Large neuropathological studies show the post-mortem presence of infarcts, lacunes, leukoencephalopathy, atherosclerosis, or hemorrhages in 80% of AD patients compared to 67% of similarly aged people without cognitive impairment (Toledo et al., 2013).

Interestingly, the effects of vascular pathology and neurodegeneration on cognitive decline seem to be synergistic, particularly in patients with moderate AD pathology (Zekry et al., 2002; Choi et al., 2011; Lee et al., 2014). Studies show that the worse the vascular pathology in patients with AD, the worse the cognitive impairment (Snowdon et al., 1997; Song et al., 2007; White, 2009). AD patients with infarcts or microangiopathic white matter disease also experience faster cognitive decline (Silvestrini et al., 2006; Helzner et al., 2009).

CELLULAR SENESCENCE AS THE ORIGIN OF NEURODEGENERATION

Since a main feature of aging is the accumulation of senescent cells in various tissues (van Deursen, 2014; Calcinotto et al., 2019), cellular senescence has emerged as a key potential contributor to neurodegenerative and cerebrovascular diseases (Baker and Petersen, 2018; Kritsilis et al., 2018).

Cellular senescence is a phenotype characterized by a durable cell cycle withdrawal (i.e., cells do not respond to mitogens), associated with the expression of tumor suppressors $p21^{CIP1/WAF1}$ (encoded by *Cdkn1a*) and/or $p16^{INK4A}$ (encoded by *Cdkn2a*), as well as by apoptosis resistance (**Figure 1**). Senescent cells display a flattened and vacuolated morphology with abundant stress granules and accumulate lipofuscin. There is a persistent DNA damage response commonly detected by the presence of γH2AX foci, while the most common feature is an increase in the lysosomal activity of the enzyme senescence-associated beta galactosidase isoform (SA-B-Gal), which has been widely used for their detection. Some senescent cells exhibit a formation of senescence-associated heterochromatin

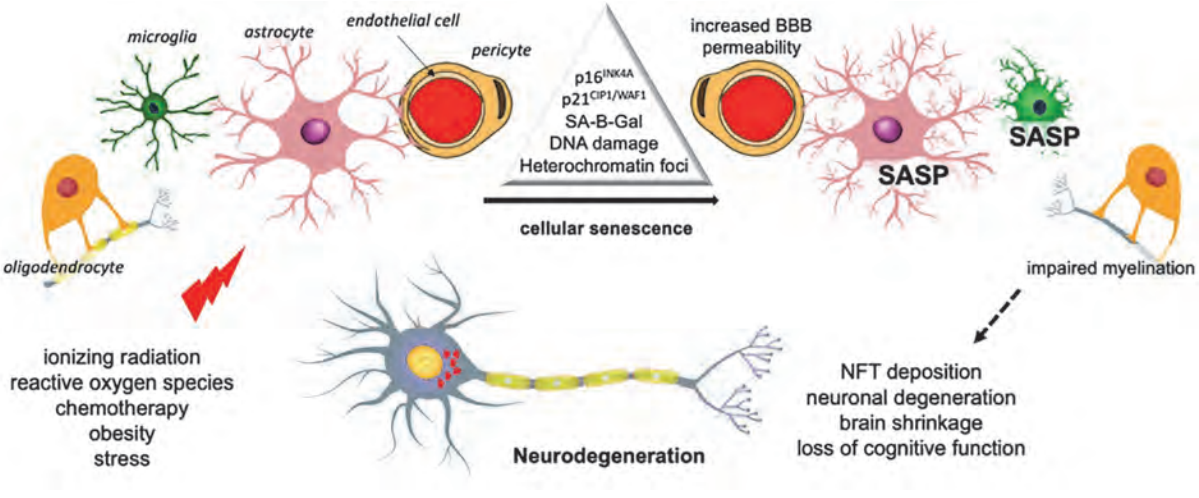

FIGURE 1 | Senescence-mediated neurodegeneration. Cellular senescence can be induced by several stimuli in the different brain cells. Senescence of microglia and astrocytes results in inflammation and the loss of trophic support. Oligodendrocyte senescence reduces myelin, which affects transmission and the BBB may be compromised by endothelial cells senescence. These changes have an impact on the integrity and viability of neurons and ultimately brain function [based on Chinta et al. (2015)]. SASP, senescence-associated secretory phenotype.

foci (SAHF), which are domains enriched in the transcription-silencing histone H2A variant, macroH2A.

However, the most important feature of senescent cells is the secretion of pro-inflammatory cytokines, growth factors, extracellular enzymes, and metalloproteases, collectively known as senescence-associated secretory phenotype (SASP) (Chow and Herrup, 2015; Ask et al., 2018). In early stages, the secretion of cytokines by senescent cells promotes the migration and infiltration of effector immune cells and the secretion of growth factors and proteases, which facilitate tissue repair and remodeling (Munoz-Espin and Serrano, 2014; Davaapil et al., 2017).

Yet, persisting cytokine signaling, as occurs in aging, contributes among other processes to chronic inflammation (*inflammaging*), a major contributor to age-related dysfunctions. SASP molecules also have an autocrine role, fostering the senescent phenotype, and a paracrine role inducing senescence in surrounding cells (Coppe et al., 2010). Notably, during aging, senescent cells accumulate and persist in different organs, including the brain, and are associated with the onset of several diseases (Munoz-Espin and Serrano, 2014).

To avoid confusion, it is however important to differentiate between aging, often termed "senescence" and cellular senescence. Aging is featured by an accumulation of senescent cells, but not all aged cells have the unique cellular senescence phenotype. Further investigations are needed to understand why senescent cells accumulate with aging, perhaps involving a combination of immune system malfunction failing to eliminate them, with changes in senescent cells themselves so that they become less efficiently recognized.

Senescence in Neurodegenerative Diseases

More recent *in vitro* and *in vivo* evidence strengthens the hypothesis of cellular senescence as causative of neurodegeneration. Dysfunctional astrocytes with senescent hallmarks have been detected in post-mortem human brain tissue from patients with ALS, PD, and AD (Bhat et al., 2012; Chinta et al., 2015, 2018; Turnquist et al., 2016). Mouse models and *in vitro* studies provide further evidence of senescence in microglia (Bussian et al., 2018), endothelial cells (Broadwell, 1989), neural stem cells and possibly oligodendrocytes (Kritsilis et al., 2018), which may contribute to neurodegenerative disorders.

Moreover, several senescent features have recently been described in studies of both physiological aging and neurodegenerative diseases using different models, including AD, PD, MS, and stroke (Kritsilis et al., 2018; Walton and Andersen, 2019), supporting the idea that cellular senescence may contribute to neurodegeneration and cerebrovascular disease in a far-reaching way (reviewed by Baker and Petersen, 2018; Walton and Andersen, 2019).

In a recent publication, using weighted gene co-expression analysis, Mukherjee et al. (2019) found a microglial signature of 17 genes that are strongly related with both aging and neurodegenerative diseases, not only in human brains but also in neurodegenerative murine models. An early study from Bhat et al. (2012) suggested that $p16^{INK4A}$-positive astrocytes may increase the risk for sporadic AD, since the prefrontal cortex of AD patients harbors a significant increase of senescent astrocytes expressing $p16^{INK4a}$ and matrix metalloproteinase-1 (MMP-1).

Also, the *in vitro* exposure of astrocytes to $A\beta_{1-42}$ triggers senescence, leading to the secretion of pro-inflammatory cytokines, including interleukin 6 (Bhat et al., 2012). Chinta and colleagues also demonstrated an increase of senescent astrocytes in brain tissue from PD patients, and found that cultured murine and human astrocytes exposed to paraquat (an herbicide associated with sporadic PD) become senescent. Interestingly, the depletion of senescent cells diminished neurodegeneration (Chinta et al., 2018), suggesting that senescence may be the cause, not the consequence of neurodegeneration.

Cellular senescence has also been considered as a therapeutic target in MS (Oost et al., 2018). Although MS is regarded as a classical autoimmune disease, it has been hypothesized that the driver of the autoreactive immune response in MS is actually a primary neurodegenerative process (Trapp and Nave, 2008). The senescence of microglia, T-cells, astrocytes, endothelial cells, and oligodendrocytes, among other cell types, is implicated in MS pathophysiology (Oost et al., 2018). Even though no study has been conducted for senescent cell detection on post-mortem tissue of MS patients, there is initial evidence in animal models about the role of cellular senescence on MS progression (Oost et al., 2018).

Senescence and Synaptic Plasticity

Another common hallmark of neurodegenerative pathologies is the alteration in synaptic structure and function during the early stages of the disease, which is related to subcellular reorganization preceding cell loss. The mechanisms underlying these pathologies are not fully understood. In fact, a decline in synaptic plasticity may be linked to the phenomenon of senescence. Unfortunately, there are only a few studies that have investigated the effect of senescence on the synaptic machinery. However, there is growing evidence of the changes in neuroplasticity caused by inflammation, oxidative stress, and protein misfolding, that may be linked to SASP action as well as the influence of senescence in glial cells, which are associated with an impairment in the neuroplasticity machinery (Gan et al., 2018).

The hippocampus has been pointed out as a brain structure with high plasticity and prone to neurodegeneration with age (Kreutzmann et al., 2015). The neurogenic capacity of the hippocampal dentate gyrus is reduced during aging. This reduction correlates with an impairment in memory formation and is accompanied by other changes, such as an increase of pro-inflammatory cytokines as well as a reduction of neurotrophic and vascular factors (Seib and Martin-Villalba, 2015; Fan et al., 2017).

Aging is also associated with changes in the hippocampal perforant pathway and its synapses, with the dentate gyrus being particularly affected (Wenk and Barnes, 2000). A decrease of synapses and changes in the morphology of dendrites and their spines have been linked to atrophy and a dysfunction of the aged hippocampus (Rogers et al., 1984). A synapto-proteome

study in old animals revealed a general decrease in the expression of neurotransmission regulation proteins, such as post-synaptic density 95, synaptosomal nerve-associated protein 25, shiga toxin 1, synapsin 1 and 2, synaptophysin, and vesicle-associated membrane protein (Wang et al., 2007; VanGuilder et al., 2010; Orock et al., 2019).

Moreover, a recent breakthrough paper, using a classical model of neurodegeneration, shows the accumulation of senescent astrocytes and microglia, but not neurons, in the brains of mice overexpressing human TauP301S. The genetic clearance of senescent glial cells prevented neurofibrillary tangle (NFT) deposition, the degeneration of hippocampal neurons, brain shrinkage, and the thinning of the dentate gyrus, thus preserving cognitive function. The transgenic mice that did not undergo a senescent transformation of microglia cells maintained their cognitive functions (Bussian et al., 2018).

Interestingly, neurogenesis and learning and memory can be impaired when blood and plasma from aged animals are transfused to young animals, showing that systemic factors can affect brain integrity. This phenomenon may be related to chemokine levels, especially the C–C Motif Chemokine Ligand 2 (CCL2), an important SASP component (Villeda et al., 2011). It is possible that when senescent astrocytes accumulate, they release SASP factors that lead to NFT deposition and other neurodegenerative hallmarks in surrounding neurons, oligodendrocytes, microglia, and endothelial cells (**Figure 1**). Investigating senescent cell accumulation in the periphery and in the nervous system should help to understand the process of aging of the brain and, more importantly, neurodegeneration in an integrative way.

Cellular Senescence in Stroke

Cellular senescence accompanying neurological conditions involves many cell types of the CNS (Walton and Andersen, 2019), which may also be of great importance in the case of brain injury following stroke (Buga et al., 2013). Most studies in this field, however, focused on the effects of aging rather than on cellular senescence. The timing of the cellular and genetic response to brain tissue injury is dysregulated in aged animal models due to a premature accumulation of BrdU-positive microglia and astrocytes, activated oligodendrocytes, and degenerated neurons (Popa-Wagner et al., 2007).

There is no consensus whether and to what extent age influences infarct size: several studies reported larger (Popa-Wagner et al., 2011) or smaller ischemic lesions in aged animals when compared to young rodents (Manwani et al., 2013; Ritzel et al., 2018). However, irrespective of the infarct size, aged animals have worse functional when compared to young ones (Popa-Wagner et al., 2011; Ritzel et al., 2018). The slow tissue recovery and rapid development of damage after injuries like stroke in aged animals may be linked to several factors such as a reduced expression of genes linked to neuroprotective pathways, high and accelerated cell death, high oxidative stress by mitochondrial dysfunction, increased permeability of the BBB, high phagocytic activity of brain macrophages, autophagic dysfunction, as well as an imbalanced inflammatory state (Popa-Wagner et al., 2007, 2011; Petcu et al., 2008).

Furthermore, the immune response to ischemic brain injury differs between aged and young mice. In a recent report, older mice displayed an increased number of brain-infiltrating and peripheral neutrophils with decreased phagocytic potential, increased levels of reactive oxygen species and extracellular matrix-degrading enzymes (Ritzel et al., 2018). Rawji and colleagues reported that aging also affects brain-resident immune cells. Aged microglia express excessive amounts of pro-inflammatory cytokines and proliferate at increased rates, but simultaneously display defective phagocytosis and decreased motility. Interestingly, aged peripheral monocytes seem to share the features of impaired phagocytosis and reduced motility, but are less prone to activation and proliferation (Rawji et al., 2016).

Since aging has been linked to the accumulation of senescent cells (van Deursen, 2014; Calcinotto et al., 2019), we speculate that cellular senescence may contribute to the outcome after stroke. However, there is a need for more studies, exploring specifically the impact of cellular senescence rather than the global effects of aging. *In vitro* and *in vivo* experiments show that aging influences the state of endothelial cells, pericytes, and tight junctions, in turn resulting in a compromised function of the BBB (Yamazaki et al., 2016). Acute stroke leads to increased permeability and BBB breakdown, associated with worse outcome in stroke patients (Brouns et al., 2011).

Astrocytes in aged brains display the features of cellular senescence and SASP (Salminen et al., 2011), possibly impacting surrounding cells also in the case of acute brain damage. In the context of senescence hallmarks, human astrocytes are highly sensitive to oxidative stress and trigger a senescence program when faced with multiple types of stressors (Crowe et al., 2016; Liddell, 2017).

Chronic low-grade inflammation contributes to the increased risk of cerebrovascular disease (Lucas et al., 2006) and was shown to be a feature of the aging (Buga et al., 2013). The SASP in many cell types, including peripheral immune cells, astrocytes and microglia may influence a chronic inflammatory state observed in aging (Buga et al., 2013).

Taking into consideration the pathogenesis of cerebrovascular diseases, it is important to mention that cellular senescence may play a role in comorbidities and conditions known as risk factors for stroke (Buga et al., 2013). Cellular senescence impacts the formation and state of atherosclerotic plaques (Ritzel et al., 2018) and endothelial cells showing the hallmarks of senescence triggered by stressors like changes in glucose levels, homocysteine or elevated blood pressure (Tian and Li, 2014) may play a role in age-related vascular diseases. Since cellular stress induces senescence, it remains to be experimentally tested whether stroke itself triggers senescence in brain cells, which may influence the CNS microenvironment, have long-term consequences and an impact on the outcome after cerebral insults.

Systemic Metabolic Disease, Cellular Senescence, and Neurodegeneration

Risk factors in many neurodegenerative disorders include systemic metabolic diseases (see section "Impact of Peripheral Metabolic Disorders on Neurodegeneration"), which, in fact, favor the accumulation of senescent cells by facilitating the

functional changes of cellular distribution and regulation of adipose tissue. As mentioned before, cellular senescence in aging may contribute to a chronic inflammatory state in the brain and peripheral tissues (Buga et al., 2013).

Interestingly, obesity generates an accelerated state of aging, pro-oxidant factors as well as glucotoxicity (Hardie et al., 2006; Eberle and Ament, 2012). It is also associated with an increased senescent cell burden and a wide range of neurodegenerative and neuropsychiatric diseases (Gariepy et al., 2011; Hryhorczuk et al., 2013; Morsi et al., 2018). Ogrodnik and colleagues demonstrated that, in obese mice, glial cells show increased markers of cellular senescence in the periventricular region of the lateral ventricle, a region in close proximity to the neurogenic niche (Ogrodnik et al., 2019).

Furthermore, the affected glial cells in obese mice display excessive fat accumulation, which is in agreement with the role of glial cells on the senescence-mediated induction of neurodegeneration. Since SASP contributes to inflammation, metabolic dysregulation, progeria, pulmonary fibrosis, geriatric syndromes, and the loss of resilience, the clearance of senescent cells may delay or even alleviate multiple age-related diseases (Kirkland and Tchkonia, 2017).

Taking into consideration the increasing body of evidence on the role of cellular senescence in neurodegenerative, cerebrovascular, and metabolic disorders, we propose to investigate senescent cell accumulation in the periphery and in the nervous system as well as the influence of SASP on processes in the CNS, such as neuroplasticity, specific cellular populations, and on the brain–body signaling. This will help to understand the normal process of aging and senescence in an integrative way.

BODY–BRAIN TROPHIC INTERACTIONS AS THE ORIGIN OF NEURODEGENERATION

The disruption of the bidirectional interaction between neurons and the cells they innervate has not been considered as a putative etiologic mechanism of neurodegeneration. According to the trophic theory of neural connections, the body is represented several times within the nervous system along the sensory and motor pathways (Purves, 1988). Thus, changes in size and function of the body must be accompanied by changes in their neural representation at a central level, which may include neurite remodeling and functional adaptations.

Furthermore, novel requirements of the body affect the peripheral and central connections of peripheral neurons. In early phases of metabolic disorders, adipocytes and immune cells are related to peripheral nerve remodeling of both sympathetic and sensory fibers (Pellegrinelli et al., 2018; Yamazaki et al., 2018). In addition, the alteration of the enteric nervous system (ENS) may be a conduit to induce changes in the CNS. Future studies oriented to understand the interactions between neurons and the cells they innervate would help to discover biomarkers for early diagnosis and to monitor disease progression. Here, we present a brief summary of the experimental evidence related to the early events of neurodegeneration in the body and discuss possible mechanisms of intercellular communication that may be operating (**Figure 2**).

Pathological Events in the Peripheral Nervous System

Various neurodegenerative diseases share common molecular and cellular mechanisms including the misfolding of proteins that undergo conformational changes leading to tissue deposition and the formation of inclusion bodies. Increasing evidence suggests that these neurodegenerative proteinopathies may originate in the peripheral nervous system (Wakabayashi et al., 2010) or even across the body.

In PD and dementia with Lewy bodies (DLBs), the histopathological hallmark is the occurrence of neuronal α-synuclein aggregates, also known as Lewy bodies. Lewy bodies are typically found in the substantia nigra in PD. However, LBs can also be present in peripheral organs, neural or not, including the sympathetic ganglia, ENS, cardiac and pelvic plexuses, submandibular gland, adrenal medulla, and the skin (Beach et al., 2010; Wakabayashi et al., 2010). Moreover, in the early pathological stages of PD, α-synuclein pathology is present first in the dorsal motor nucleus of the glossopharyngeal and vagal nerves as well as the anterior olfactory nucleus (Braak et al., 2003a).

In AD, NFTs are observed in the spinal and sympathetic ganglia. However, it seems that they develop independently of the cerebral AD pathology (Shankle et al., 1993). In ALS, TDP-43 is a major component of the ubiquitinated inclusions and also occurs in the neurons of the spinal ganglia (Nishihira et al., 2008).

Sensory abnormalities have been described in neurodegenerative diseases including PD and AD. In this regard, the loss of olfaction represents an important early clinical symptom frequently preceding motor and cognitive impairments typically observed in these neurodegenerative diseases (Driver-Dunckley et al., 2014; Doty, 2017; Marin et al., 2018; Rey et al., 2018). The olfactory system may be particularly affected in neurodegenerative diseases as seen by the accumulation of pathological protein aggregates in olfactory structures including the anterior olfactory nucleus, the olfactory bulb, and the olfactory epithelium (OE) (Doty, 2017; Marin et al., 2018; Rey et al., 2018).

Given that the OE is directly accessible to external factors, it is vulnerable to environmental insults. Thus, external agents (toxins, bacteria, viruses, air pollutants) may trigger neurodegeneration through the OE (Rey et al., 2018). Once these agents enter the brain via the OE, they may cause protein misfolding and the spreading of protein aggregates in a prion-like manner throughout the olfactory pathway to other anatomically connected brain regions (Doty, 2017).

Moreover, xenobiotics and particles in contact with the OE can also induce the production of reactive oxygen species triggering a local inflammatory reaction in a similar way to that induced by misfolded proteins (Lema Tome et al., 2013). Alternatively, the enhanced expression of misfolding-prone proteins in olfactory structures may make those regions prone to develop certain diseases (Duda et al., 1999; Taguchi et al., 2016; Kim et al., 2018).

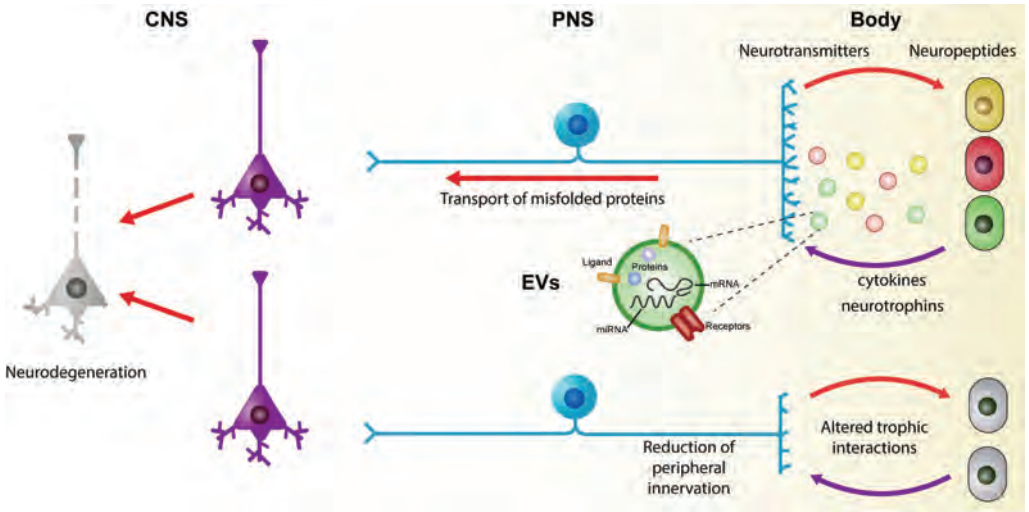

FIGURE 2 | The role of trophic interactions between the brain and the body in the development of neurodegenerative diseases. Under physiologic conditions, there is a continuous exchange of information between neurons and their targets. Neurons control several aspects of the cells they innervate by the release of neuropeptides and neurotransmitters. Reciprocally, peripheral cells modulate neuronal physiology by the release of several molecules including neurotrophins and cytokines. Recently, extracellular vesicles (EVs) have been considered as key players in the development and progression of chronic and degenerative diseases. An alteration of the homeostatic state of peripheral cells is reflected on the molecular cargo of EVs which, in turn, can affect the functioning of the neurons. Common to several chronic and neurodegenerative diseases, there is a reduction of peripheral innervation which leads to a disturbance of the trophic relation between the body and the central nervous system. A continuous alteration of these interactions during maturity of individuals may underlie some of the early events that reflect on neuronal death during aging. CNS, central nervous system; EVs, extracellular vesicles; PNS, peripheral nervous system.

Pain abnormalities are part of the clinical features in patients with PD and the impaired nociceptive processing depends on nociceptor degeneration (Nolano et al., 2008; Reichling and Levine, 2011; Conte et al., 2013). Skin biopsies of PD patients reveal a decrease in cutaneous autonomic innervation, free epidermal nerve endings, and encapsulated sensory endings (Dabby et al., 2006; Nolano et al., 2008). The severity of PD correlates with the loss of Meissner corpuscles and epidermal nerve fibers, accompanied by a reduction in cold and pain perception (Nolano et al., 2008).

The accumulation of misfolded proteins such as α-synuclein and parkin due to a dysfunction of the ubiquitin-proteasome system may partially explain the painful nociceptor dysfunction (Saha et al., 2000). In AD, pain perception seems not to be reduced. However, more studies are necessary to document whether sensory innervation is modified in AD and other neurodegenerative diseases (Cole et al., 2006). Of note, it is important to mention that different mechanisms involving both peripheral and central pain pathways may play a role in sensory dysfunction.

Autonomic dysfunction is present in several neurodegenerative diseases including PD, multiple system atrophy, AD, and other types of dementia such as DLB, PD with dementia, and frontotemporal lobar degeneration (Idiaquez and Roman, 2011; Coon et al., 2018). Orthostatic hypotension has been widely reported in patients with PD and DLBs as seen by the decreased cardiac uptake of the noradrenaline analog meta-iodobenzylguanidine (Orimo et al., 2005).

The presence of orthostatic hypertension may be due to the depletion of cardiac vagal sympathetic nerves as well as the α-synuclein pathology in sympathetic ganglia and adrenal gland that have been reported in Lewy body diseases, which includes PD, PD with dementia, and DLB (Wakabayashi et al., 2010). Interestingly, sympathetic denervation precedes neuronal loss in the sympathetic ganglia (Orimo et al., 2005). Autonomic dysfunction in AD may also be affected by neuropathological changes in central autonomic networks (Collins et al., 2012). Future studies should focus on the temporality of autonomic alterations in neurodegenerative diseases.

Gastrointestinal dysfunction is closely linked to the dysfunction of the ENS. Enteric dysfunction has been reported in PD, AD, ALS, and frontotemporal dementia (Rao and Gershon, 2016). Biopsies of PD patients have demonstrated the presence of Lewy-type pathology in enteric neurons suggesting a role of the ENS in the onset of the disease (Kupsky et al., 1987; Wakabayashi et al., 1988, 1990). The unmyelinated axons of enteric neurons may increase their susceptibility to PD and due to their multiple synaptic terminals may promote the propagation of α-synuclein aggregates via connected ganglia (Chalazonitis and Rao, 2018).

Likewise, in AD patients, Aβ immunoreactivity is found in the submucosa of the intestine (Joachim et al., 1989). In addition, amyloid precursor protein expression is present in the enteric neurons of AD patients (Arai et al., 1991). However, in contrast to PD, data from human samples in AD are still sparse. Other autonomic dysfunctions reported include urinary symptoms, sexual and thermoregulatory, dysfunction, and sleep disturbances (Postuma et al., 2015; Racosta et al., 2015; Pfeiffer, 2016). A better characterization of peripheral damage is required

in those cases where there is evidence of alteration in the peripheral innervation.

Impact of Peripheral Metabolic Disorders on Neurodegeneration

An increasing body of evidence suggests that metabolic disturbances may contribute to neurodegenerative processes in the CNS. We discuss here briefly the impact of diabetes mellitus (DM) and obesity on neurodegeneration.

Diabetes mellitus is one of the most common metabolic diseases and a major disorder of insulin regulation with increasing incidence (Duarte et al., 2012). Especially type 2 diabetes (T2D) is a highly complex, multifactorial metabolic disease, characterized by a progressive pancreatic β-cell failure (relative insulin deficiency), decreased insulin action and peripheral insulin resistance (Campbell, 2011; Carvalho et al., 2012).

T2D develops under a cluster of risk factors that includes high blood glucose, obesity, increased blood triacylglycerols and insulin resistance, which individually or collectively, also increase the risk for neurodegeneration/neuronal death, functional and structural brain changes, culminating in cognitive dysfunction that underlies dementia-type disorders (e.g., AD), which may arise from a complex interplay between T2D and brain aging. Additionally, decreased brain insulin levels/signaling and glucose metabolism in both pathologies further suggests that an effective treatment strategy for one disorder maybe also beneficial in the other (Duarte et al., 2013).

Obesity is clinically identified based on measurements of body mass index, but can be generally defined as the condition in which excess body fat has accumulated to an extent that can negatively affect health. This definition is based on the dramatically enhanced risk for a myriad of disorders, including T2D, CVD, gastrointestinal and respiratory disorders, and several types of cancer (for review, see Haslam and James, 2005). Furthermore, abdominal obesity is a component of the metabolic syndrome, which additionally combines insulin resistance or glucose intolerance, atherogenic dyslipidemia, elevated blood pressure, and increased expression of prothrombotic and proinflammatory markers (for review, see Olufadi and Byrne, 2008) and is an important risk factor for T2D, CVD, and stroke.

While the consequences of obesity on metabolic and cardiovascular pathophysiology are well-studied, epidemiological and experimental data are beginning to reveal that the CNS may also be detrimentally affected by obesity and obesity-induced metabolic dysfunction. In particular, data show that obesity is associated with cognitive decline and enhanced vulnerability to brain injury, while experimental studies in animal models confirm a profile of increased susceptibility to brain damage and decreased cognitive function (Bruce-Keller et al., 2009).

Recent data suggest that both AD and PD can manifest systemic alterations in energy metabolism (e.g., increased insulin resistance and dysregulation of glucose metabolism). Moreover emerging evidence that dietary restriction can forestall the development of AD and PD is consistent with a major "metabolic" component to these diseases, and provides optimism that these devastating brain disorders of aging may be largely preventable (Blum-Degen et al., 1995; Mattson et al., 1999).

Advanced glycation end products generated by chronic hyperglycemia and their receptor RAGE provide critical links between diabetes and AD (Vicente Miranda et al., 2016; Fleitas et al., 2018). Obesity, diabetes, and metabolic syndrome increase the risk of cognitive decline and dementia, including not only vascular dementia, but also AD and PD (Roriz-Filho et al., 2009).

However, due to increased incidence, especially in the aging population, the impact of metabolic disease on neurodegenerative processes will increase tremendously in the upcoming decades. We believe therefore that potential therapeutic approaches aiming at preventing/treating neurodegenerative diseases should include metabolic disorders.

Altered Body–Brain Trophic Communication

Accumulating evidence suggests that patients with neurodegenerative diseases commonly develop sensory and autonomic dysfunctions during maturity. This raises the possibility that the peripheral nervous system may be the gateway to alter brain physiology. The trophic theory of neural connections states that there is a mutual dependence between neurons and their targets (Purves, 1988; Qureshi and Mehler, 2013; Holm et al., 2018). Olfactory or gastrointestinal alterations may reflect a distortion of the communication between a variety of cell types and peripheral neurons. The repercussion of these altered interactions on the development of neurodegenerative diseases are still underexplored. Moreover, the mechanisms of cellular communication between peripheral cells and the nervous system are not fully characterized.

Recently, a novel system of intercellular communication has been proposed to modulate changes in neuronal physiology and to participate in the propagation of misfolded proteins (Fevrier et al., 2004; Asai et al., 2015; Grey et al., 2015; Polanco et al., 2016). This system is mediated by membranous organelles denominated as EVs, which can travel from the periphery to the brain and vice versa (Li et al., 2018).

Apparently, all the cell types of the body can release EVs to transmit information in the form of proteins, RNAs, and lipids. EVs are classified according to their subcellular origin in exosomes when originating from multivesicular bodies and in ectosomes (or microvesicles) when formed from the plasma membrane (Thery et al., 2018). Despite the technical challenges to study the functional role of different EVs subpopulations, their participation in both the maintenance of tissue homeostasis and the progression of chronic degenerative diseases is becoming clearer.

Extracellular vesicles are involved in several processes of brain development and normal functioning, including synapse formation, synaptic plasticity, and communication between glia and neurons. The signaling proteins of hydrophobic nature, such as the Wnt family members and other regulatory proteins, are loaded into EVs (Korkut et al., 2009; Coulter et al., 2018; Lee et al., 2018). During mammalian brain development, the vesicular secretion of the

growth factor sonic hedgehog promotes the proliferation of neural progenitors.

Interestingly, the loss of function of the complex charged multivesicular body proteins 1A reduces the number of intraluminal vesicles and the secretion of a specific subtype of EVs whose functions can be directly related to sonic hedgehog signaling (Coulter et al., 2018). At the *Drosophila* neuromuscular junction, EVs containing the Wnt-binding protein Evennes Interrupt and the Wnt 1 homolog Wingless promote synaptic growth when released from the presynaptic terminal (Korkut et al., 2009; Koles et al., 2012).

There is a constant reciprocal exchange of information through EVs between the pre- and post-synapse to modulate fine aspects of synaptic maturation and remodeling. In rat hippocampal neurons, excitatory synapses can be eliminated by a mechanism dependent on the delivery of Proline-Rich 7 by exosomes to induce the degradation of the post-synaptic density protein-95 (Lee et al., 2018).

Extracellular vesicles contents also influence long-term memory and synaptic plasticity. In neuronal cultures from mouse hippocampus and in neuromuscular junction preparations from *Drosophila*, oligomers of the activity-regulated cytoskeleton-associated protein and its own mRNA are transported through exosomes to the post-synapse (Ashley et al., 2018; Pastuzyn et al., 2018). The translation of the exosomal activity-regulated cytoskeleton-associated protein mRNA increases by the activation of the group 1 metabotropic glutamate receptors (Pastuzyn et al., 2018). The notion that neurons constantly use EV-mediated communication is reinforced by the fact that the release of EVs is activity-dependent and that the delivery of the cargo from presynaptic cells enables retrograde signaling from the post-synaptic cells (Lachenal et al., 2011; Korkut et al., 2013; Lee et al., 2018).

The general hypothesis on the role of EVs related to the development of neurodegenerative diseases relies on their potential to transport protein aggregates, which has been reviewed elsewhere (Howitt and Hill, 2016). Here, we would like to center the discussion on the possibility that a bidirectional exchange of information through EVs between peripheral cells and neurons may have a long-term impact on the brain physiology.

Emerging evidence suggests that both central and peripheral neurons can uptake EVs from a variety of cell types. Thus, under certain circumstances, EVs derived from peripheral cells contain proteins or RNAs that can be deleterious for neuronal functioning. In agreement with this notion, exosomes derived from hyperglycemic Schwann cells contain microRNAs that suppress axonal growth *in vitro* (Jia et al., 2018). Moreover, hyperglycemic Schwann cell-derived exosomes contribute to the development of diabetic peripheral neuropathy when injected into a diabetic mouse (Jia et al., 2018).

Similarly, the CNS can also be affected by the information transported by systemic exosomes. An increase of inflammatory cytokines in the brain and microglial and astrocytic activation is observed after the intravenous injection of serum-derived exosomes from lipopolysaccharide (LPS)-challenged mice (Balusu et al., 2016; Li et al., 2018). Dorsal root ganglion neurons modulate immune cells in the periphery by the release of neuropeptides.

Recent findings also indicate that EV-mediated communication can be an additional mechanism operating during trauma. After nerve injury, dorsal root ganglia neuron-derived exosomes loaded with microRNA-21 increase the infiltration of inflammatory macrophages, which contributes to neuronal sensitization (Simeoli et al., 2017). Further work is required to obtain insights whether EVs from peripheral cells modulate cellular processes in the brain under physiological conditions and which factors can alter the messages coming from the periphery (Ridder et al., 2014).

Despite the few studies focusing on the influence of peripherally derived EVs on peripheral neurons, it is likely that peripheral terminals establish a bidirectional interaction with the cellular elements surrounding them. Both sensory and autonomic axon terminals usually end as free nerve endings in the extracellular matrix intercalated between different cell types. Peripheral neurons are responsive to EVs derived from mesenchymal stem cells and Schwann cells (Lopez-Verrilli et al., 2013, 2016; Ching et al., 2018; Sun et al., 2018; Shiue et al., 2019). The general observation of these studies, performed in conditions of neuronal damage, is that EVs reduce the inflammatory state and have a beneficial role in axonal growth both *in vivo* and *in vitro*.

Taken together, these findings indicate that neurons are susceptible to modify their functioning or gene expression profile as a result of incorporating EVs from neighboring cells. A challenge for future studies is to determine if EVs from any cell source can modify neuronal functioning and how these events are associated with physiological alterations that precede neurodegeneration in the brain.

GUT DYSBIOSIS AS THE ORIGIN OF NEURODEGENERATION

Microbiota is defined as a community of all microorganisms living in our body. Microbiota therefore includes all taxonomic domains such as fungi, protozoa, viruses, and bacteria. Bacterial microbiota living in the gut (further referred as GM) represent about 90% of all microbiota in the body (Thursby and Juge, 2017), with an estimated ratio of human:bacterial cells close to 1:1 (Sender et al., 2016). This large number of bacteria offers different benefits to the host, confers protection against pathogens (Baumler and Sperandio, 2016), regulates host immunity (Gensollen et al., 2016), and products originating from bacterial fermentation can be used as a source of energy for colonocytes (den Besten et al., 2013).

A delicate balance exists between the GM composition and its interaction with the host, while an imbalance in this composition is commonly known as dysbiosis. Gut dysbiosis has been implicated in the development of chronic diseases, such as irritable bowel syndrome (Raskov et al., 2016), coeliac disease (Verdu et al., 2015) as well as metabolic disorders, including obesity, metabolic syndrome, and T2D (Holmes et al., 2011;

Carding et al., 2015; Zhang et al., 2015; Baothman et al., 2016; Org et al., 2017).

Notably, those metabolic diseases, when developed during adulthood, are considered important risk factors for AD (Alzheimer's Association, 2016; Livingston et al., 2017). Furthermore, metabolic alterations are known to induce peripheral low-grade chronic inflammation, associated with higher incidence of neurodegenerative diseases. In AD, systemic inflammation during prodromal stages shortens disease onset (Tao et al., 2018), whereas dysregulation of the gastrointestinal function and colonic inflammation diminished immune competence and preceded motor symptoms in PD patients (Dobbs et al., 1999; Braak et al., 2003b; Lebouvier et al., 2009; Villaran et al., 2010; Forsyth et al., 2011).

During aging, there is an increased permeability of the gut epithelium (Tran and Greenwood-Van Meerveld, 2013). This condition allows bacteria and bacterial products to translocate through the disrupted gut barrier reaching peripheral organs (Zevin et al., 2016). Newest reports suggest that translocated bacteria may even reach the brain (Roberts et al., 2018), where an exacerbated immune reaction can lead to neurodegeneration. These observations remain however to be investigated in detail.

Gut Microbiota Alterations in Neurodegenerative Diseases

Recent reports concomitantly demonstrate a gut dysbiosis in PD (Minato et al., 2017; Wu et al., 2017), ALS, and AD patients (Cattaneo et al., 2017; Vogt et al., 2017).

Understanding how GM may be implicated in brain pathologies requires a clear comparison among the data reported from different research groups. The GM is mainly dominated by four phyla: Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria (Szablewski, 2018). The first studies described GM alterations only at the phylum level. However, recent advances in sequencing techniques allow distinction at the species level, which is advantageous since the different species of bacteria belonging to the same genus affect host physiology in a different manner. We compared previously published GM data obtained from AD patients and AD mice models. We noted a strong variation between studies: at phylum level, most transgenic models coincide with an increased abundance of Firmicutes but a decreased abundance of Bacteriodetes (**Table 1**). Whereas at the family and upper taxonomical levels (i.e., genus/species), there is no more consistency (**Table 2**).

Importantly, variations in the experimental design or the type of samples can be observed. Moreover, differences in the animal model, chronological stage of the pathology (age), handling and diet significantly impact GM (Mueller et al., 2006; Hufeldt et al., 2010; Sanchez-Tapia et al., 2017). Thus, experimental variations among published studies may explain discrepancies in the GM composition in AD.

Despite this strong variation, we can observe a general increased abundance of pro-inflammatory bacteria in AD mice and AD patients (Kountouras et al., 2009; Zhan et al., 2016; Cattaneo et al., 2017; Shen et al., 2017; Vogt et al., 2017; Zhang et al., 2017; Syeda et al., 2018) compared to controls. Furthermore, in AD transgenic mice, longitudinal studies clearly indicate an age-associated gut dysbiosis, culminating in a strong pro-inflammatory environment along the development of brain pathological hallmarks (Shen et al., 2017; Zhang et al., 2017; Syeda et al., 2018).

How Can the GM Affect Brain Function or Even Cause Neurodegeneration?

A bidirectional communication between the gastrointestinal system and the brain has been described and has led to the concept of gut-brain axis (Collins and Bercik, 2013). Recent studies illustrated the role of GM in brain Aβ aggregation, as GM absence in germ-free condition (Harach et al., 2017) or GM partial depletion by antibiotic treatment (Minter et al., 2016) reduced the amyloid burden and microglia activation in AD transgenic mice. However, it is still unclear which factors may be associated with the above described gut-brain axis in brain pathologies.

Several groups have implicated the neurotoxin LPS present in the outer membrane of gram-negative bacteria. LPS plays key roles in the host-pathogen interactions of the innate immune system (Hill and Lukiw, 2015; Maldonado et al., 2016). Alterations in the GM composition/abundance are associated with enhanced plasma levels of LPS (Avila-Nava et al., 2017;

Sanchez-Tapia et al., 2017), which may result in an exacerbated metabolic endotoxemia (Cani et al., 2012), a condition characterized by inflammation and the increased release of pro-inflammatory cytokines.

Systemic infections have been related to a higher possibility to develop AD (Holmes et al., 2009) as well as early motor dysfunction in PD patients (Dobbs et al., 1999). Therefore, long-term gut microbiota alterations and gut dysbiosis resulting in a pro-inflammatory environment and inflammation may be linked to brain dysfunction in aging.

As a proof of concept, LPS is detected in the parenchyma and blood vessels of both, non-demented aged and AD brain samples, but at a higher level in diseased tissues (Zhao et al., 2015, 2017; Zhan et al., 2016). LPS also increases in the plasma of AD transgenic mice compared to wild type controls (Syeda et al., 2018). In PD patients, higher plasma LPS correlates with α-synuclein aggregation (Forsyth et al., 2011). Furthermore, LPS is a well-known neuroinflammatory agent driving the generation of $A\beta_{1-42}$ (Lee et al., 2008; Asti and Gioglio, 2014; Hill and Lukiw, 2015; Zhao et al., 2015). LPS administration to mice results in memory impairment, Aβ aggregation, and astrocyte activation (Lee et al., 2008). Therefore, gut dysbiosis may enhance LPS to the blood circulation and even to the brain, producing glia activation and protein aggregation, both important features of neurodegenerative diseases.

Another bacterial product related to the development of neurodegenerative diseases are short-chain fatty acids (SCFAs). SCFAs are produced by the GM after the degradation of non-digestible polysaccharides, with butyrate, acetate, and propionate being the more abundant fermentation products (Wong et al., 2006). About 95% of the SCFAs produced in the gut are absorbed within the colon (Hoyles et al., 2018), while butyrate is used by the colonocytes as an energy source. In order to maintain an optimal equilibrium between intestinal SCFAs and the concentration in the body, the gut intestinal barrier increases its mucus production

(Rios-Covian et al., 2016), while the liver clears the majority of propionate and butyrate from the portal circulation (Bloemen et al., 2010). However, SCFAs can be transported through the bloodstream to reach the brain.

Some alterations in fecal SCFAs concentration have been described in AD transgenic mice compared to controls (Bonfili et al., 2017; Zhang et al., 2017). Butyrate, a well-known neuroprotective agent (Minamiyama et al., 2004; Govindarajan et al., 2011; Liu et al., 2015), is reduced in the fecal samples of AD mice (Zhang et al., 2017). Other reports show increased propionate levels in brain tissue of AD transgenic mice compared to wild type controls, an event associated with GM dysbiosis (Syeda et al., 2018). Although, propionate has some beneficial effects [e.g., on the BBB (Hoyles et al., 2018)], excessive propionate alters dopamine, serotonin, and glutamate systems in a manner similar to that observed in autism spectrum disorders (El-Ansary et al., 2012; Li et al., 2017).

Fecal samples of children with autism spectrum disorder present an increased level of propionate (Wang et al., 2012). In addition, genetic diseases that affect the function of the enzyme propionyl-CoA carboxylase (such as propionic acidemia) are characterized by high levels of propionate and high incidence of dementia (Grunert et al., 2013), while in AD patients, increased levels of acetate and propionate have been found in saliva samples compared to healthy controls (Figueira et al., 2016; Yilmaz et al., 2017). Although, the effects of butyrate and propionate are still controversially discussed, several data support a role of the imbalance between butyrate and propionate in the pathogenesis of AD (Syeda et al., 2018).

Another important pathway connecting the brain and the GM is the involvement of the immune system (Fung et al., 2017) studied, e.g., in stroke. According to recent reports, in the experimental rodent models, stroke leads to dysbiosis (Benakis et al., 2016; Houlden et al., 2016; Singh et al., 2016; Stanley et al., 2018) and dysbiosis may have an effect on the course of the disease (Benakis et al., 2016; Singh et al., 2016; Stanley et al., 2016). This may be linked to GM-related fine-tuning of the balance between pro-inflammatory/anti-inflammatory immune responses primarily in the gut, followed by an infiltration of immune cells to the CNS after injury. Interestingly, pro-inflammatory T-helper cell 17 and γδ T cells found in the ischemic CNS originate from the intestine and the infiltration of these subpopulations has been linked with unfavorable outcome (Benakis et al., 2016; Singh et al., 2016).

However, the optimal (in terms of prognosis after stroke) composition of the GM has not been identified yet and is possibly difficult to pinpoint. Some findings indicate that the complete absence (in germ-free mice) or deep antibiotic depletion of GM can be detrimental, leading to increased infarct volumes (Singh et al., 2018) or increased mortality not related to lesion size (Winek et al., 2016). Alterations in GM have also been identified in stroke patients (Yin et al., 2015; Stanley et al., 2016). Due to its metabolic capacities, GM can also contribute to the pathogenesis of the diseases considered as the risk factors of stroke, like obesity (for review Torres-Fuentes et al., 2017) and atherosclerosis (Karlsson et al., 2012; Tang et al., 2013) (for review, see Li and Tang, 2017).

We can conclude that a predominantly pro-inflammatory GM and the release of neurotoxic substances may negatively affect brain functions, causing systemic and central inflammation over decades. This is in support of the recent hypothesis of an infectious etiology for neurodegenerative diseases, such as AD (Bhattacharjee and Lukiw, 2013; Little et al., 2014; Maheshwari and Eslick, 2015; Itzhaki et al., 2016). The substances released from the GM (i.e., LPS and SCFAs) may be implicated in the pathogenesis of several neurodegenerative diseases; however, more data are still needed to clearly understand this gut-brain-immune interaction.

FROM CONSEQUENCES TO CAUSES: ACADEMIC AND PRECLINICAL CONSIDERATIONS

As we have described above, the neurocentric view entertained as the predominant focus of our effort in treating neurodegeneration is likely insufficient to ensure successful therapeutic intervention.

The Lack of Adequate Experimental Models to Study the Etiology

Investigating the pathophysiological processes behind neurodegeneration in detail requires the use of animal models. A plethora of animal models of neurodegeneration exists, and the nuances of these models are beyond the scope of this manuscript (for recent reviews, see Gitler et al., 2017; Dawson et al., 2018; Ransohoff, 2018).

However, two general problems with current models seem to be particularly widespread and contribute to our limited success in extrapolating findings from preclinical research to patients. Firstly, they often fail to fully integrate our understanding of the etiology of the diseases they are meant to represent, often being restricted to inducing the disease in a single way, despite multiple inducing factors being responsible for the human disease. Secondly, animals used as the model organism of specific diseases often do not exhibit similar comorbidities and demographic characteristics (such as age or gender) seen in human patients. Examples of such problems are the rodent models of stroke, particularly ones that involve surgical ligation or occlusion of blood vessels in otherwise healthy, young animals (van der Worp et al., 2010; Mergenthaler and Meisel, 2012).

Another important issue is the way these models are characterized. For animal models to be used to study neurodegeneration, two essential steps must be taken. First, the validity of the model for the question at hand should be thoroughly and systematically investigated. This is preferably done in a multi-centric and multi-disciplinary way to ensure the generalizability and robustness of the results. Second, the external (face, construct, and predictive) validity of the model (Willner, 1984) should be empirically and thoroughly tested, as well as the inter-rater agreement on, and replicability of, the model's characteristics (McKinney and Bunney, 1969). Such studies aimed at characterizing the model should be very clearly

and unequivocally separated from experiments using the model to test hypotheses, such as the effect of an intervention on the course of the model's progression.

For these strategies to be successful, research into and using these models must be conducted in the setting of appropriate, rigorous, and transparent experimental design and reporting (Kilkenny et al., 2010; Holman et al., 2016; Percie du Sert et al., 2017). Beyond that, we should make an active effort to think of the drawbacks of the models and methods we have used and how this may restrict or bias the knowledge we gain from such studies (Garner et al., 2017). Finally, we need a framework for integrating the knowledge gained from individual studies using different models and methods to address similar research questions. Systematic reviews and quantitative meta-analyses, widely used for knowledge synthesis in clinical research, may be helpful tools to help us achieve this.

Studying Human Disease in Human Systems

Although animal models are a powerful tool toward understanding the etiology of neurodegenerative diseases, they still present considerable limitations (Jucker, 2010). As a consequence, there has been little success translating the knowledge obtained from model organisms to therapeutically valuable outcomes. This constraint can only be addressed by studying neurodegenerative diseases directly on humans.

The recent increase in the generation of digital data including imaging, genotypic, and phenotypic information coupled with a fast development of computational methods allows us to obtain new insights from this massive amount of data. Major efforts from consortiums such as the Alzheimer's Disease Initiative (ADNI), the Australian Imaging, Biomarkers & Lifestyle Study of Ageing (AIBL), the Parkinson's Progression Markers Initiative (PPMI) or more recently the United Kingdom Biobank have made available an unprecedented amount of data, which can be exploited through the use of big data algorithms.

Having large amounts of information coming from heterogeneous populations and acquisition systems increases the power of statistic approaches and reduces the risk of bias. Big data approaches are inherently limited since in general they cannot be used to perform causal inference, but rather to find correlations or associations between variables. However, these correlations have proven to be an invaluable tool for hypothesis generation, drug and safety surveillance, disease and treatment heterogeneity among many other applications (Lee and Yoon, 2017).

Such computational models have been used for example to build a model of senescence signaling via DNA damage, insulin-TOR, FoxO3a transcription factors, oxidative stress response, mitochondrial regulation, and mitophagy using a systems biology approach (Dalle Pezze et al., 2014). A recent review of mathematical models in neurodegenerative diseases reports several mathematical models involving some of the processes we addressed above, such as energy metabolism and synaptic plasticity (Lloret-Villas et al., 2017). A multivariate Bayesian model of biomarker measurements was used to estimate AD dementia onset age (Bilgel and Jedynak, 2019). Similarly, multivariate models have been used to relate image based morphological features to the risk of dementia (Gutierrez Becker et al., 2018; Cole et al., 2019).

Recent trends in stem cell methods have also opened new possibilities for human brain cell cultures, which can in turn be used to model neurodegeneration. Induced pluripotent stem cells and neural stem cell cultures can now be used to generate human neurons from human and sometimes patient cells (Abud et al., 2017; Korhonen et al., 2018). This has been reviewed extensively elsewhere (Xie and Tang, 2016; Robbins and Price, 2017).

CONCLUSION

Disease is typically defined in juxtaposition to the state of health, which has been even more generally defined as "a state of complete physical, mental, and social well-being" (International Health Conference, 2002). However, in order to characterize a bodily or mental state as diseased, we need a more practical, operational definition of the healthy state, characterized in terms of physiological parameters and defined by the description of the steady state functioning of the body and its subsystems.

Typically, pathophysiological events of neurodegeneration are detected through behavioral observations and self-reporting and subsequently confirmed and classified using neurological examination and diagnostic imaging. The result of this diagnostic approach usually reveals typical defining features for each neurological disease (such as hemorrhage, tumor, or deformations), that allows the classification of the disorder. However, these defining characteristics are not necessarily the root causes of the disease but rather elements of the disease manifestation or even merely epiphenomena. In addition to the complex and usually obscure causal relationships giving rise to brain disorders, a parameter that further complicates the identification of causation is the widespread and intricate comorbidities between presumably distinct and unrelated disorders.

Together, these facts limit the therapeutic potential to treat the symptoms rather than the causes. The complex causality chain hinders the early detection and treatment of the root causes of brain disorders overall and neurodegeneration more specifically. These limitations highlight the critical need for a drastic shift of perspective and the improvement of the models used to investigate and understand neurodegenerative diseases.

Given the complexity of the brain and its disorders, researchers and clinicians have retreated to a highly segregated approach, focusing on describing subsets of the symptoms of each disease and trying to identify mechanistic explanations and treatments for those symptoms. However, the lack of a holistic perspective, taking into account the deviations from the default homeostatic state at an organismal level, renders this endeavor nearly impossible and doomed to fail.

Importantly, characterizing the expected, default healthy brain, is a necessary precondition to being able to identify and meaningfully interpret the deviations from it. Thus, characterizing and understanding the brain function in health is of paramount importance in the attempt to understand and treat the diseased brain.

In summary, there is an identifiable need for an interdisciplinary approach to explore the brain function at multiple levels, from molecular to systems, while maintaining a holistic perspective that treats the brain as an element of a complex system, rather than a separate entity. Using this approach, fundamental research can proceed hand-in-hand and maintain a constant dialogue with clinical research, to propose, improve, and revise current models of health and disease.

We hope that our work inspires the opening of new research avenues among those interested in understanding and pursuing the complexities of the "neuro-degenerating" brain focusing on lifespan processes. Therefore, the proposed etiological paths and suggestions will be important guidelines for future cross-discipline research to overcome the translational roadblock and to develop causative treatments for neurological disorders.

AUTHOR CONTRIBUTIONS

AP, GG-O, and MZ applied for funding and organized the workshop. AK, AP, AV, BG-B, MZ, NK, and XC were participants of the subgroup "The Vascular Origin of Neurodegeneration." AV-C, JP-V, KR, KW, LR, and SC-O of the subgroup "Cellular Senescence as the Origin of Neurodegeneration." CP-C, EM-M, GG-O, HG, and JL-N of the subgroup "Body–Brain Trophic Interactions as the Origin of Neurodegeneration." Accordingly, the authors wrote the respective sections of this manuscript, except CP-C who together with TS wrote the section "Gut Dysbiosis as the Origin of Neurodegeneration" with contributions from KW. AP contributed to the section "Body–Brain Trophic Interactions as the Origin of Neurodegeneration." BG-B wrote the section on "Studying Human Disease in Human Systems." AK on "The Lack of Adequate Experimental Models to Study the Etiology." NK wrote the conclusion. MZ wrote the remaining sections of the manuscript. AV commented on the manuscript. All authors discussed and commented on the final version of the manuscript.

FUNDING

This work was supported by a grant from the German Federal Ministry of Education and Research (BMBF grant number 01DN18054) to MZ, AP, and GG-O.

ACKNOWLEDGMENTS

This is a spin-off article from the workshop "German-Mexican Roundtable Exploring New Etiological Paths Towards Neurodegeneration," which took place at the Instituto de Investigaciones Biomédicas at the National Autonomous University of México, Mexico City, on October 15–17th, 2018. Miguel Morales Pacheco helped in the design of **Figure 1**.

Abstract

Neurological disorders are a public health problem worldwide for which there is currently no direct treatment of the cause of the disorder. The goal of this study was to investigate the potential in vitro neuroprotective property of plants used in Mayan traditional medicine. Plant ethanolic extracts were prepared and tested on models in which neuronal damage was induced by glutamate, i.e., a human neuroblastoma cell line (SH-SY5Y) and rat cortical neurons. HPLC profiles from active extracts were also obtained. A total of 51 plant species were identified in the literature as plant species used in Mayan traditional medicine for the treatment of symptoms suggestive of neurological disorders, and we studied 34 of these in our analysis. Six extracts had a neuroprotective effect on SH-SY5Y cells, with the most active extract being that from *Schwenckia americana* roots (half maximal effective concentration [EC_{50}] 11.3 ± 2.9 µg/mL), and three extracts exhibited a neuroprotective effect in the rat neuron cortical model, with the most active extract being that from *Elytraria imbricata* aerial parts (EC_{50} 6.8 ± 3.1 µg/mL). These results suggest that the active extracts from such plants have the potential to be a great resource. Future studies should be performed that are more extensive and which isolate the active constituents.

Keywords Mayan traditional medicine · Neuroprotective effect · Glutamate · Rat cortical neuron · SH-SY5Y cell line

Introduction

Neurological disorders, such as cerebrovascular and neurodegenerative diseases, are a public health problem worldwide [1]. Damage to and loss of neurons are the main characteristics of these disorders, and the mechanisms involved comprise oxidative stress, inflammation, excitotoxicity, misfolded protein accumulation, and others [2].

Current treatments are palliative, only relieving the symptoms without dealing with the cause of the condition. Thus, neuronal damage remains even during and after treatment, and the disease progresses [3].

There is a vast amount of information available on traditional medicines, including those used in Mayan traditional medicine, and the application of these plants to treat different disorders. Much research has focused on identifying the bioactive extracts/compounds of such plants [4, 5]. However, to date no studies on native plants from the Yucatan Peninsula with neuroprotective effects have been reported.

The goal of this study was to test plants reported to be used in Mayan traditional medicine to treat symptoms related to a neurological disorder in two in vitro models of neuronal

damage induced by glutamate, namely, in a human neuroblastoma cell line (SH-SY5Y) and in rat cortical neurons.

Materials and methods

Literature search

The selection of the plant species included in this study was based on information derived from Mayan traditional medicine records [4, 5]. Criteria for the selection of the species were as follows: (1) plant species used against symptomatology suggestive of neurological conditions (such as headache, convulsions, depression, dementia, loss of speech, loss of orientation, and neuralgia); (2) plant species mentioned in the ethnobotanical literature with full scientific name; (3) endemic or native plant species of the Yucatan Peninsula; (4) plant species for which no more than ten neuroprotective and/or chemical studies reported.

Plant material and preparation of ethanolic extract

Plant species were collected from different locations around the Yucatan Peninsula in Mexico (see Electronic Supplementary Material [ESM]). The plant material was identified and authenticated by a taxonomist from the Department of Natural Resources of the Centro de Investigación Científica de Yucatán (CICY). Voucher specimens were deposited at CICY's U Najil Tikin Xiw herbarium.

Plant material was dried first at room temperature for 48 h and then at 40 °C in a herbarium drying box for 48 h before being ground into powder. Dried plant material (20 g) was macerated with ethanol (100%) for 72 h at room temperature. The supernatants were filtered and evaporated under vacuum using a rotary evaporator.

Cell culture

Cercopithecus aethiops kidney (Vero cells; ATCC® CCL-81™) and human neuroblastoma SH-SY5Y (ATCC® CRL-2266™) cell lines from the American Type Culture Collection (ATCC; Manassas, VA, USA) were used for the in vitro assays. Vero cells were cultured with Dulbecco's Modified Eagle medium (DMEM) supplemented with fetal bovine serum (FBS) (10%, v/v), 100 U/mL of penicillin G and 100 µg/mL of streptomycin. SH-SY5Y cells were cultured in DMEM/F12 (1:1) medium supplemented with FBS (15%, v/v), 100 U/mL of penicillin G, and 100 µg/mL of streptomycin. Both cell lines were maintained at 37 °C in an atmosphere of 5% CO_2.

Cell viability assay in the Vero and SH-SY5Y cell lines

Cell viability in Vero cells was determined using sulphorhodamine B (SRB; Sigma–Aldrich, St. Louis, MO, USA) and in SH-SY5Y cells using calcein-AM (Sigma–Aldrich). For each assay, 1×10^5 cells per well were seeded in 96-well plates, and the assays were performed 24 h later. Cells were exposed to the plant extracts at concentrations of 500, 250, 125, and 62.5 µg/mL for 48 h. Vero cells were then fixed with 10% trichloroacetic acid at 4 °C for 20 min, following which SRB (0.1%, p/v) was added for 20 min at room temperature; the cells were later washed with acetic acid (1%, v/v). A solution of 10 mM TRIS-base was used to solubilize SRB, and optic density was read in a microplate reader. For the SH-SY5Y cells, calcein-AM (4 µM) was added to the cells and the wells incubated for 30 min at 37 °C. The plates were then washed twice with phosphate buffered saline (PBS) 1×(pH 7.4), and fluorescence was read in the same microplate reader as that used for the assay of Vero cells.

Neuroprotection assay in SH-SY5Y cells

For the assays 1×10^6 cells per well were seeded in 96-well plates, and the assays were performed 24 h later. Cells were pretreated with the extracts at concentrations of 25, 12.5, 6.25, and 3.125 µg/mL for 24 h. Ascorbic acid (Sigma–Aldrich) was employed as positive control due to its antioxidant activity. The cells were then exposed to glutamic acid (Sigma–Aldrich) at 25 mM for 30 min, following which the medium was removed and replaced with fresh medium, and incubated continued for 24 h. Calcein-AM (4 µM) was added and the cells incubated for 30 min at 37 °C before being washed twice with PBS 1×(pH 7.4); fluorescence was read in a microplate reader.

Experimental animals and rat cortical neurons isolation

All procedures were approved by the Institutional Animal Care and Use Committee and complied with Mexican regulations (NOM-062-ZOO-1999). The animals were housed in animal units under a photoperiod of 12 h light/12 h dark and at a temperature of 22 °C; food and water were provided ad libitum. Pregnant Wistar rats (E17–E18 days gestation) were anesthetized with sevoflurane and sacrificed by decapitation. Primary cultures of mixed cortical cells containing both neuronal and glial cells were prepared from the fetal Wistar rats aged E17 to E18 days of gestation. The cortex was dissociated mechanically and with 0.25% trypsin (1 µL/mL), and dissociated cells were cultured in 96-well culture plates coated with poly-L-ornithine at a density of 1×10^5

as the positive control. The neurons were then exposed to glutamic acid (12.5 mM) for 30 min, following which the medium was removed and replaced with fresh medium; the neurons were then incubated for a further 24 h. Calcein-AM (4 µM) was added to the cells and the cells incubated for 30 min at 37 °C. The cells were washed twice with PBS 1×(pH 7.4), and fluorescence was read in a microplate reader.

HPLC profiles

Ethanolic extracts were diluted 1:100, and 10- to 20-µL aliquots were injected into an Agilent Infinity 1260 HPLC system (Agilent Technologies, Santa Clara, CA, USA) equipped with a C-18 pre-column (Zorbax Extend, 12.5 mm × 4.6 mm × 4.5 µm) and a reverse column (Persil Gold C-18, 150 mm × 4.6 mm × 5.0 µm).).

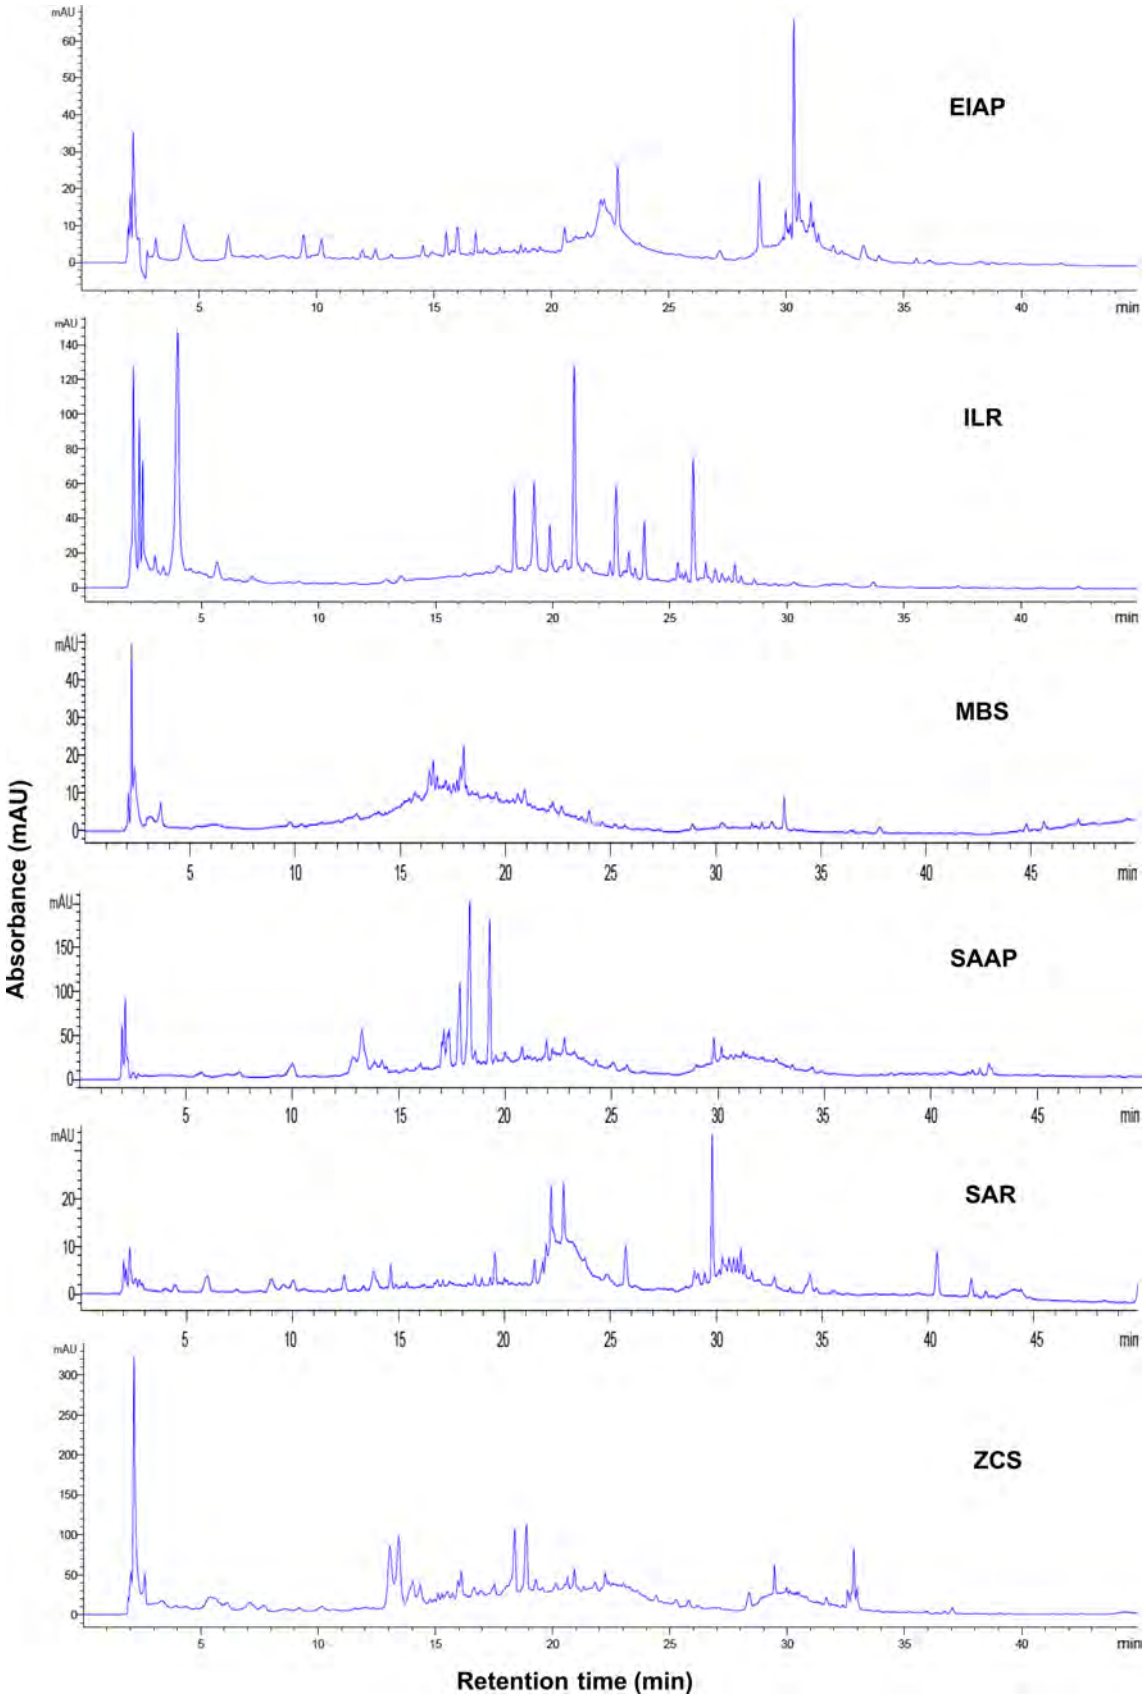
The ultraviolet detector was set at 254–274 nm and the flow rate at 1 mL/min. Samples were eluted with a linear gradient of 1–100% acetonitrile and water with 3% acetic acid.

Statistical analysis

The experiments were performed in duplicate and repeated at least three times. The half maximal effective concentration (EC_{50}) was determined from sigmoidal dose–response variable-slope curves using employing GraphPad Prism ver. 6 statistical software (GraphPad Software Inc., San Diego, CA, USA).

Results and discussion

In this study, we identified 51 plant species from the literature search, of which 38 met the criteria and 34 were collected (Table 1); four species were not collected because the specimens were difficult to find (see ESM), and 13 plant species were excluded (Table 2). Sixty-five ethanolic extracts were prepared using different parts of the plant or whole plant (see ESM). Cytotoxic activity of the ethanolic extracts was tested against the Vero cell line to show that the extracts were innocuous to a normal cell line. Extracts with an CC_{50} of < 125 µg/mL were excluded from the neuroprotective assays. Four extracts were found to be cytotoxic to the Vero cells, 12 extracts were cytotoxic to SH-SY5Y cells, and five extracts were cytotoxic to rat cortical neurons (Table 3).



The viability percentage of SH-SY5Y cells exposed to glutamic acid (25 µM) to induce neuronal damage was 47.29 ± 5.61%, and based on this value we calculated the EC_{50} of the extracts. Ascorbic acid (positive control) had an EC_{50} of 20 µM. Six extracts exerted a neuroprotective effect against glutamate-induced toxicity in this model (Table 3), of which the extract of *Schwenckia americana* roots was the most active (EC_{50} 11.3 µg/mL).

The viability percentage of rat cortical neurons exposed to glutamic acid (12.5 mM) to induce neuronal damage was 47.00 ± 1.82%, and based on this value we calculated the EC_{50} of the extracts. MK-801 (positive control) had an EC_{50} of 10 µM. Three extracts were found to have a neuroprotective effect against glutamate-induced toxicity in this model (Table 3), of which the most active extract was that of *Elytraria imbricata* aerial parts (EC_{50} 6.8 µg/mL).

The chromatographic profile can be used in future studies to isolate the metabolites responsible for the effect of the standardized herbal extract. Therefore, we determined the chromatographic profiles of the six most active extracts (Fig. 1).

To date there are no reports of a phytochemical study of *E. imbricata* nor on the neuroprotective effect of its extracts.

Journal of Natural Medicines (2019) 73:672–678

INFORME DE LABORES 2019

◂**Fig. 1** HPLC profiles of active extracts. *EIAP Elytraria imbricata* aerial parts (254 nm), *ILR Isotoma longiflora* roots (254 nm), *MBS Mimosa bahamensis* stems (274 nm), *SAAP Schwenkia americana* aerial parts (254 nm), *SAR Schwenkia americana* roots (254 nm), *ZCS Zanthoxylum caribaeum* stems (254 nm)

Isotoma longiflora is reported to be a Mayan traditional medicine used to treat depression, a disorder which presents high levels of glutamate [7]. Thus, the neuroprotective effect shown by *I. longiflora* in both assays provides support for its use in Mayan traditional medicine. Piperidine and tetrahydropyiridine alkaloids have been isolated from *E. imbricata* plants, and the methanolic extract from whole plant contains saponins and glycosides [8, 9].

There is no report to date on the neuroprotective effect of *M. bahamensis*; however, *M. pudica* has been widely studied in neuroprotective assays [10, 11].

A phytochemical profile of the ethanolic extract from *Schwenckia americana* has been reported in which the presence of alkaloids, tannins, phenols, flavonoids, saponins, terpenoids, steroids, and phytosteroids was shown [12]. Both parts of the plants (aerial parts and roots) were shown to have a neuroprotective effect, suggesting that the active metabolites are distributed throughout the whole plant.

Zanthoxylum caribaeum is reported to be a Mayan traditional medicine used to treat epilepsy and to possess anesthetic properties. There are no reports of a neuroprotective effect but a species of the same genus, *Z. capense*, has been reported to have neuroprotective properties [13].

Conclusion

Traditional medicine is a source of plant species that can be potential novel drugs, including those which could be used to treat neurological disorders. In this study, we analyzed 34 plant species utilized in Mayan traditional medicine to treat symptoms suggestive of neurological disorders and tested these in two models of neuronal damage induced by glutamate, namely, in SH-SY5Y cells and rat cortical neurons. According to our results, five of the plant species tested, i.e., *E. imbricata*, *I. longiflora*, *M. bahamensis*, *S. americana*, and *Z. caribaeum*, have distinct in vitro neuroprotective effect.

Because there is no drug that is currently commercially available to treat directly the causes of neuronal damage observed in neurological diseases, we suggest that it is worthwhile to conduct more in vitro studies on these extracts and to purify the active compounds.

Acknowledgements The research reported herein was partially supported by Red Temática de Células Troncales y Medicina Regenerativa, project number 271609. We are grateful to Paulino Simá-Polanco from the Department of Natural Resources of the Centro de Investigación Científica de Yucatán (CICY) for identifying the specimens and to the Departamento de Nutrición e Inmunología Acuícola of CINVESTAV-Mérida for the facilities provided. SUMMARY

Reactive oxidative species (ROS) and *S*-glutathionylation modulate the activity of plant cytosolic triosephosphate isomerases (cTPI). *Arabidopsis thaliana* cTPI (AtcTPI) is subject of redox regulation at two reactive cysteines that function as thiol switches. Here we investigate the role of these residues, AtcTPI-Cys13 and At-Cys218, by substituting them with aspartic acid that mimics the irreversible oxidation of cysteine to sulfinic acid and with amino acids that mimic thiol conjugation. Crystallographic studies show that mimicking AtcTPI-Cys13 oxidation promotes the formation of inactive monomers by reposition residue Phe75 of the neighboring subunit, into a conformation that destabilizes the dimer interface. Mutations in residue AtcTPI-Cys218 to Asp, Lys, or Tyr generate TPI variants with a decreased enzymatic activity by creating structural modifications in two loops (loop 7 and loop 6) whose integrity is necessary to assemble the active site. In contrast with mutations in residue AtcTPI-Cys13, mutations in AtcTPI-Cys218 do not alter the dimeric nature of AtcTPI. Therefore, modifications of residues AtcTPI-Cys13 and AtcTPI-Cys218 modulate AtcTPI activity by inducing the formation of inactive monomers and by altering the active site of the dimeric enzyme, respectively. The identity of residue AtcTPI-Cys218 is conserved in the majority of plant cytosolic TPIs, this conservation and its solvent-exposed localization make it the most probable target for TPI regulation upon oxidative damage by reactive oxygen species. Our data reveal the structural mechanisms by which *S*-glutathionylation protects AtcTPI from irreversible chemical modifications and re-routes carbon metabolism to the pentose phosphate pathway to decrease oxidative stress.

Keywords: *Arabidopsis thaliana*, glutathionylation, thiol-based redox modulation, triosephosphate isomerase, X-ray structure.

INTRODUCTION

Triosephosphate isomerase (TPI) interconverts glyceraldehyde 3-phosphate to dihydroxyacetone near the rate diffusion limit during glycolysis, gluconeogenesis, and the Calvin–Benson cycle (Blacklow *et al.*, 1988; Wierenga *et al.*, 2010; Michelet *et al.*, 2013). TPI folds as a $(\beta-\alpha)_8$ barrel and its dimerization is necessary to assemble a functional active site (Banner *et al.*, 1975; Alber *et al.*, 1987; Wierenga, 2001; Lara-Gonzalez *et al.*, 2015; Jiménez-Sandoval *et al.*, 2017). Dimerization is achieved by an extensive set of protein–protein interactions, and among these, an interaction between loop1 of one subunit with loop 3 from the neighboring subunit is the main contributor to the dimer interface area (Wierenga *et al.*, 2010; Lara-Gonzalez *et al.*, 2015). The role of TPIs in central metabolic

© 2019 The Authors
The Plant Journal © 2019 John Wiley & Sons Ltd

pathways drives the conservation of this enzyme from bacteria to animal and plants. The nuclear genome of flowering plants encodes two fully functional TPIs, one cytosolic and one targeted into the chloroplast (Chen and Thelen, 2010; Dumont *et al.*, 2016; López-Castillo *et al.*, 2016). Chloroplast TPI (pdTPI) arose by a gene duplication event from cytosolic TPI (cTPI) that replaced the cyanobacterial-derived TPI (Reyes-Prieto and Bhattacharya, 2007).

The activity of cytosolic and plastidic TPIs in land plants is subject to diverse regulatory mechanisms. For example, the activity of cTPI increases during growth to provide acetyl-CoA for the citric acid cycle and this enzyme is inhibited by glutathionylation, whereas 2-phosphoglycolate decreases pdTPI activity (Ito *et al.*, 2003; Dorion *et al.*, 2005; Flugel *et al.*, 2017). Yeast and potato (*Solanum tuberosum*) harboring cTPI variants with decreased catalytic activities re-route their carbon flux toward the pentose phosphate pathway (PPP) (Ralser *et al.*, 2007; Dorion *et al.*, 2012; Valancin *et al.*, 2013). In plants, reactive oxidative species (ROS) are produced as metabolic byproducts and by abiotic stress (Kim *et al.*, 2011), targeting a diverse set of enzymes for redox modifications (Dixon *et al.*, 2005; Zaffagnini *et al.*, 2012b, 2013). Specific cysteines from those enzymes play a predominant role as direct redox modifications targets. The thiolate group is reactive to hydrogen peroxide (H_2O_2), hydroxyl radical (OH•), and the superoxide anion (O_2-•). Therefore, oxidative stress can induce progressive post-translational modifications (PTM) of the thiol group to sulfenic (−SOH), sulfinic ($-SO_2H$), and sulfonic acids ($-SO_3H$) (Ito *et al.*, 2003). Oxidation to sulfinic and sulfonic acids is an irreversible, reaction unless is mediated by an enzymatic process involving sulfiredoxins (Jacob *et al.*, 2004; Murray *et al.*, 2012). Also, cysteines can be reversibly modified by glutathionylation, nitrosylation, and disulfide bond formation (Zaffagnini *et al.*, 2012a, 2012b). Different studies have shown that TPIs from photosynthetic organisms are targets for *S*-glutathionylation and nitrosylation (Ito *et al.*, 2003; Dixon *et al.*, 2005; Zaffagnini *et al.*, 2014; Dumont *et al.*, 2016; López-Castillo *et al.*, 2016). However, the effect of glutathionylation differs among these TPIs. For example, *S*-glutationylation in cTPI from *A. thaliana* produces a concomitant loss of enzymatic activity, and this reaction is reverted by the addition of reduced glutathione (GSH) or dithiothreitol (DTT) (Ito *et al.*, 2003), whereas *S*-glutationylation only induces a slight reduction in the activity of chloroplastic from Arabidopsis and *Chlamydomonas* (CrTPI) (Zaffagnini *et al.*, 2014; López-Castillo *et al.*, 2016) and has a negligible effect on the enzymatic activity of the TPI from the photosynthetic bacteria *Synechocystis* (SyTPI) (Zaffagnini *et al.*, 2014; López-Castillo *et al.*, 2016).

With basis on the crystal structure of cTPI from *A. thaliana* (AtcTPI) it was hypothesized that *S*-glutationylation and chemical modifications of residues AtcTPI-Cys13 and AtcTPI-Cys218 would result in enzyme inactivation by promoting the formation an inactive monomeric species or by modifying the enzyme active site (López-Castillo *et al.*, 2016). To understand how *S*-glutathionylation and ROS-mediated modifications at residues AtcTPI-Cys13 and AtcTPI-Cys218 decrease AtcTPI enzymatic activity, we mutated those residues to amino acids that mimic the oxidation of cysteine (Asp) (Miyata *et al.*, 2012), conjugation with thiol-conjugating adducts (Tyr or Lys) and to conserved amino acids. We found that the mutation of AtcTPI-Cys13 to aspartic acid promotes monomer formation. Conversely, mutations to AtcTPI-Cys218 to Tyr, Asp, and Lys result in enzymes with decrease catalytic activities by virtue of conformational changes near the enzyme active site. In summary, our data show that chemical modifications at residues AtcTPI-Cys218 and AtcTPI-Cys13 renders inactive enzymes by two different mechanisms. We propose that cAtTPI glutathionylation may protect the enzyme from irreversible cysteine oxidation and decrease AtcTPI activity to re-route carbon metabolism into the PPP and decrease oxidative stress by modifications of the oligomeric state and the active site of the enzyme (Dumont *et al.*, 2016; López-Castillo *et al.*, 2016).

RESULTS AND DISCUSSION

Residues Cys13 and Cys218 react with thiol-conjugating agents

AtcTPI harbors four cysteines at positions Cys13, Cys67, Cys127, and Cys218. From those residues, Cys13, Cys127, and Cys218 are found to be glutathionylated *in vitro* (Dumont *et al.*, 2016; López-Castillo *et al.*, 2016). The crystal structure of AtcTPI shows that the thiol groups of residues Cys13 and Cys218 are solvent exposed, whereas the thiol groups of residues Cys67 and Cys127 are completely buried (Figure 1a) (López-Castillo *et al.*, 2016). The identity of residue 127 corresponds to a cysteine in all TPIs known to date (Olivares-Illana *et al.*, 2017) and its glutathionylation is unforeseen, as the thiol group of this residue is always buried. Mutations of cysteine 127 decrease thermal stability and dimer association, revealing that this residue is critical to stabilize the dimer interface by interacting with amino acids that assemble this interface (Gonzalez-Mondragon *et al.*, 2004; Samanta *et al.*, 2011). However, proteomic analysis has shown that cysteines analogous to AtcTPI-Cys127 are glutathionylated in TPIs from human, yeast, and *Synechocystis* sp. (SyTPI) (McDonagh *et al.*, 2009; Chardonnet *et al.*, 2015; Dumont *et al.*, 2016). The inaccessibility of the thiol group of residue Cys127 and its tendency to be a target of glutathione are paradoxical. Most TPIs including, *Zea mays* TPI (ZmTPI), dissociate into unfolded monomers, suggesting the possibility that glutathionylation at residue Cys127 may occur at the unfolded state (Tellez *et al.*, 2008; Romero-Romero *et al.*, 2018) or it

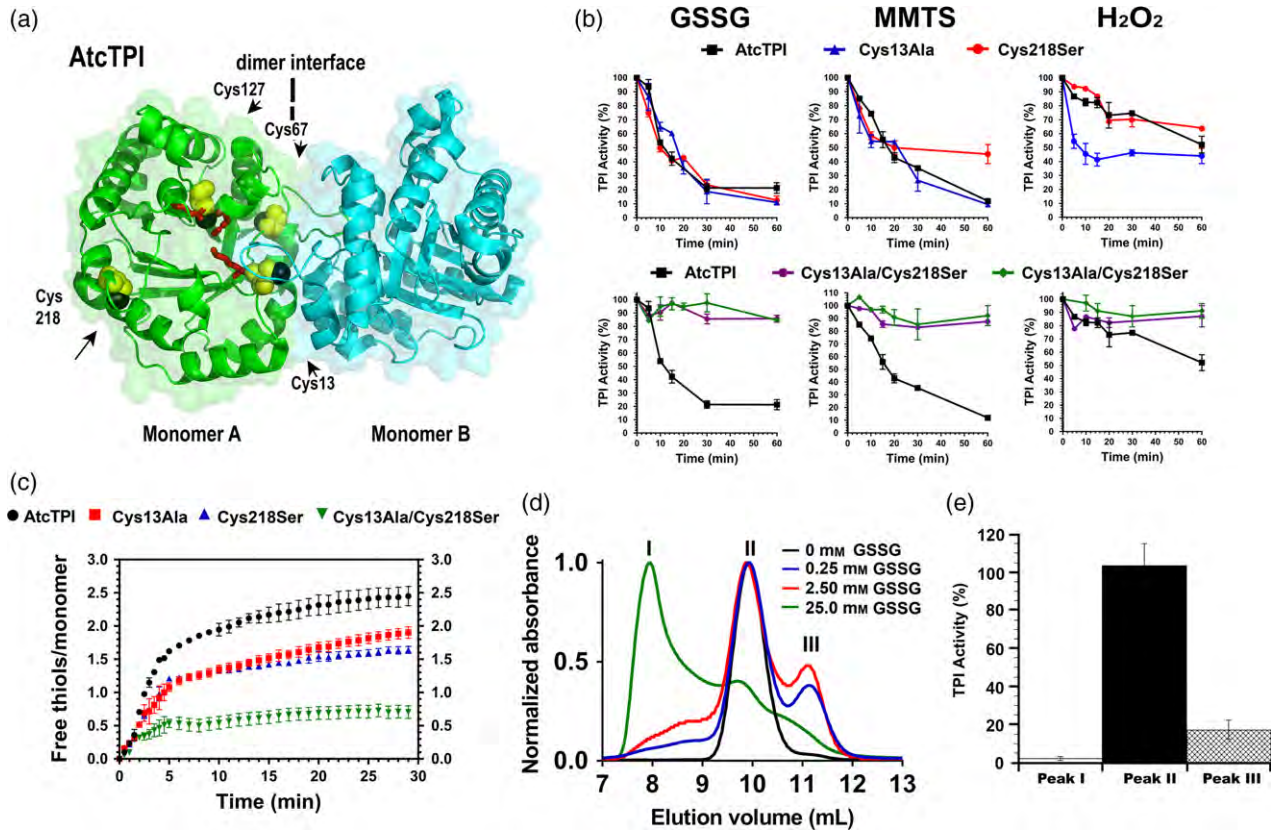

Figure 1. Structural analysis of AtcTPI and its inactivation by thiol-conjugating agents. (a) Ribbon representation of the crystal structure of AtcTPI showing the localization of its four cysteines in monomer A and its dimer interface. The conserved catalytic amino acids are in ball-stick representation and red colored. (b) Time-course experiment showing the inactivation of AtcTPI by thiol-derivatizing agents. AtcTPI present at 0.184 nM was incubated with a 200-fold excess of either MMTS, GSSG or H_2O_2 (36.8 nM). The graphs represent the percentage of AtcTPI activity with respect to an untreated sample during the time course. (c) Thiol content determination of wild-type and AtcTPI mutants by DTNB analysis. The graph shown the total number of reactive thiols per TPI monomer during a 30 min incubation with DTNB. The experiment was performed by triplicate and shows the average data and the corresponding standard deviation. (d) Effect of glutathione incubation on the oligomeric state of AtcTPI. AtcTPI was incubated with three different GSSG concentrations from 0.25 to 25 mM. The AtcTPI oligomeric state was assessed by running the samples on a gel filtration column. Untreated AtcTPI eluted as a dimer with as estimated molecular mass of *c.* 50 kDa (peak II). Incubation with 0.25 and 2.5 mM of GSSG resulted in the appearance of a protein peak with a molecular mass that corresponded to a monomer of 25 kDa (peak III), whereas incubation with 25 mM GSSG resulted migrate in a way that corresponded to protein aggregates (peak I). (e) Enzymatic activity of TPIs recovered from peaks I and II. AtcTPI recovered from peaks I and II exhibited less than 20% and 4% of enzymatic activity untreated samples, respectively. Samples recovered from peak II present similar enzymatic activity as untreated samples. All experiments were conducted in triplicate.

may reflect a transient exposure of its thiol group to the surface, as suggested to occur for SyTPI (Castro-Torres *et al.*, 2018). Residue AtcTPI-Cys13 is located in the middle of loop 1 and forms part of the dimer interface by interacting with residues from loop 3 of the neighboring subunit (Figure 1a). Residue AtcTPI-Cys13 has an accessible surface area (ASA) of *c.* 2.7 $Å^2$ in a dimeric AtcTPI structure, whereas its ASA as a monomer corresponds to 129.3 $Å^2$ (López-Castillo *et al.*, 2016). Residue AtcTPI-Cys218 is located at the N-terminus of α-helix 7, near the phosphate binding loop, and in one monomer exhibits an ASA of 6.7 $Å^2$ (López-Castillo *et al.*, 2016) (Figure 1a). The solvent accessibility of residues AtcTPI-Cys13 and AtcTPI-Cys218 makes them a more plausible target for plant oxidoreductases of the thioredoxins and glutaredoxins families and the subject of study in this work.

To understand if residues AtcTPI-Cys13 and AtcTPI-Cys218 are the main targets for glutathionylation and oxidation we constructed mutants aimed to eliminate their thiol groups and have minimal structural consequences. We designed a recombinant version of wild-type AtcTPI that only contains three extra amino acids before its initial methionine, the latter in contrast with previous recombinant protein versions that harbor a poly-histidine tail or a long non-related sequence (Dumont *et al.*, 2016; López-Castillo *et al.*, 2016). Using this recombinant AtcTPI, that closely resembles the native enzyme, we chose to mutate residue AtcTPI-Cys13 to both serine and alanine. A mutation to serine is expected to have minimal effect on the van der Waals interactions and is predicted to create minimal structural perturbations. The rationale to mutate AtcTPI-Cys13 to alanine is because of the hydrophobic

© 2019 The Authors

INFORME DE LABORES 2019

characteristics of residues surrounding AtcTPI-Cys13 that correlate with the hydrophobic nature of cysteine (Nagano *et al.*, 1999). We initially mutated AtcTPI-Cys218 to serine because of the structural similarities between both amino acids. Steady-state kinetic analysis indicated that AtcTPI-Cys13Ala and AtcTPI-Cys218Ser mutants decreased their catalytic efficiency by 4.3-fold and 2.5-fold, respectively. In contrast, an AtcTPI-Cys13Ser mutant exhibited a 30-fold decrease in catalytic efficiency (Table 1). These data suggest that the introduction of an alanine at position 13 and a serine at position 218 are tolerated in AtcTPI. The observed 2.5-fold reduction in the catalytic activity of the AtcTPI-Cys218Ser mutant contrasts with the 142-fold reduction previously reported using an AtcTPI with a large non-related amino acid sequence in its N-terminal (López-Castillo *et al.*, 2016). This differential in activity correlates with the presence a long sequence tag in the previous constructs that may hamper their activity (Panek *et al.*, 2013; Sabaty *et al.*, 2013; Booth *et al.*, 2018).

To determine if modification in residues AtcTPI-Cys13 and Cys218 affect TPI enzymatic activity, we measured the susceptibly of mutants AtcTPI-Cys13Ala and AtcTPI-Cys218Ser to oxidized glutathione (GSSG), methyl methanethiosulfonate (MMTS), and H_2O_2 in a 1-h time-course experiment instead of the dose-dependent experiment previously conducted (López-Castillo *et al.*, 2016). AtcTPIs carrying individual mutations at residues Cys13 and Cys218 exhibit similar susceptibility with respect to wild-type AtcTPI to thiol-conjugating agents, whereas the AtcTPI-Cys13Ala mutant is more susceptible to H_2O_2 (Figure 1a,b). These data suggest that both AtcTPI-Cys13 and AtcTPI-Cys218 residues react with similar efficiency to thiol derivatizing and oxidative agents, and suggest that both residues are targets for ROS-mediated modifications.

Table 1 Catalytic parameters

Enzyme	K_m (mM)	K_{cat} (sec^{-1})	K_{cat}/K_m (M^{-1} sec^{-1})	Fold decrease
AtcTPI wt	0.47 ± 0.08	1140 ± 46.7	2.40×10^6	–
Cys13Met	0.52 ± 0.03	353 ± 16.7	6.87×10^5	3.49
Cys13Ala	0.37 ± 0.04	209 ± 8.1	5.54×10^5	4.32
Cys13Ser	0.51 ± 0.07	41.6 ± 3.1	8.00×10^4	30.0
Cys13Asp	0.63 ± 0.09	32.1 ± 2.4	5.09×10^4	47.1
Cys218Met	0.82 ± 0.09	468 ± 19.2	5.68×10^5	4.22
Cys218Val	1.03 ± 0.18	642 ± 42.2	6.25×10^5	3.84
Cys218Ser	0.49 ± 0.09	465 ± 26.9	9.44×10^5	2.54
Cys218Lys	0.53 ± 0.02	165 ± 14.2	3.11×10^5	7.71
Cys218Tyr	0.88 ± 0.07	455 ± 37.1	5.11×10^5	4.69
Cys218Asp	0.50 ± 0.12	115 ± 6.67	2.27×10^5	10.5
Cys13Ala/ Cys218Ser	1.75 ± 0.21	789 ± 138	4.51×10^5	5.37
Cys13Ser/ Cys218Ser	3.76 ± 0.45	209 ± 35.9	5.57×10^4	43.5

To further test if those residues are the sole responsible for ROS-mediated inhibition by conjugation or oxidation, we measured the enzymatic activity of the double AtcTPI-Cys13Ala/Cys218Ser and AtcTPI-Cys13Ser/Cys218Ser mutants upon the exposure of thiol-conjugating agents and H_2O_2 using a time-course experiment (Figure 1b).

The observed differential in enzymatic activity with the previously reported AtcTPI mutants is intensified in the double mutants (López-Castillo *et al.*, 2016), further suggesting that non-related sequences in the N-terminal of AtcTPI affect catalysis. The current protein constructs harboring the double mutant AtcTPI-Cys13Ser/AtcTPI-Cys218Ser decreases its catalytic efficiency by 43.5-fold, whereas the double mutant AtcTPI-Cys13Ala/AtcTPI-Cys218Ser only decreases its catalytic efficiency by 5.3-fold (Table 1). As previously reported for the AtcTPI-Cys13Ser/AtcTPI-Cys218Ser mutant, both double mutants are not susceptible to thiol derivatizing agents and H_2O_2, supporting the role of both residues AtcTPI-Cys13 and AtcTPI-Cys218 as the only ROS targets in AtcTPI (López-Castillo *et al.*, 2016) (Figure 1b). To further verify this analysis, we measured the accessibility of cysteine thiols in wild-type and mutant AtcTPIs by 5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB) conjugation. In concordance to a previously report, wild-type AtcTPI contains approximately two accessible thiols per monomer, whereas AtcTPI-Cys13Ala and AtcTPI-Cys218Ser mutants harbors near to one thiol per monomer (Figure 1c). A double mutant AtcTPI-Cys13Ala/Cys218Ser presents limited reactivity to DTNB conjugation indicating that the only exposed thiol groups in AtcTPI is from residues Cys13 and Cys218. Overall the data agree with western blot analysis that identified residues Cys13 and Cys218 as the main targets of glutathione and suggest that the observed glutathionalytion of residue AtcTPI-Cys127 may occur at the unfolded state or as a consequence of a transient solvent exposure of its thiol group (Dumont *et al.*, 2016; López-Castillo *et al.*, 2016).

GSSG incubation promotes the formation of inactive AtcTPI monomers

We have hypothesized that the decrease in activity by AtcTPI upon its incubation with oxidative and thiol-conjugating agents is due to the formation of inactive monomers (López-Castillo *et al.*, 2016).

The reversible characteristics of glutathionylation make this post-translational modification a common modulator of enzymatic activity by conjugation of the glutathione moiety to the thiol groups of a cysteine. We have shown that incubation of AtcTPI with GSSG resulted in conjugated proteins with an apparent molecular mass that is lower than the molecular mass of a monomer (López-Castillo *et al.*, 2016). The aberrant migration of a conjugated AtcTPI on a gel filtration column upon glutathionylation is counterintuitive. Because of this atypical result, we decided to

The Plant Journal © 2019 John Wiley & Sons Ltd,

test the effect of *S*-glutathionylation using a shorted incubation period and three different GSSG concentrations (Figure 1d). As expected, non-derivatized AtcTPI eluted in a single peak at an elution volume that corresponds to a AtcTPI dimer of ~50 kDa (Figure 1d, peak II). Incubation of AtcTPI with 25 mM of GSSG induced the formation of inactive protein aggregates of high molecular weight (Figure 1d, peak I). These aggregates may be a consequence of dimer dissociation and monomer unfolding, as previously reported for other TPIs (Chanez-Cardenas *et al.*, 2002; Maithal *et al.*, 2002). AtcTPIs incubated with 2.5 or 0.25 mM GSSG resulted in the appearance of a protein peak that corresponds to an AtcTPI monomer of ~25 kDa (Figure 1e, peak III). Proteins from these monomeric fractions displayed less than 20% of enzymatic activity in comparison with the activity of the dimeric fractions that displayed the same activity than untreated AtcTPI samples (Figure 1e). These data further suggest that glutathionylation alters the oligomeric state of cTPI resulting in enzymes with reduced activity because of monomerization or total loss of activity because of aggregation.

Redox modification can be mimicked by site-directed mutagenesis

To understand the fate of AtcTPI upon oxidation and conjugation at residues Cys13 and Cys218, we use site-directed mutagenesis to mimic redox modifications of those cysteines (Figure 2a). We further mutated AtcTPI-Cys13 to aspartic acid that resembles the irreversible chemical modification of cysteine to sulfinic acid and to methionine because human and yeast TPIs harbor this amino acid in an analogous position to AtcTPI-Cys13 (Lolis *et al.*, 1990; Mande *et al.*, 1994; Permyakov *et al.*, 2012). We mutated AtcTPI-Cys218 to Met, Val, and Lys that resemble the

conjugation to linear adducts like MMTS or *S*-glutathionylation and to Tyr because this modification would resemble the chemical conjugation to a bulky aromatic adduct line DTNB, and finally to aspartic acid that mimics its oxidation to sulfinic acid. We did not mutate residue AtcTPI-Cys13 to bulky amino acids like Tyr or Lys, because amino acids with larger side chains are not present at this position in any TPI reported to date and because the large van der Waals radius of these residues would hamper dimer formation (Lara-Gonzalez *et al.*, 2015; Olivares-Illana *et al.*, 2017) (Figure 2a).

As a first step to assess the effect of modifications in residues Cys13 and Cys218, we measured the complementation of a bacterial strain deficient of endogenous triosephosphate isomerase activity by plasmids harboring AtcTPI mutants (Lara-Gonzalez *et al.*, 2015) (Figure 2b). Wild-type AtcTPI, AtcTPI-Cys13Ala, and AtcTPI-Cys13Met mutants efficiently complemented the transformed bacterial strain. In contrast, construct AtcTPI-Cys13Asp failed to complement the *E. coli* Δ*tpi* strain and construct AtcTPI-Cys13Ser exhibited a decrease in the observed number of colonies (Figure 2b). Bacterial cells harboring AtcTPI-Cys218Asp and AtcTPI-Cys218Lys mutants exhibited a defect in complementation, whereas bacteria harboring AtcTPI-Cys218Val, AtcTPI-Cys218Tyr, AtcTPI-Cys218Ser and AtcTPI-Cys218Met constructs present similar complementation compared with the wild-type AtcTPI (Figure 2b). Steady-state kinetic analysis indicated that AtcTPI-Cys13Asp and AtcTPI-Cys13Ser mutants showed a 47-fold and 30-fold reduction in their catalytic efficiency, whereas mutations to alanine and methionine exhibit less than a five-fold reduction in catalytic efficiency (Table 1). Therefore, the lack of complementation for AtcTPI-Cys13Asp and AtcTPI-Cys13Ser mutants correlated with their decrease in catalytic efficiency (Figure 2b). AtcTPI-Cys218Asp and AtcTPI-Cys218Lys mutants showed a 10.5-fold and 7.7-fold reduction in their catalytic activity, in contrast AtcTPI-Cys218Met, AtcTPI-Cys218Val, and AtcTPI-Cys218Tyr mutants presented enzymatic activities near wild-type AtcTPI levels (Table 1). Therefore, the observed difficulty of Asp and Lys mutants in residue AtcTPI-Cys218 to complement a Δ*tpi* bacterial strain, also correlated with a decrease in catalytic efficiency (Figure 2b). To assess if mutations in residues Cys13 and Cys218 affect the stability of AtcTPI, we measured their thermal stability in comparison with the wild-type enzyme (Table 2). Point mutants in residue Cys13 decreased their melting temperature (T_m) between 4.5–3°C with respect to the T_m exhibited by wild-type AtcTPI. In contrast, mutants in residue Cys218 decrease their T_m between 2–10°C (Table 2). The mutants that decrease the most the catalytic activity of AtcTPI, AtcTPI-Cys13Ser and AtcTPI-Cys13Asp, only present a small decrease in their T_m. In contrast, mutants in residue Cys218 have a large decrease in T_m and only a moderate, 7.7-fold to 10.6-fold, decrease in catalytic activity. These data suggest that modification in residue Cys13 does not present large structural changes, and mutations in residue Cys218 induce structural modification that alters the protein structure, but with only a moderate effect on catalysis.

Table 2 Thermal stability and apparent dissociation constant

Enzyme	T_m, °C	$^{app}Kd_{diss}$ (M)
AtcTPI	52.0 ± 0.0	1.45E-07 ± 2.10E-08

Site-directed mutagenesis of AtcTPI-Cys13 promotes the formation of non-catalytic monomers

To investigate if the loss of enzymatic activity by mutations at residues AtcTPI-Cys13 is due to alterations in the dimeric nature of AtcTPI, we assessed the oligomeric state of purified AtcTPI on a size-exclusion chromatography column at two protein concentrations: 1 mg mL^{-1} and 0.1 mg mL^{-1} (Figure 3a). At a concentration of 1 mg mL^{-1}, wild-type AtcTPI and all AtcTPI-Cys13 and AtcTPI-Cys218 point mutants eluted in a single peak at an elution volume that corresponds to the retention volume of a dimer of ~50 kDa. In contrast, at a concentration of 0.1 mg mL^{-1}, AtcTPI-Cys13Asp, AtcTPI-Cys13Ser, and AtcTPI-Cys13Met mutants exhibited a displacement in their migration profile to an elution volume that corresponds to a monomeric species of 25 kDa. The only AtcTPI-Cys13 mutant that migrates as a dimer is the one corresponding to AtcTPI-Cys13Ala (Figure 3a). In contrast, all mutations in residue AtcTPI-Cys218 eluted in a volume that corresponded to dimers at both protein concentrations (Figure 3a).

In all TPIs studied to date, this enzyme is an obligatory dimer, meaning that TPI monomers are catalytically incompetent (Zarate-Perez *et al.*, 2009; Jiménez-Sandoval *et al.*, 2017). To assess the role of monomerization in catalysis, we measured the specific activities of wild-type and point mutant AtcTPIs incubating the enzymes for 24 h at 25°C at protein concentrations that rank from 50 ng mL^{-1} to 1000 μg mL^{-1} (Table 2). Dilution promotes the concentration-dependent dissociation of active dimeric AtcTPI into inactive monomers, with a concomitant loss in specific activity (Figure 3b) (Mainfroid *et al.*, 1996; Reyes-Vivas

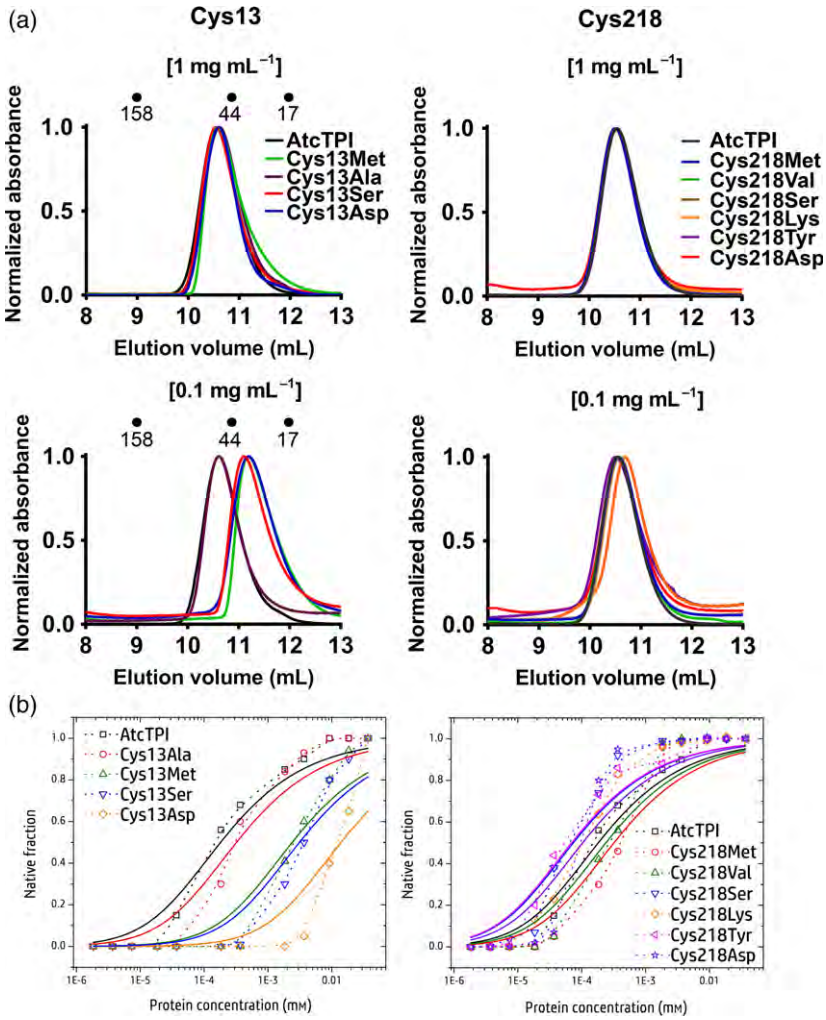

Figure 3. Elution profiles of AtcTPIs upon oxidation mimicry by site-directed mutagenesis. (a) Gel filtration elution profiles of wild-type and point mutants of residues Cys13 and Cys218 at protein concentrations of 1 and 0.1 mg mL^{-1}. The elution profile of Cys13 mutants at 0.1 mg mL^{-1} shows the displacement of the elution profile to one that corresponds to an elution profile of a monomeric species of *c.* 25 kDa. (b) Determination of the apparent K_{diss} of wild-type and point mutants of AtcTPI. The graph represents the relative enzymatic activity after serial dilutions of three independent experiments.

et al., 2002; Romero-Romero *et al.*, 2018). The fraction of native molecules shows a more pronounced transition than the one expected for a reversible two-state equilibrium nevertheless, the midpoint of the transitions (K_{diss}) are well described by this model.

In TPIs as well as in other obligated oligomers, this behavior has been related to reversible and/or irreversible conformational changes in the dissociated monomers such that processes shift the equilibrium towards inactive states (Mainfroid *et al.*, 1996; Reyes-Vivas *et al.*, 2002; Romero-Romero *et al.*, 2018). From these data we calculated an apparent dissociation constant ($^{app}K_{diss}$). Wild-type AtcTPI exhibited an $^{app}K_{diss}$ of 1.5^{-7} M, that is similar to the one observed for other TPIs (Reyes-Vivas *et al.*, 2002). Point mutants AtcTPI-Cys13Ala, AtcTPI-Cys13Met, and AtcTPI-Cys13Ser decrease the binding affinity of the dimer by 2-fold, 16-fold, and 21-fold, respectively. In sharp contrast the AtcTPI-Cys13Asp mutant decreases the dimer stability by more than 100-fold, indicating that a mutation that resembles the oxidation of Cys13 results in stable monomeric enzymes (Figure 3b). In comparison to the influence of residue AtcTPI-Cys13 in promoting the appearance of monomeric species, mutations in residue AtcTPI-Cys218 do not alter their specific activity upon dilution, supporting the finding that mutations in this residue do not alter the dimeric nature of AtcTPI (Figure 3a,b and Table 2). The shift in the dimer–monomer equilibrium of AtcTPI-Cys13Ser and AtcTPI-Cys13Asp mutants correlates with a 30-fold and 47-fold reduction in their catalytic efficiency. Interestingly, a mutant AtcTPI-Cys13Met is only 3.5-fold less active than wild-type AtcTPI (Table 1). The difference in enzymatic activity observed between monomeric AtcTPI-Cys13Ser, AtcTPI-Cys13Asp, and AtcTPI-Cys13Met may be related to the formation of AtcTPI dimers assisted by substrate binding as occurs in TPI from *Trichomonas vaginalis* (Lara-Gonzalez *et al.*, 2015) and meaning that dimer assembly from dissociated monomers is favorable in the AtcTPI-Cys13Met mutant, but not in the AtcTPI-Cys13Ser and AtcTPI-Cys13Asp mutants.

Structural basis for the formation of non-catalytic monomers by modifications at residue AtcTPI-Cys13

To test how the mimicry of the thiol oxidation of residue AtcTPI-Cys13 induces the formation of non-catalytic monomeric species, we solved the crystal structures of AtcTPI-Cys13Asp and AtcTPI-Cys13Ala mutants (Figure 4a). In comparison with the presence of cysteine at position 13, a mutation to alanine decreases the van der Waals volume by 19 Å^3 and a mutation to aspartic acid increases its volume by 10 Å^3. The crystal structures of AtcTPI-Cys13Ala and AtcTPI-Cys13Asp revealed that these mutations do not significantly alter the AtcTPI structure, as these structures present a root-mean-square deviation (RMSD) of 0.1350 and 0.1750 Å, respectively, with respect to wild-type AtcTPI. The crystal structure of AtcTPI-Cys13Ala only presented a small variation in the amino acids corresponding to loop 3, that is displaced *c.* 0.6 Å, presumably to compensate the smaller alanine side chain (Figure S1). The minimal changes in the crystal structure of AtcTPI-Cys13Ala with respect to wild-type AtcTPI are in agreement with the unaltered catalytic efficiencies and dimeric nature of this mutant, which is resistant to dilution. The crystal structure further showed that the aromatic amino acids from the neighboring subunit that surround residue at position 13 were organized in a similar fashion when an alanine replaces a cysteine (Figure S1). Both AtcTPI-Cys13Ala and AtcTPI-Cys13Asp mutants do not create severe changes in the overall structural of the enzyme or alter its dynamics (Figure S2). The crystal structure of AtcTPI-Cys13Asp shows that a substitution to aspartic acid, that mimics cysteine oxidation by virtue of its negative charge, places the carboxyl side chain in a similar position to the thiol group of the cysteine residue. However, the placement of the carboxylate produced subtle conformational changes in loop 1 and loop 3 of the neighboring subunit

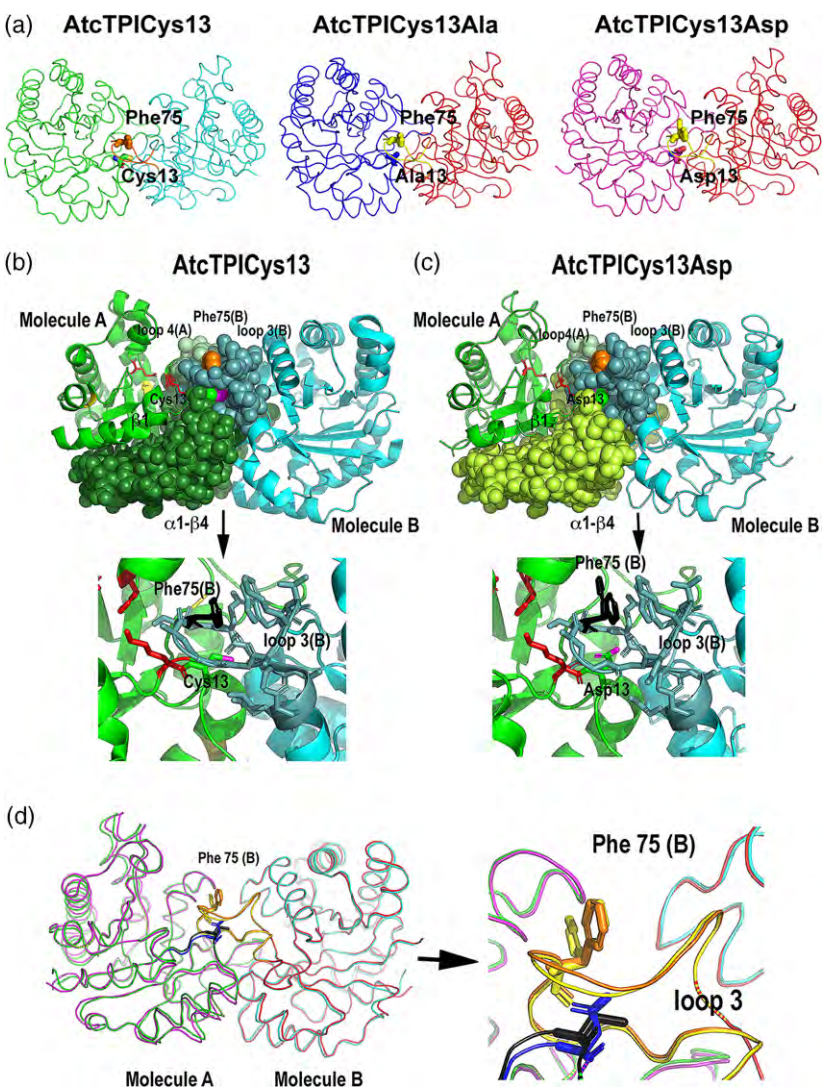

Figure 4. Structural consequences of oxidation mimicry at residue AtcTPICys13. (a) Structural comparison of AtcTPI crystal structures harboring alanine and aspartic acid substitutions at position 13 in a ribbon representation. (b, c) Dimer interface representation. The thiol group and carboxyl groups of residue 13 in wild-type or mutant AtcTPIs are colored in magenta and residues from the loop 3 of the neighboring subunit are colored in cyan in a ball-stick representation. Residue Phe75 is colored in magenta. Residues corresponding to the first-half of the TIM barrel (α1 to β4) present a subtle displacement (colored green and lime in wild-type and AtcTPICys13Asp mutant, respectively). A close-up view (bottom part) of wild-type and AtcTPICys13Asp mutants. Illustrates the dual conformation of residue Phe75 (black) due to presence of the carboxyl group instead of the thiol group at residue 13. (d) Ribbon representation of the superposition between the crystal structures of wild-type and AtcTPICys13Asp and close-up view at loop 3 of their dimer interface. The AtcTPICys13Asp structure illustrates that the oxidative mimicry of residue Cys13 induces a re-orientation of residue Phe75 from the neighboring subunit.

(Figure 4a). Being the most dramatic consequences of the AtcTPI-Cys13Asp mutation the appearance of residue AtcTPI-Phe75 of the neighbor subunit in two alternate conformations (Figure S2).

Residue AtcTPI-Cys13 exerts inter-subunit interactions with residues from the loop 3 of the neighboring subunit. Residue AtcTPI-Cys13 interacts with the following residues from the neighboring subunit: Gly72, Gly73, Ala74, Phe75, Thr76, Glu78, Ser80, and Met83. These residues form part of conserved GGAFTG motif located in loop 3 (Figure 4b). The interaction between loop 1 from one subunit and loop 3 from the neighbor subunit is critical for dimer formation. For instance, engineered monomeric versions of several TPIs were designed by the decreasing in the length of loop 3 (Borchert *et al.*, 1994; Saab-Rincon *et al.*, 2001; Jiménez-Sandoval *et al.*, 2017). Derivatization of the residue to corresponding AtcTPI-Cys13 with alkylating agents generate TPIs monomers in TPIs from *P. falciparum* and *E. histolytica*, and also protein aggregation in TPIs from *T. cruzi* and *T. brucei* (Garza-Ramos *et al.*, 1998; Maithal *et al.*, 2002; Rodríguez-Romero *et al.*, 2002). The presence of the carboxyl group in the AtcTPI-Cys13Asp mutants displaced the phenyl side chain of residue AtcTPI-Phe75 of the neighboring subunit, so this residue adopts a double conformation. As a consequence of this alternate conformation, half of the α/β triosephosphate isomerase (TIM) barrel ($\alpha1$ to $\beta4$) shifted its orientation relative to AtcTPI (Figure 4b,c). This conformational change is reminiscent of the small changes in subunit orientation observed in pathogenic mutants of superoxide dismutase (Hough *et al.*, 2004). The double conformations of residue AtcTPI-Phe75 of the neighboring subunit displaced loop 3 residues by 1 Å, to accommodate the carboxylate side chain (Figure 4d).

A diagram of the B-factors for the interface residues shows that their overall mobility is conserved (Figure S3). The structural changes observed in the AtcTPI-Cys13Asp mutant correlated with the fact that point mutants Ser, Met, and Asp are monomeric at a concentration of *c.* 1.8 μM (of 0.1 mg mL^{-1}). As the AtcTPI-Cys13Asp mutant resembles the oxidation of Cys13, our data suggest that AtcTPI monomerization is a mechanism to rapidly decrease the enzymatic activity of TPI upon oxidative stress. TPI activity modulation is observed in yeast expressing human TPI variants deficient in dimer assembly that are more resistant to oxidative stress, presumably by re-routing the carbohydrate flux (Ralser *et al.*, 2006). Another example of TPI modulation activity is the stimulation of rice TPI activity by interaction with a transmembrane receptor-like kinase. In this putative allosteric TPI modulation mechanism, a plant resistant to bacterial infection presents a strengthened interaction between the transmembrane receptor-like kinase and TPI, this high interaction stimulates TPI activity with a concomitant increase in ROS production that leads to bacterial infection resistance (Liu *et al.*, 2018).

Modifications at residue AtcTPI-Cys218 decrease enzymatic activity

Two independent studies have shown that residue AtcTPI-Cys218 is a glutathionylation target (Dumont *et al.*, 2016; López-Castillo *et al.*, 2016). Steady-state kinetic analysis indicated that a mutant protein harboring an aspartic acid substitution decreased its catalytic efficiency by 10-fold, whereas replacements with bulky or linear branched amino acids decreases their catalytic efficiency between 5-fold to 8-fold (Table 1). These mutants present similar dimer stability compared with wild-type AtcTPI, ruling out the possibility that an alteration in the dimer–monomer equilibrium is responsible for the observed decrease in catalytic efficiency. Therefore, it is unknown how modifications in residue AtcTPI-Cys218 affect catalysis.

Modifications at residue AtcTPI-Cys218 drive structural rearrangements in loops 6 and 7

To understand the mechanisms by which modifications in residue AtcTPI-Cys218 affect the catalytic activity of AtcTPI, we solved the structures of AtcTPI-Cys218 with residues that mimic cysteine conjugation with bulky or aromatic groups or its oxidation (Table S1). A structural comparison between these crystal structures shows that the point mutations do not induce gross structural changes with respect to wild-type AtcTPI (Figure 5a). However, a close inspection shows that all mutants present alternate conformations in loops 6 (residues 166–176) and 7 (residues 210–218) (Figure 5b,c). These structural changes are localized only in this region and are not observed in other regions, like the active site or the dimer interface (Figure S4). Loop 6 or the phosphate binding loop suffers open to closed transitions upon substrate binding (Wierenga *et al.*, 1991, 1992; Wierenga, 2001) and it is highly flexible structural element. Loop 6 in the AtcTPI-Cys218Ser mutant is partially disordered, whereas this loop moves near 2.5 Å in AtcTPI-Lys and Tyr mutants (Figure 5b). Point mutations of residue AtcTPI-Cys218 also increase the thermal mobility of loop 6, suggesting that point mutants alter the dynamics of the phosphate binding loop (Figure 5c,d). In contrast with the flexibility of loop 6, loop 7 is located in the same position in all TPIs studied to date. Loop 7 harbors the YGGS (residues 209–212) motif whose integrity is indispensable for enzymatic activity, as modifications of this motif reduce TPI catalytic activity more than 1000-fold (Sampson and Knowles, 1992a,1992b). Point mutations, especially substitutions to Asp, Lys and Tyr, also alter the orientation of loop 7 (Figure 5b,c). Residue AtcTPI-Cys218 interacts with residue AtcTPI-Gly211 of the YGGS motif, therefore structural variations in AtcTPI-Cys218 are expected to affect this interaction. A mutation of residue AtcTPI-Cys218 to Ser does not alter the orientation of loop 7 (Figure 5b), in contrast mutations to Asp, Lys, and Tyr

(b, c) Close-up of the region corresponding to loops 6 and 7 for cysteine mutants to Ser and Asp (b) and Lys and Try (c). The corresponding point mutant is represented in a ball–stick representation. (c) Structural comparison between wild-type AtcTPI and point mutants. Plot of the RMSD analysis per residue (Roberts *et al.*, 2006) shows the structural differences among the AtcTPI-Cys218 mutants. (d) Structural comparison between wild-type cAtcTPI and the point mutants showing the normalized B-factors for the wild-type and AtcTPI mutants.

that induce conformation changes in the Cα of residues Val213 to Asn217 that are located immediately after the YGGS motif (Figure 5b,c). These conformational changes are subtle in the case of Asp and Lys mutants. In these structures, a segment of loop 7 from residues Val213 to Asn217 moves between 2 to 2.3 Å. In contrast, the AtcTPI-Cys218Tyr mutation results in abrupt re-orientation of 6.3 Å in loop 7 (Figure 5b). The side chains of residue 218 harboring mutations to Asp, Lys, and Ser are in an equivalent position to the side chain of residue Cys218. Distinctly, the side chain of AtcTPI-Cys218Tyr mutant occupies the space that corresponds to residue Val213 located immediately after the YGGS motif (Figure 5b). Mutations in a residue analogous to AtcTPI-Cys218 in *G. lambia* TPI (GlTPI) also exhibit a decrease in their catalytic activity (Hernandez-Alcantara *et al.*, 2013) and crystallographic studies of the GlTPI-Cys222Asp mutant also present structural variation on loops 6 and 7 that correlate with the loss of enzymatic activity (Hernandez-Alcantara *et al.*, 2013). The AtcTPI-Cys218Asp mutant decreases its catalytic efficiency by approximately 11-fold, in contrast the AtcTPI-Cys218Tyr and Lys mutants decrease the catalytic efficiency by 4.7-fold and 7.7-fold, respectively. In contrast with the severe loss in catalytic activity observed by an aspartic acid mutation in residue AtcTPI-Cys13, an aspartate mutation in residue AtcTPI-Cys218 resulted in an 11-fold decrease. Although this loss in activity seems modest, the 4-fold decrease caused by the Ile170Val mutation in human TPI induces hyper-resistance against oxidative stress in yeast (Ralser *et al.*, 2006). This suggests that small changes in enzymatic activity of this key glycolytic enzyme are sufficient to alter and re-route central metabolic pathways (Ralser *et al.*, 2006, 2007).

A dual mechanism for redox-based modulation in plant cytosolic TPIs

The identity of residues Cys 13 and Cys218 is conserved in TPIs from green algae and in the majority of plant cytosolic TPIs, being one exception *Medicago truncatula* (Zaffagnini *et al.*, 2014; López-Castillo *et al.*, 2016) (Figure 6a). However, the identity of the residue corresponding to Cys218 in all plastidic TPIs and TPIs from photosynthetic bacteria is a serine or a hydrophobic amino acid, suggesting that cysteine-based modulation at this position is only conserved in green algae and land plants (López-Castillo *et al.*, 2016). Seminal work by Zaffagnini and coworkers show that TPI from *Chlamydomonas reinhardtii* (CrTPI) harbors a cysteine residue (CrTPI-Cys219) that is structurally analogous to AtcTPI-Cys218 (Zaffagnini *et al.*, 2014). A structural comparison between the crystal structures of CrTPI and AtcTPIs shows that in both TPIs crystal structures, the exposed thiol groups of residues CrTPI-Cys219 and AtcTPI-Cys218 are located at the N-terminal cap of an α-helix and, in both cases, two lysines are in close proximity to the thiol groups

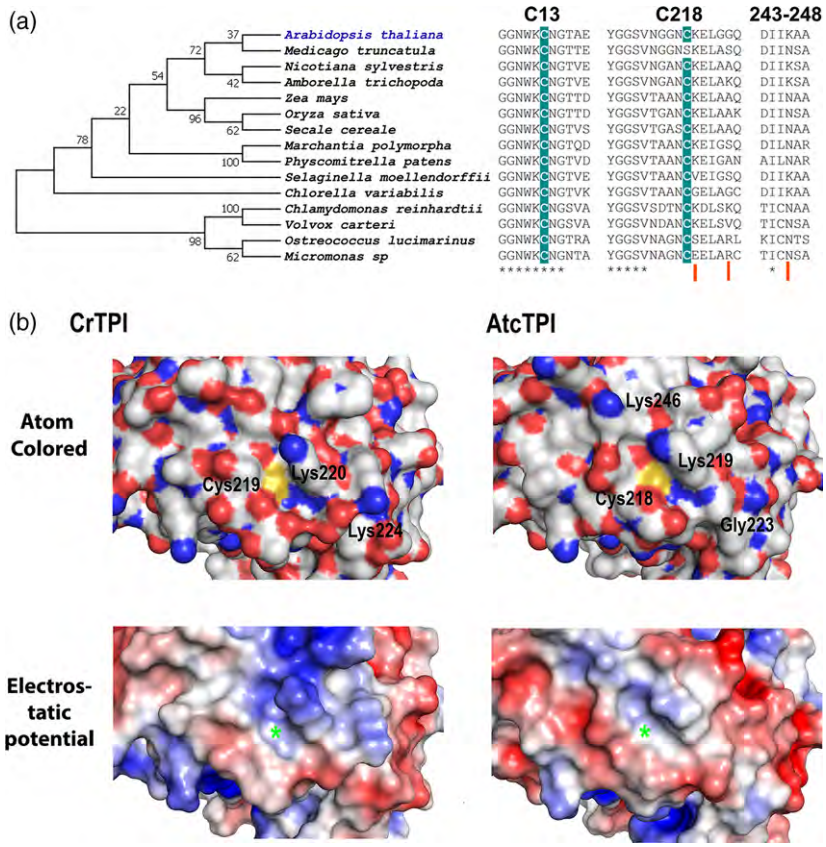

Figure 6. Residue AtcTPI-Cys218 is a conserved *S*-glutathionylation target to modulate glycolysis in land plants and green algae. (a) Multiple sequence alignment of amino acids near AtcTPI in selected green algae and land plants. The identity of residues analogous to AtcTPI-Cys218 and lysines that contribute to create a positively charged region near CrTPI-Cys219 and AtcTPI-Cys218 are indicated. (b) Surface and electrostatic potential representations near residues CrTPI-Cys219 and AtcTPI-Cys218. The thiol group is colored in yellow, nitrogens in blue, oxygen in red and carbons in white. The bottom figure shows the chemical environment near residues CrTPI-Cys219 and AtcTPI-Cys218. Positively charged regions are colored in blue and negatively charged regions in red. The thiol groups are indicated with a green asterisk.

(Figure 6b) (Zaffagnini *et al.*, 2014). These chemical characteristics produce a positively charged environment that may exhibit, as a consequence, a decrease in the pK_a of both cysteines that stabilizes the formation of a deprotonated cysteine form (thiolate) that is prone to react with GSSG. Although the amino acids surrounding CrTPI-Cys219 and AtcTPI-Cys218 are not conserved, the chemical environment of these residues surrounded by positively and negatively charged amino acids is conserved (Figure 6b). Therefore, the three-dimensional structures show that the chemical propensity of the residue corresponding to AtcTPI-Cys218 to be a target of glutathione is conserved from green algae to land plants. The absence of a thiol group in the residue corresponding to AtcTPI-Cys218 in plastidic TPI from land plants may be explained by the need of plastidic TPIs to cope with higher concentrations of oxidative agents (López-Castillo *et al.*, 2016).

In sum, here we elucidated the mechanisms by which cTPI from land plants modulate their activity by modifying two cysteine residues: AtcTPI-Cys13 and AtcTPI-Cys218. Redox-based modifications of those residues result in a decrease in TPI catalytic efficiency. This reduction in enzymatic activity is associated with a reduction in ROS production by re-routing the central metabolism (Ralser *et al.*, 2006, 2007). A crystal structure that mimics cysteine oxidation in residue cATP-Cys13 induces enzymatic inactivation due to monomerization and mimicry of residue AtcATP-Cys218 to sulfinic acid or *S*-thiolation induces a conformation change in the enzyme that is concomitant with a decrease in enzymatic activity. Here, we propose a model in which the solvent-exposed residue AtcTPI-Cys218 is the primary target for ROS and *S*-glutathionylation (Figure 7). The solvent-exposed localization of residue AtcTPI-Cys218 make it a plausible target for plant oxido-reductases of the thioredoxins and glutaredoxins families that could modulate TPI enzymatic activity. Furthermore, this chemical environment is conserved in TPIs from green algae and cytosolic TPIs, suggesting the possibility of a conserved evolutionary mechanism to control glycolysis in plants. *S*-glutathionylation of residue AtcTPI-Cys218 both protect the redox sensitive thiol to non-reversible oxidation products and decreases TPI activity. The localization of residue cATP-Cys13 at the dimer interface makes it a difficult target for enzymatic *S*-glutathionalytion, however conditions of elevated ROS could trigger its oxidation. Oxidation of this amino acid, and the induced loss of dimeric assembly may generate a severe drop in catalysis as a rapid response to oxidative stress, shifting the sugar metabolism into the PPP (Ralser *et al.*, 2006, 2007) (Figure 7). In summary, our study describes how *S*-glutathionylation and thiol oxidation in AtcTPI are part of the tuning mechanism of plant glycolysis based on redox status (Scheibe *et al.*, 2005; Holtgrefe *et al.*, 2008).

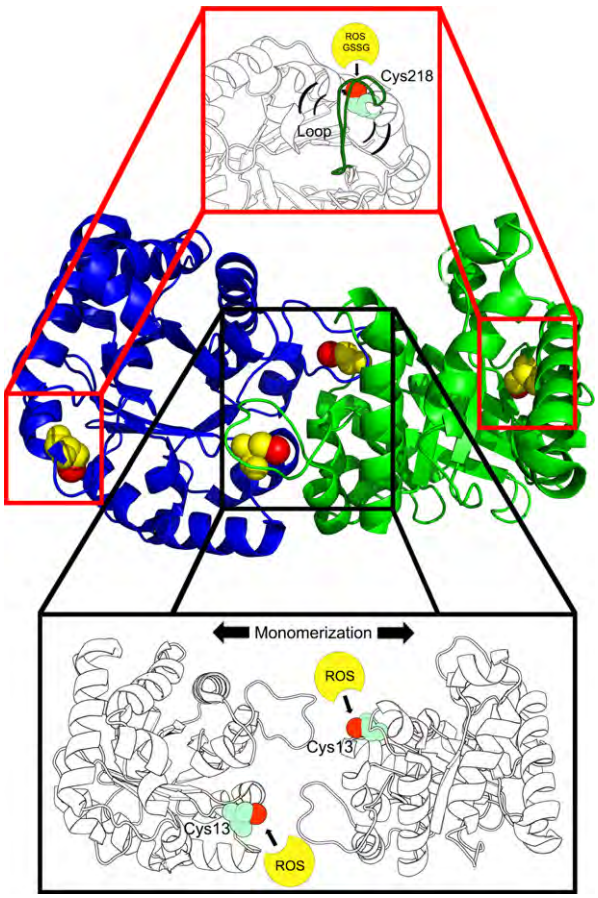

Figure 7. Model for the role of residues AtcTPI-Cys13 and AtcTPI-Cys218 in modulating TPI enzymatic activity by oxidation or glutathionylation. (a) Irreversible oxidation of residue Cys13 at the AtcTPI dimer interface induces subtle conformation changes in loop 3 of the neighboring subunit that lead to dimer dissociation with a concomitant loss in enzymatic activity. Oxidation or glutathionylation at residue Cys218 alters the structure of loops 6 and 7. These structural changes decrease the enzymatic activity of AtcTPI. The reversibility of the *S*-glutathionylation reaction at residue AtcTPI is a potential redox switch to cope with ROS in plants.

EXPERIMENTAL PROCEDURES

Synthetic gene design for AtcTPI expression and site-directed mutagenesis

The open reading frame of AtcTPI was codon optimized for its recombinant expression in *E. coli* and subcloned into *Nde*I and *Bam*HI restriction sites of a modified pET19 vector. Site-directed mutagenesis for residue AtcTPI-Cys13 was performed using the polymerase chain reaction (PCR) and AtcTPI-Cys218 mutants were constructed using the quick-change site-directed mutagenesis protocol (New England Biolabs, Beverly, MA, USA). Oligonucleotides used for site-directed mutagenesis are shown in Table S1.

Protein expression and purification

Bacterial codon optimized AtcTPIs were expressed in BL21 (DE3) *Δtpi E. coli* cells for both crystallographic and biochemical studies (Sullivan *et al.*, 2011). Bacterial pellets were resuspended in lysis buffer (25 mM Tris–acetate–EDTA (TAE) pH 7.4, 150 mM NaCl). Recombinant AtcTPI was purified by metal chelate affinity chromatography (IMAC). Protein eluate was dialyzed in lysis buffer with the addition of 2 mM ethylene diamine tetraacetic acid (EDTA) and 1 mM dithiothreitol (DTT). PreScission protease was added during dialysis at a final concentration of 0.1 mg mL^{-1} to cleavage the histidine tag. After affinity tag removal, AtcTPI and mutant variants were concentrated using centrifugal ultrafiltration units of 10 kDa MWCO (Millipore, Burlington, MA, USA), and further purified by size-exclusion chromatography on a Superdex 75 Column (GE Healthcare, Waukesha, WI, USA). Once the histidine tag is removed recombinantly purified proteins contain only three amino acids (Gly, Pro, His) before the initial methionine.

Protein crystallization

AtcTPI mutants were concentrated to 14 mg mL^{-1} in 20 mM Tris pH 8, 50 mM NaCl and 2 mM DTT. Four sparse matrix crystallization screens of 96 conditions each were used mixing 1 μL of reservoir solution and protein using the sitting drop method. Crystals for each mutant were obtained in specific conditions (Table S2). Datasets for each mutant were collected at the Advanced Photon Source using a single protein crystal. Datasets were processed with MOSFLM (Battye *et al.*, 2011) and scaled with AIMLESS, using the CCP4 Software Suite (McNicholas *et al.*, 2011). The X-ray structures for mutants AtcTPIs were solved by molecular replacement. PDB accession numbers, data collection and refinement statistics are presented in Table S3.

In vivo functional assays and determination of catalytic parameters

In vivo complementation assays, and catalytic activities were measured as previously reported (Sullivan *et al.*, 2011; Figueroa-Angulo *et al.*, 2012). Briefly, catalytic activity of AtTPIs was measured spectrophotometrically by a coupled enzyme assay with α-GDH in the direction G3P to DHAP. Assays were performed according to Benítez-Cardoza *et al.* in 100 μL of 0.1 TAE pH 7.4, containing 10 mM EDTA, 0.01% BSA, 0.2 mM NADH (Sigma, St. Louis, MO, USA), 1 μg α-GDH (Roche, Basel, Switzerland) and 1 mM of D-L glyceraldehyde 3-phosphate (Sigma) (Benítez-Cardoza *et al.*, 2001). The reaction was started by addition of AtTPIs and activity was calculated by the decrease in absorbance at 340 nm, monitored each 30-sec using an Infinite M1000 reader (TECAN, Männedorf, Switzerland). For the determination of the apparent kinetic constants (K_M and K_{cat}), assays were carried out by increasing G3P concentrations, from 0 to 4.0 mM.

INFORME DE LABORES 2019

Dilution experiments for apparent dissociation constants

The apparent dissociation constants ($^{app}K_{diss}$) of the AtcTPI dimer and those of the Cys-13 and Cys-218 mutants were estimated from dilution experiments followed by catalytic activity. Proteins were incubated for 24 h at 25°C and different protein concentrations (1000 μg mL^{-1} to 50 ng mL^{-1}) in buffer 100 mM TAE, 10 mM EDTA and 1 mM DTT, pH 8.0. Subsequently, activity was determined as indicated previously at 25°C with 5 ng mL^{-1} of TIM and 2 mM G3P. Data were normalized (f_N) to the highest activity value obtained. As TPI is a homodimer, a decrease in total protein concentration favors dimer dissociation. $^{app}K_{diss}$ was calculated from the following equation, derived from the simplest equilibrium two-state model that describes the change in the fraction of active dimers f_N as a function of TPI concentration (P_C expressed on a monomer basis) (Neet and Timm, 1994; Romero-Romero *et al.*, 2015)

$$f_N = \frac{^{app}K_{diss} + 4P_C - \sqrt{^{app}K_{diss}{}^2 + 8K_{diss}P_C}}{4P_C}$$

ACKNOWLEDGEMENTS

This project was supported by CONACYT-Fronteras de la ciencia grant # 11 (LGB). Data were collected at the Life Sciences Collaborative Access Team beam lines 21-ID-G and F at the Advanced Photon Source, Argonne National Laboratory by the Michigan Economic Development Corporation and the Michigan Technology Tri-Corridor (Grant 085P1000817). This research used resources of the Department of Energy (DOE) under Contract No. DE-AC02-06CH11357.

AUTHOR CONTRIBUTIONS

LGB, ECT, and PJS conceived the project. ECT, PJS, SRR, AFP, LMLC, CDQ, DAFV, and ATL performed experiments and data analysis. LGB wrote the manuscript. ECT, PJS, SRR, DAFV, and ATL edited the manuscript.

CONFLICT OF INTEREST

characterize the interplay between tumor cells and angiogenesis, as well as their proliferation, phenotypic transitions, and death. We use this model to predict–early in course of neoadjuvant therapy–the eventual response of the individual patient. Success in this endeavor would enable replacing an ineffective treatment with an alternative regimen, thereby potentially improving outcomes and curtailing unnecessary toxicities. Furthermore, our approach can be applied to any disease site for which neoadjuvant therapy is indicated and the requisite data is accessible.

***Wolbachia pipientis* Colonizes *S cerevisiae* with High Yields. Effects on the Host**

Natalia Chiquete Felix[1], Cristina Uribe-Alvarez[2], Ulrik Pedroza-Dávila[3], Isareli Cruz-Cruz[3], Salvador Uribe-Carvajal[3].
[1]Dept Molec Gene, Inst Cell Physiol, Mexico, Mexico, [2]Molecular, Inst Fisiología Celular UNAM, Mexico, Mexico, [3]Inst Fisiol Celular, Univ Natl Autonoma Mexico, Mexico, Mexico.

Wolbachia pipientis is an obligate-endosymbiotic gram-negative bacterium, that naturally colonizes 40-60% of all insect species. It may be transmitted vertically transmitted via germinal cells or horizontally. Each Wolbachia strain is quite different to the rest, as *Wolbachia* coevolves with the host, where it manipulates protein expression, fertility and metabolism. *Wolbachia* may protect its host against infection by other organisms such as pathogenic viruses or bacteria. A major problem to study *Wolbachia* has been its inability to grow *ex-vivo* and the low yields obtained from insect cell cultures. The unicellular yeast *Saccharomyces cerevisiae* was infected with *Wolbachia pipientis*, obtaining large biomass yields. *Wolbachia* did not contribute to oxidative phosphorylation, but instead it seemed to rely on external supply of ATP, possibly precipitating premature death of the host. In contrast, Wolbachia does seem to contribute some coenzymes to the host. It also modifies the actin cytoskeleton. Premature death has been reported also in the artificially infected mosquito *A. aegypti* probably accounting for the decrease in vector disease activity of this host.

Tuberculosis is a lung infection caused by *Mycobacterium tuberculosis*. One third of the world population is thought to be infected. Antibiotic treatment with antibiotics lasts 6 month, which is difficult to achieve in low-income countries. The uncommon ability of tuberculosis bacteria to persist during long periods is linked to various factors, one of which potentially being cell growth asymmetry. However, growth symmetry or asymmetry of mycobacteria remains a controversial topic as opposing descriptions have been reported in the literature.

Observing bacterial growth at the single cell level is inherently challenging due to the diffraction limit of optical microscopes and the small size of the cells. We built a new dedicated platform for long-term, correlated Atomic Force Microscopy (AFM) and fluorescence microscopy and obtained time-lapses of bacterial growth at an unprecedented resolution.

Surprisingly, the AFM high-resolution time-lapses did not match any of the two previously reported models of pure symmetry and pure asymmetry. Mycobacterial pole growth dynamics was rather an intermediate between the two, reminiscent of the well-known ''new end take off'' mechanism for fission yeast. Using AFM nanomanipulation we show that growth asymmetry is not a physical occlusion phenomenon, but is inherent to mycobacterial growth. Finally, using fluorescent photoconversion microscopy we identify biomolecular mechanisms linked to growth asymmetry, which in the future could be used to develop novel treatments for tuberculosis infection.

Molecular Motors Govern Liquid-Like Ordering and Fusion Dynamics of Bacterial Colonies

Tom Cronenberg, Anton Welker, Robert Zöllner, Claudia Meel, Katja Siewering, Niklas Bender, Marc Hennes, Enno R. Oldewurtel, Berenike Maier.
Institute for Biological Physics, University of Cologne, Cologne, Germany.

Many bacteria are able to form communities called biofilms. Within these structured communities, they benefit from various advantages including facilitated gene transfer and increased antibiotic resistance. Bacteria can adjust the structure of colonies and biofilms to enhance their survival rate under external stress. The human pathogen *Neisseria gonorrhoeae* is able to aggregate into spherical colonies due to active retraction of its type 4 pili.Here, we explore the link between bacterial interaction forces and colony structure and dynamics. First, we show that the simultaneous expression of a functional and a nonfunctional variant of the motor protein PilT affects motor activity, namely the retraction velocity and the probability to be in the retracting, elongating or pausing state, respectively. Second, we demonstrate that motor activity enhances local ordering and accelerates fusion dynamics of bacterial colonies. Motor activity strongly affects the probability of two cells to be bound to each other. The radial distribution function of mature colonies shows local fluid-like order. The degree and dynamics of ordering are dependent on motor activity. At a larger scale, the fusion dynamics of two colonies shows liquid-like behavior whereby motor activity strongly affects the ratio between surface tension and viscosity. An estimate of colony surface tension using molecular interaction characteristics shows that surface tension is hardly affected by motor activity, indicating a strong effect on colony viscosity.

DNA Origami as a Tool in the Targeted Destruction of Bacteria

Ioanna Mela[1], Masayuki Endo[2], Hiroshi Sugiyama[2], Robert M. Henderson[3], Clemens F. Kaminski[1].
[1]Chemical Engineering and Biotechnology, University of Cambridge, Cambridge, United Kingdom, [2]Kyoto University, Kyoto, Japan, [3]Dept Pharmacology, Univ Cambridge, Cambridge, United Kingdom.

Antibiotic resistance is a growing worldwide human health issue. It is now threatening to render us vulnerable once again to infections that have been treatable for decades. Various approaches have been proposed in the effort to overcome this threat and effectively treat bacterial infections. We explore the possibility of creating and using DNA origami nanostructures as a vehicle for delivering functional molecules in a specific and efficient manner, in order to destroy bacterial targets. In the past few years, DNA origami has been used to successfully target eukaryotic cancer cells, with impressive results. However, there are no reports of the use of DNA origami to specifically target bacterial cells. We have created a DNA origami tile with five ''wells'' that can carry up to 10 molecules of antibacterial lysozyme. The origami tile has been modified to carry four aptamers that are specific to *Escherichia coli* bacteria and enable anchoring of tiles onto a bacterium. Each origami tile measures approximately 100 x 100 nm, allowing for multiple tiles to attach to any bacterium. We use direct stochastic optical reconstruction microscopy (dSTORM) to assess the efficiency of targeting the tile to the bacteria and we show that treatment with lysozyme-functionalised tiles slows bacterial growth more effectively than treatment with free lysozyme. We also assess the mechanical properties of the origami-treated bacteria with atomic force microscopy. Our study introduces DNA origami as a tool in the fight against antibiotic resistance, and our results demonstrate the specificity and efficiency of the nanostructure as a drug delivery vehicle.

HEAT repeats
Peripheral stalk
Polytomella

ABSTRACT

The mitochondrial ATP synthase of *Polytomella* exhibits a peripheral stalk and a dimerization domain built by the Asa subunits, unique to chlorophycean algae. The topology of these subunits has been extensively studied. Here we explored the interactions of subunit Asa3 using Far Western blotting and subcomplex reconstitution, and found it associates with Asa1 and Asa8. We also identified the novel interactions Asa1-Asa2 and Asa1-Asa7. *In silico* analyses of Asa3 revealed that it adopts a HEAT repeat-like structure that points to its location within the enzyme based on the available 3D-map of the algal ATP synthase. We suggest that subunit Asa3 is instrumental in securing the attachment of the peripheral stalk to the membrane sector, thus stabilizing the dimeric mitochondrial ATP synthase.

1. Introduction

The F_1F_O-ATP synthase, an electrochemical gradient-driven nanomotor, is crucial for oxidative phosphorylation and its dimerization/oligomerization determines the morphology of mitochondrial cristae [1–3]. In the yeast and mammalian enzymes the rotor is formed by a membrane-embedded *c*-ring and subunits γ/δ/ε; the stator includes subunit *a*, subunits α_3/β_3 of the catalytic core, OSCP/*b*/*d*/F6 of the peripheral stalk (PS), and A6L/*e*/*f*/*g* of the dimerization module. Subunit *a* and the *c*-ring create an interface that defines the proton translocation pathway [4–6]. The divergence and structural heterogeneity of PSs and of the dimer interfaces has prompted the reclassification of mitochondrial F-ATPases into metazoan-type (*i.e.* those of yeast and mammals) and protozoan-type (*i.e.* those of *Trypanosoma brucei*, *Tetrahymena thermophila*, *Paramecium tetraurelia*, *Euglena gracilis*, chlorophycean algae, etc.) [7]. In the ATP synthase of the colorless chlorophycean alga *Polytomella* sp. the PS and the dimer interface are built by subunits Asa1 to 9 [8]. Asa1 to 5 and Asa7 are the PS main building blocks, Asa6, Asa8 and Asa9 have predicted transmembrane segments, and Asa6 and Asa9 participate in the dimerization module [9–11]. Despite the lack of similarity of Asa subunits with orthodox PS components, they share some structural features: *i)* Asa1 spans the whole length of the PS like subunit *b* [12]; *ii)* Asa1, Asa2, Asa4 and Asa7 adopt coiled-coil structures as all PS subunits [13]; and *iii)* Asa6 has a V-shape similar to the membrane-embedded region of subunit *b* [14]. The arrangement of the Asa subunits in the *Polytomella* ATP synthase has been addressed [8,9,11–13] but little is known of Asa3; here we explore its structure, its location, and its association with other PS components.

2. Materials and methods

2.1. Algal strains and growth conditions

Polytomella sp. cells (198.80 Culture Collection of Algae, University of Göttingen, Germany, identical to *Polytomella parva*) were grown as reported [15] and collected in the middle of the logarithmic phase by centrifugation 7000×*g* for 20 min. Cells were stored at −70 °C until use.

2.2. Mitochondria isolation and ATP synthase purification

Algal cells were broken mechanically and mitochondria

INFORME DE LABORES 2019

obtained by differential centrifugation [8]. The dimeric ATP synthase was purified as in Ref. [15].

2.3. Cloning of cDNAs encoding ATP synthase subunits in expression vectors

The constructs expressing Asa1 [12], Asa2, Asa4, Asa7 [13], Asa8 [12], OSCP [12,16] and OSCPΔC [9,12,13] were used here to overexpress the proteins with a hexa-histidine tag in the N-terminus (using vector pET28a) or without this tag (using vector pET3a). The cDNAs of Asa1ΔC (Asa1$^{1-367}$ lacking 205 residues from its C-terminus) and Asa3ΔN$_{term}$ (Asa3$^{74-325}$) were amplified by PCR from a *Polytomella* sp. cDNA library cloned in λ-ZapII phages using specific oligonucleotide primers. For Asa1ΔC: forward 5′-GCGGCATGCGCTAGCTACCTTGCCCCCCTCCGCTCTGAT-3′ and reverse 5′-GCGGCCGCTTAAGTGTACCTGTGCTCGGTAAT-3′ and for Asa3ΔN$_{term}$: forward 5′-CGCCATATGTCCTCTGGTCCTTCCCAGAACCTT-3′ and reverse 5′-CGCGGATCCTTAATGACCATGGGCACCTTC-3′. The amplification products were cloned into the pET28a vector with the restriction sites *Nhe*I/*Not*I for Asa1ΔC and *Nde*I/*Bam*HI for Asa3ΔN$_{term}$.

2.4. Overexpression of recombinant subunits

Competent *Escherichia coli* BL21 Codon Plus (DE3) RIL cells (Agilent Technologies) were transformed with the plasmid of interest by heat shock. Transformed cells were grown in LB medium containing 64 μg/mL chloramphenicol and 50 μg/mL kanamycin. Overexpression of proteins was induced with 0.1 mM IPTG (Isopropyl β-D-1-thiogalactopyranoside) for 8 h.

2.5. Purification of recombinant subunits

Asa1, Asa2, Asa4, Asa7, Asa8, OSCP and OSCPΔC were purified as in Refs. [12,13]. The overexpressed proteins ^{6H}Asa1ΔC and ^{6H}Asa3ΔN$_{term}$ were obtained in bacterial inclusion bodies (ICBs), which were isolated, washed and stored as previously described [13]. ICBs were solubilized in PBS buffer (500 mM NaCl50 mM NaH_2PO_4, pH 7.8) with 8.0 M urea under mild agitation for 8 h at 4 °C. The insoluble material was removed by centrifugation at 17,500 g for 10 min. Both proteins were purified under denaturing conditions using affinity chromatography. Samples were diluted to a final concentration of 4.0 M urea with PBS buffer containing 15 mM imidazole and loaded into an equilibrated 5 mL HisTrap FF crude column (GE Healthcare Life Sciences). The column was washed with 30 mM imidazole and proteins were eluted with a 30–500 mM imidazole linear gradient in the same buffer. Resulting fractions were analyzed by Tricine–SDS–PAGE, those enriched with the protein of interest were pooled, concentrated, and stored at −70 °C until used.

2.6. Protein interactions assayed by Far Western Blots

Far Western Blot (FWB) analysis was performed as previously described [13]. The purified algal ATP synthase or the purified recombinant subunits were resolved in Tricine-SDS gels, transferred to nitrocellulose membranes and visualized by Ponceau S red staining (0.1% in 5.0% acetic acid). Membranes were blocked overnight, washed, and incubated for 4 h with the externally added recombinant protein at increasing concentrations in subunit-specific buffers [Asa1/^{6H}Asa1ΔC: 150 mM NaCl, 2% glycerol, 0.05% DDM, 0.5 M urea, 50 mM NaH_2PO_4, pH 7.8; Asa2: 0.5 mM EDTA, 1 mM DTT, 2% glycerol, 0.05% Tween-20, 50 mM CAPS, pH 10; ^{6H}Asa3ΔN$_{term}$: 150 mM NaCl, 5 mM DTT, 2% glycerol, 0.05% DDM, 0.5 M urea, 50 mM Tris, pH 8.4 and Asa4, Asa7 and Asa8 in TBST buffer (500 mM NaCl, 0.05% Tween-20, 20 mM Tris, pH 7.5)] supplemented with 1.0% powdered milk. The protein of interest was recognized using primary and secondary antibodies, both incubated with TBST buffer containing 1.0% powdered milk. Finally, the membranes were immunochemically stained as described in Ref. [13].

2.7. Subcomplex reconstitution from recombinant subunits

All steps were performed at 4 °C. Solubilized ICBs containing the same molar ratio of each protein were mixed (Asa1+^{6H}Asa3ΔN$_{term}$ + OSCP or Asa1+Asa2+^{6H}Asa3ΔN$_{term}$ + Asa4+Asa7+OSCP) and diluted 1:1 with dialysis buffer (150 mM NaCl, 10% glycerol, 0.01% DDM, 50 mM Tris, pH 8.4). Samples were supplemented with a mini protease inhibitor tablet (cOmplete EDTA-free, Roche) and with 10% glycerol, 0.01% DDM and 1.0 mM DTT (final concentrations). Protein refolding was carried out by slow dilution (from 8.0 to 4.0 M urea) followed by sequential dialysis steps yielding final concentrations of 0.5 M urea and 150 mM NaCl. After each dialysis step samples were centrifuged at 20,000 rpm in a Type 70Ti rotor for 20 min. The final supernatant was concentrated to 500 μL with an Amicon Ultra 30,000 MWCO and injected into a Superose 6 10/300 GL column connected to an ÄKTA FPLC (GE Healthcare). After elution at 0.5 mL/min, the resulting fractions were analyzed by Tricine-SDS-PAGE, pooled and incubated with a nickel resin (Ni-NTA Agarose, Qiagen) in the presence of 20 mM imidazole for 7 h. For batch purification the resin was centrifuged at 2000 rpm for 5 min (Centrifuge 5424 R, Eppendorf) and washed ten times. Proteins were eluted with increasing concentrations of imidazole (100–300 mM in steps of 50 mM) and analyzed in Tricine-SDS-PAGE.

2.8. Structural modeling of subunit Asa3

F_1-OSCP-ac_{10}-Asa6 subcomplex was modeled using PDB files 2JDI, 2WSS and 6F36 as templates [14,17,18] and fitted in the cryo-EM map (EMD 2852 [4]) using UCSF Chimera [19]. Approximately sixty helical segments were automatically built into the map with the Phenix suite [20]. Secondary structure (2D) and membrane helix (TM) predictions were carried out on the Asa subunits (Asa1, $\alpha_5\beta_1\alpha_{16}$; Asa2, $\alpha_{18}\beta_2\alpha_1$; Asa3, $\alpha_{13}\beta_1$; Asa4, $\alpha_7\beta_1\alpha_5$; Asa5, $\alpha_3\beta_1$/1TM; Asa6, $\alpha_3\beta_1\alpha_3$/2TM; Asa7, $\beta_3\alpha_4\beta_1\alpha_4$/1TM; Asa8, $\alpha_3\beta_2\alpha_2$/1TM; Asa9, $\alpha_2\beta_2\alpha_1$/1TM) using PsiPred [21] and MEMSAT-SVM [22], respectively. The segments were linked and assigned on the basis of predictions and biochemical data using COOT [23]. The model was finely refined against densities in real space in Phenix.

3. Results and discussion

3.1. On the association of subunit Asa3 with other ATP synthase subunits

The interactions of Asa3 were evaluated with FWB experiments performed on the isolated algal enzyme and on the purified recombinant proteins Asa1, Asa2, Asa4, Asa7, Asa8 and OSCP. Membrane strips with the same protein concentration were incubated with increasing concentrations of purified ^{6H}Asa3ΔN$_{term}$ and decorated with anti-Asa3 antibodies. Besides Asa3, the antibody recognized a degraded form of Asa3 (Asa3$_{deg}$), Asa1, and an oligomeric form of subunit *c* (c_x) [12] (Fig. 1A). The last signal did not increase at higher concentrations of Asa3 and was considered non-specific. Thus, Asa3 seems to bind only to Asa1 in this assay. To confirm the observed Asa1-Asa3 interaction, higher quantities of the purified recombinant subunits Asa1, Asa2, Asa4, Asa7 and OSCP were blotted on a membrane and incubated with the highest amount of ^{6H}Asa3ΔN$_{term}$ used in the previous experiment. After decorating the membrane with anti-Asa3 antibodies only the Asa1

Left panel: WB of a gel parallel to the one shown in E decorated with anti-Asa8 antibodies, dimeric and tetrameric forms of SDS-resistant Asa8 were observed. Right panel: Membrane strips containing ^{6H}Asa3ΔN$_{term}$ incubated with increasing concentrations of Asa8 and decorated with anti-Asa8 antibodies.

signal was detected (Fig. 1B), confirming the previous result and suggesting ^{6H}Asa3ΔN$_{term}$ does not associate with the other assayed proteins. FWB experiments performed with both recombinant subunits, incubating membrane strips with increasing concentrations of each protein, confirmed the Asa1-Asa3 interaction (Fig. 1C and 1D).

Previous cross-linking experiments revealed an Asa3-Asa8 interaction [11,16]. Asa8 has a predicted transmembrane segment and therefore is likely located in the membrane domain of the PS. We confirmed this Asa3-Asa8 interaction using purified recombinant subunits (Fig. 1E and IF). When testing the binding of ^{6H}Asa3ΔN$_{term}$ on the isolated ATP synthase (see Fig. 1A) we could not detect an Asa8 signal, which may be due to: *i)* the high hydrophobicity of Asa8 that is not ideal when assessing interactions by FWB experiments or *ii)* only faint quantities of Asa8 are being transferred to the membrane.

3.2. On the structure and location of subunit Asa3 in the algal ATP synthase

A 3D model of the dimeric *Polytomella* ATP synthase was built [24] in the available 3D cryo-EM map (EMD 2852 [4]) using map2model, real_space_refine and refine of the Phenix suite [20].

The *Asa3* gene encodes a preprotein of 325 residues. Initially, it was established by Edman degradation that Asa3 from the purified complex starts at residue 74 [8], hence the Asa3ΔN$_{term}^{74-325}$ construct. A MTS of 30 residues predicted for *Polytomella* sp. Asa3 using MitoFates [25] agrees with the MTS of *C. reinhardtii* Asa3 determined experimentally [8].

2D structure predictions of Asa3$^{31-325}$ revealed thirteen consecutive helices made of 12–18 residues (H1-13) linked by short loops (Fig. S1) and threading methods predict an α-solenoid fold [26]. Multiple sequence alignment of Asa3 from different sources revealed a conserved region of 16 aa (196–211) belonging to H8 and the longest loop (208–215), which connects H8 and H9 (see Fig. S1). Only one chain of our 3D model unequivocally matches such a fold and thus was assigned to Asa3 (Fig. 2A). Therefore, Asa3 must be located at the base of the peripheral stalk, lying on top of the matrix side of the mitochondrial inner membrane. Despite the lack of any sequence homology with proteins of known structure, DALI [27] suggests that it is related to HEAT repeat-containing proteins. Six HEAT repeats (helix-loop-helix motif) pack together

INFORME DE LABORES 2019

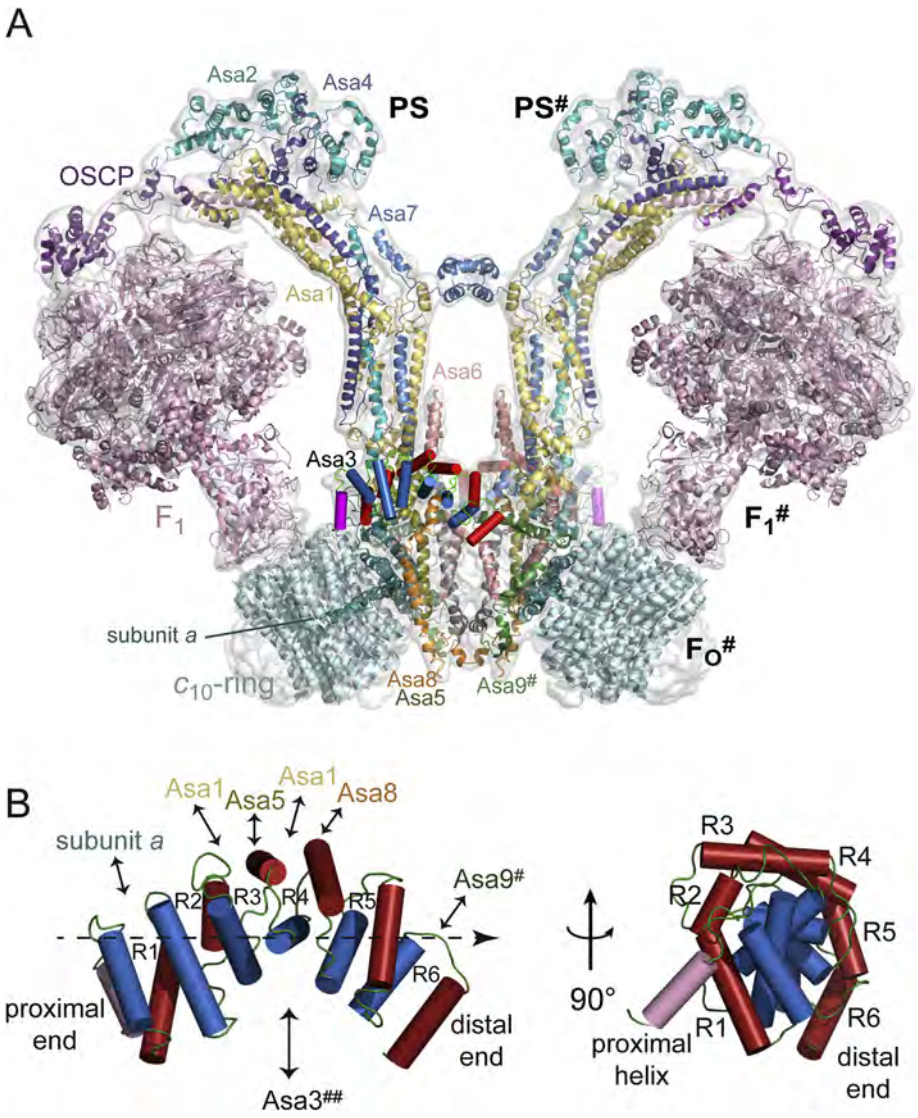

Fig. 2. Molecular model and location of subunit Asa3 in the *Polytomella* ATP synthase. A. Side view of the dimeric ATP synthase model built in the cryo-EM map [4,24]. **B.** Longitudinal (left) and axial (right) schematic views of Asa3. R1-6 HEAT repeats are labeled from the proximal end. Interactions with neighbor subunits are indicated with arrows. # and ## refer to dimeric and oligomeric species, respectively.

forming half a turn of a right-handed super helix of 55 Å length and 20 Å diameter, capped by one helix at the distal extremity (Fig. 2B). Attempts to detect any apparent repetition within successive repeats failed. The low resolution and the regular tandem repeat structure prevent to unambiguously determine the chain orientation. The repeats were labeled R1 to R6 starting at the proximal extremity. The concave face of the super helix groove is shaped by a ladder of 32°–52° tilted helices (Fig. 2B, right panel) turned towards the oligomeric interface, which is likely nested in the neighboring Asa3$^{\#\#}$ (Asa3 of the adjacent dimer). On its convex face, the proximal helix and R1-2 strongly interact with subunit *a* (*a*H2 and *a*C$_{term}$), R3-4 with Asa1, Asa5 and Asa8, whereas R6 interacts with Asa9$^{\#}$ belonging to the neighbor monomer at the dimer interface (Fig. 2B, left panel).

Interestingly, the extended C-terminal domain of the bovine mitochondrial factor B of F-type ATPase is composed of four leucine-rich repeats (LRR, β-strand-loop-helix motif) [28] and cross-linking studies reveal its proximity with subunits *e* and *g* [29] that are involved in dimer stabilization [30]. The N-terminal domain of the H subunit of the *S. cerevisiae* V-type ATPase displays an armadillo fold (three α-helices motif) [31] and links the foot of one of the three peripheral stalks to the soluble domain of the *a* subunit [32]. Thus, it can be argued that three different repeat protein classes, LRR and closely related HEAT and armadillo, were independently selected during the evolution of F- and V-type ATPases to serve as a scaffold for protein-protein interactions.

3.3. Reconstitution of subcomplexes corresponding to the peripheral stalk

Given the Asa1-Asa3 interaction, the previously identified Asa1-OSCP interaction [12], and to further explore these interactions with another approach, a reconstitution protocol was designed to obtain an ^{6H}Asa3ΔN$_{term}$-Asa1-OSCP subcomplex (see Materials and Methods). Starting from solubilized ICBs, proteins were refolded and recovered in a soluble fraction (Fig. 3A). The concentrated sample was subjected to size exclusion cromatography and the elution profile was analyzed by Tricine-SDS-PAGE (Fig. S2). The fractions that corresponded to an ^{6H}Asa3ΔN$_{term}$-Asa1-OSCP subcomplex, identified by SDS-PAGE, were pooled and purified by

INFORME DE LABORES 2019

P: pellet, S: supernatant. **D.** Co-elution of a reconstituted ^{6H}Asa3ΔN$_{term}$-Asa1-Asa2-Asa4-Asa7-OSCP subcomplex after size exclusion and batch purification. Abbreviations as in B.

affinity chromatography. After extensively washing the resin to ensure all unbound material was removed, fractions were recovered following a batch procedure eluting at increasing imidazole concentrations, after which the three subunits were recovered together (Fig. 3B). This result supports the idea that Asa1 spans the entire peripheral stalk [12] bridging Asa3 with OSCP.

Asa1, Asa3 and Asa8 seem to connect tightly, since they are consistently found in subcomplexes generated after treating the algal ATP synthase with heat, detergent or amphipol [8,10,12]. The Asa1-Asa3 and Asa3-Asa8 interactions, as well as the previously reported Asa1-Asa8 interaction [11,12], may explain why these proteins remain associated in subcomplexes after dissociating the enzyme. In the 3D map of the dimer Asa3 bridges both PSs [4]; our results suggest that this subunit may act as a clamp that joins the extrinsic part of the PS with its membrane-bound sector, a connection instrumental for enzyme function. Thus, we thought it was feasible to reconstitute the membrane-extrinsic section of the PS, and hypothesized that the ^{6H}Asa3ΔN$_{term}$-Asa1-OSCP subcomplex should interact with the previously identified Asa2-Asa4-Asa7 subcomplex [13]. Following the same reconstitution protocol, now including the recombinant proteins Asa2, Asa4 and Asa7, most of the proteins were recovered in the soluble fraction after refolding (Fig. 3C). The concentrated sample was subjected to size exclusion chromatography and the elution profile was analyzed in Tricine-SDS-PAGE (Fig. S3). The fractions that were consistent with a large subcomplex were pooled and incubated with a nickel resin for a batch purification. At the end of the two-step purification process an ^{6H}Asa3ΔN$_{term}$-Asa1-Asa2-Asa4-Asa7-OSCP subcomplex that represents a large fraction of the PS was recovered (Fig. 3D).

3.4. Other associations of subunit Asa1 in the peripheral stalk

The fact that a six-component subcomplex could be reconstituted suggested Asa1 must associate with other proteins besides Asa3 and OSCP, given the location and interactions of the latter two subunits. We thus explored the interactions of Asa1 with Asa2, Asa4 and Asa7 with FWB analyses. Asa1 and Asa2 were tested having one protein on the membrane and incubating with increasing concentrations of the other protein and vice versa. When the membranes containing Asa1 were incubated with increasing concentrations of Asa2 and decorated with anti-Asa2 antibodies, a signal corresponding to Asa1 was obtained (Fig. 4A); the same happened in the complementary experiment (Fig. 4B). An Asa1-Asa7 interaction was detected using the same approach (Fig. 4C and D). In contrast, an Asa1-Asa4 interaction was not detected (data not shown).

Having previously identified an Asa1-OSCP interaction [12], reminiscent of the *b*-OSCP interaction in orthodox F-ATPases, we explored which part of Asa1 contacts OSCP. Accordingly, a truncated version of Asa1 (Asa1ΔC) was generated to evaluate its binding to OSCP. Membranes containing OSCP or OSCPΔC were incubated with Asa1 or with Asa1ΔC and decorated with anti-Asa1 antibodies. The membranes containing OSCP that were incubated with Asa1 exhibited the expected Asa1-OSCP interaction (Fig. 4E), whereas the ones incubated with Asa1ΔC showed a strongly diminished signal (Fig. 4F); finally, when the membranes containing the truncated OSCPΔC were incubated with Asa1ΔC, no signal

INFORME DE LABORES 2019

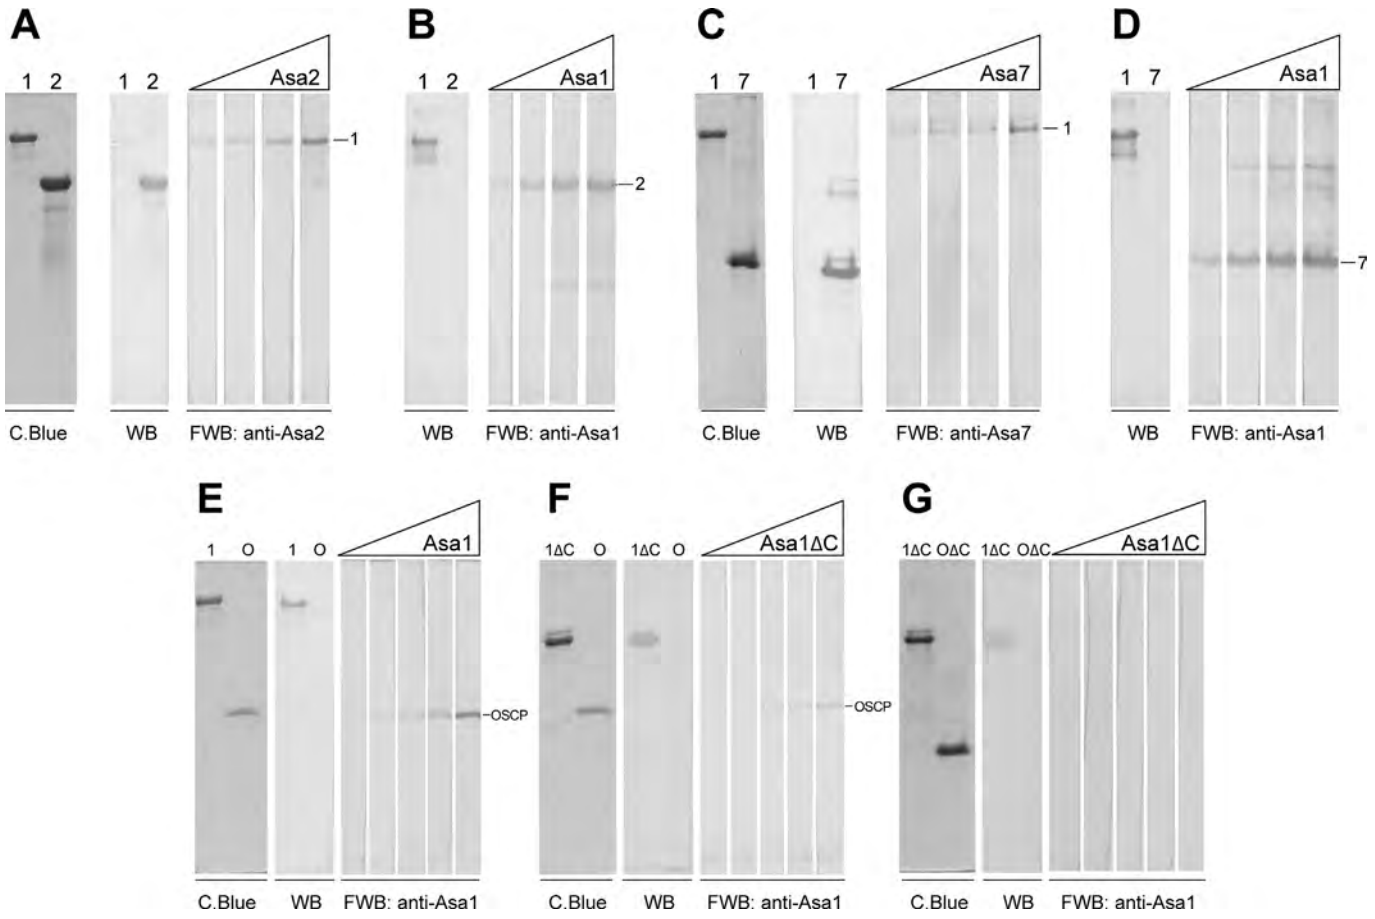

Fig. 4. Associations established by subunit Asa1 assayed by FWB. A-B. Asa1-Asa2 interaction. Asa1 (A) and Asa2 (B) in the membranes incubated with increasing concentrations of Asa2 (A) and Asa1 (B) and decorated with anti-Asa2 (A) and anti-Asa1 (B) antibodies. **C-D.** Asa1-Asa7 interaction. Experiment with Asa1 (C) and Asa7 (D) in the membranes incubated with increasing concentrations of Asa7 (C) and Asa1 (D) and decorated with anti-Asa7 (C) and anti-Asa1 (D) antibodies. **E-F-G.** Asa1-OSCP interaction assayed with complete and truncated subunits. Experiments with OSCP (E and F) and OSCPΔC (G) in the membranes incubated with increasing concentrations of Asa1 (E), Asa1ΔC (F) and Asa1ΔC (G). The membranes were decorated with anti-Asa1 antibodies (E–G).

was obtained (Fig. 4G). This suggests that some of the residues of the C-terminus region of Asa1 must be involved in binding OSCP. Altogether, these results show that Asa1 binds to Asa2 and Asa7, hence their presence in the ^{6H}Asa3ΔN$_{term}$-Asa1-Asa2-Asa4-Asa7-OSCP subcomplex. The fact that we did not detect an Asa1-Asa4 interaction suggests that the presence of Asa4 in the subcomplex occurs through its contact with either Asa2 or Asa7, as previously observed [13]. We also conclude the Asa1-OSCP interaction must occur through the C-terminal regions of both proteins, similar to what happens in the *b*-OSCP interaction in orthodox ATP synthases.

Transplantation of dopaminergic (DA) cells into the striatum can rescue from dopamine deficiency in a Parkinson's disease condition, but this is not a suitable procedure for regaining the full control of motor activity. The minimal condition toward recovering the nigrostriatal pathway is the proper innervation of transplanted DA neurons or their precursors from the substancia nigra pars compacta (SNpc) to their target areas. However, functional integration of transplanted cells would require first that the host SNpc is suitable for their survival and/or differentiation. We recently reported that the intact adult SNpc holds a strong neurogenic environment, but primed embryonic stem cells (ie, embryoid body cells, EBCs) could not derive into DA neurons. In this study, we transplanted into the intact or lesioned SNpc, EBCs derived from embryonic stem cells that were prompt to differentiate into DA neurons by the forced expression of *Lmx1a* in neural precursor cells (R1B5/NesE-Lmx1a). We observed that, 6 days post-transplantation (dpt), R1B5 or R1B5/NesE-Lmx1a EBCs gave rise to Nes^+ and Dcx^+ cells within the host SNpc, but a large number of Th^+ cells derived only from EBCs exogenously expressing *Lmx1a*. In contrast, when transplantation was carried out into the 6-hydroxidopamine-lesioned SNpc, the emergence of Th^+ cells from EBCs was independent of exogenous *Lmx1a* expression, although these cells were not found by 15 dpt. These results suggest that the adult SNpc is not only a permissive niche for initiation of DA differentiation of non-neuralized cells but also releases factors upon damage that promote the acquisition of DA characteristics by transplanted EBCs.

Keywords: transplantation, substantia nigra, dopaminergic differentiation, adult neurogenesis

Introduction

Parkinson's disease (PD), the second most common neurodegenerative disease, is characterized by the selective loss of A9-subtype ventral midbrain neurons that project to the striatum [1]. The current therapy for PD is the administration of dopamine analogs that, although effective for reducing some motor symptoms, their effects are lost after long-term administration and, in addition, can generate severe side effects [2]. Hence, there is a pressing demand for more effective therapies.

Among the promising alternative therapies is the replacement of damaged neurons by cell transplantation. Studies in PD patients or animal models have indicated that these therapies can result in significant symptomatic improvements [3–5]. To date, cell transplantation into the striatum is the most common strategy to rescue from dopamine deficiency; however, cell transplantation into the substancia nigra pars compacta (SNpc) followed by a proper rewiring should provide a better condition for the re-establishment of motor functions. In contrast with transplantations to the striatum, the latter strategy requires cells with the potential of getting the full characteristics of mesencephalic dopaminergic (DA) neurons and a host environment for efficient survival and differentiation, the minimal conditions for functional integration.

Pluripotent stem cells (PSCs), self-renewable cells with high differentiation potential, are a promising cell source for the treatment of degenerative disorders, including PD [6]. Although significant improvements in protocols for specific PSC differentiation have been accomplished [7,8], undesirable

fates or incomplete differentiation could influence functional integration, resulting in poor recovery and/or unwanted side effects after grafting. The in vitro DA differentiation of PSCs goes through several stages including ectodermal specification, neuralization, and neuronal differentiation [7,9,10]. Cells at each stage bear distinct characteristics some of which could fit those required, not only for efficient DA differentiation, but also for their integration after being transplanted.

Of interest, embryoid body cells (EBCs), embryonic stem cell (ESC) derivatives representing the cell population at the epiblast stage of embryonic development, differentiate efficiently into DA neurons when transplanted to the DA niche of the developing mesencephalon. However, the efficiency of this specific differentiation was markedly reduced when cells are differentiated in vitro [11]. These observations indicate that a large proportion of EBCs hold the full potential to acquire the DA neuronal phenotype when they are in a DA differentiation context, but this is lost or affected when in vitro neuronal differentiation is allowed.

The SNpc, site where mesencephalic DA neurons reside in the adult brain, has shown the ability to support DA neuronal survival when mesencephalic fetal cells are implanted after a pharmacological DA neuron depletion. Remarkably, differentiated neurons are able to project axons to the striatum [12–14]. Similarly, DA neurons derived from human ESCs also could survive in the rodent-lesioned adult SNpc [14].

We recently reported that EBCs directly transplanted to the intact adult SNpc, although do not give rise to DA neurons, differentiate into neurons with a similar efficiency to that of EBCs implanted in a well-known neurogenic area, the subventricular zone of lateral ventricles or the rostral migratory tract [15]. In contrast, EBCs cannot differentiate into neurons in the intact striatum, but when they are transplanted after an ischemic lesion, they can derive into neurons, suggesting that a lesion creates a condition that favors neurogenesis [15]. Therefore, the intact SNpc allows EBCs neuronal differentiation, possibly triggered by inductive signals present in this region, but an open question is whether the factors required for directing specific differentiation or survival can emerge upon damage.

In this study, we tested the possibility of in vivo DA neuronal differentiation in the intact and lesioned SNpc of ESCs at their earliest stage of differentiation (ie, after forming EBC) using wild-type ESCs and ESCs prompted to differentiate into DA neurons by the Nestin-enhancer-controlled expression of a *Lmx1a* transgene (R1B5/NesE-Lmx1a cell line). R1B5/NesE-Lmx1a EBCs acquired neuronal and DA markers at 6 days post-transplantation (dpt) in the adult SNpc, whereas wild-type EBCs derived into neural precursors cells (NPCs) and neuroblasts but did not acquire DA markers. Of interest, either R1B5/NesE-Lmx1a or wild-type EBCs efficiently differentiate into Th^+ cells within the 6-hydroxidopamine (6-OHDA)-lesioned SNpc. Therefore, brain damage not only generates conditions that allow neurogenesis of transplanted EBCs but also favor those that promote acquisition of DA characteristics.

Materials and Methods

Generation of the R1B5/NesE-Lmx1a cell line

R1B5 cells (a gift from Andras Nagy) were propagated on mitomycin c-treated mouse embryonic fibroblast cells (feeder cells) in ESC media (also called M15) composed of Dulbecco's modified Eagle's medium (DMEM; Gibco, Grand Island, NY) supplemented with 15% heat-inactivated fetal bovine serum, GPS (1×Glutamax; Gibco; 0.3 mg/mL of penicillin and 0.5 mg/mL of streptomycin; Sigma, St. Louis, MO), 1×MEM nonessential amino acids (from a 100×stock; Gibco), 1 mM sodium pyruvate (Gibco), 0.55 mM 2-mercaptoethanol (Sigma), and 1,000 U/mL of leukemia inhibitor factor (LIF; Chemicon, Temecula, CA). Before differentiation, cells were cultured in the 2i media containing the selective Gsk3β and Mek1/2 inhibitors, CHIR99021 (3 μM) and PDO325901 (1 μM), respectively (Stemgent, Beltsville, MD). To generate R1B5/NesE-Lmx1a ESC line, R1B5 cells were electroporated with the pNesE-Lmx1a vector (gift from Elisabet Andersson), and 24 h after reseeding them, cultured in the presence of 400 μg/mL G418 (Sigma) for clone selection. Individual clones were picked and expanded for 14 days, as described for R1B5 cells.

In vitro differentiation of ESCs

Unbiased neural differentiation was carried out using the one-step short-term protocol based on cells grown as a monolayer [9]. Cells were plated on gelatin-coated dishes and incubated in M15 medium for 12–15 h. Thereafter, cells were washed once with phosphate-buffered saline (PBS) and grown in N2B27 medium, composed of 50% DMEM/nutrient mixture F12 (F12), 50% neurobasal medium, and supplemented with 1×N2 and 1×B27 (from a 100×and 50×stocks, respectively; Gibco). RNA from putative NPCs derived from each clone was extracted to determine the *Lmx1a* transgene expression levels. For specific DA differentiation, we used the progressive 5-stage protocol [7]. In brief, ESCs were expanded on a feeder cell monolayer in M15 medium for 3 days. Then, trypsin-dissociated cells were seeded on gelatinized dishes in feeder-free conditions and cultured in M15 medium supplemented with LIF for 3 days (Stage 1: feeder-free ESC growth). After clearing ESCs from feeder cells, the cells were seeded on non-adherent bacterial culture dishes and cultured for 4 days in M15 media, without LIF or 2i, to form embryoid bodies (EBs; Stage 2). For the selection of NPCs (Stage 3), EBs were seeded on adherent conditions using gelatin-coated culture dishes in M15 medium for 24 h, then, 7 days in the selection medium composed of DMEM/F12 without HEPES (Gibco) plus 1×insulin/transferrin/selenium/sodium pyruvate supplement (100×ITS-A stock; Gibco), 1 mg/mL fibronectin (Gibco) and GPS. For expansion of NPCs (Stage 4), trypsin-dissociated NPCs were seeded on 24-well culture dishes, previously treated with poly-D-lysine (10 μg/mL; Sigma) and fibronectin (1 μg/mL; Gibco), in the expansion medium composed of DMEM/F12 without HEPES supplemented with 10 ng/mL Fgf2, 100 ng/mL Fgf8; and 500 ng/mL Sonic Hedgehog (all growth factors from Peprotech, Rocky Hill, NJ) for 7 days. To promote terminal differentiation (Stage 5), cells were cultured in differentiation medium composed of the expansion medium without growth factors for 6 days. Immunolabeling and real time polymerase chain reaction (PCR) were performed at fourth and fifth stage to detect expression of specific genes of neural or neuronal cells and the transgene expression.

Animal and cell transplantation procedures

Animals were housed under a 12-h light/dark cycle with ad libitum access to food and water. All procedures were approved by the bioethical committees of the Instituto de Biotecnología and of the Instituto de Fisiología Celular (MGC08). Embryos used were from CD1 mice at 10.5 days postcoitum (E10.5; 0.5 was the day of mating plug detection); pregnant mice were killed by cervical dislocation. E10.5 midbrain explant cultures and the transplant-into-explant procedure were performed as previously described [11]. The brains of adult male Wistar rats (250 g) were used as the host for EBCs. For transplantation, animals were anesthetized with a mix of xylazine (8 mg/kg; PiSA, Guadalajara, México) and ketamine (10 mg/kg; PiSA) and those with transplanted cells were killed by an overdose of pentobarbital (PiSA) at 6 or 15 dpt. Cell transplantations to adult rat brains were performed by stereotaxic surgery; coordinates for SNpc were obtained from Paxinos and Watson (−4.7, −1.6, and −8.1 mm; posterior, lateral, and ventral to bregma, respectively) [16]. One to two microliters of EB-derived cell suspension (~150,000 cells) was injected using a 5 µL Hamilton syringe. Animals were lesioned with 6-OHDA as previously described [17]. In brief, animals were anesthetized under ketamine–xylazine (as described previously) and 40 µg 6-OHDA (Sigma) in 0.5 µL of saline solution were injected at a rate of 0.1 µL per minute into the left SNpc (coordinates were the same as for cell transplantations). Cell suspensions were obtained from three independent cultures and each transplanted to brains of groups of three rats.

Tissue processing and immunolabeling

Midbrain explants, after 4 or 7 days in culture, were fixed with 4% paraformaldehyde (PFA; Sigma) for 2 h at 4°C. After dehydration with 30% sucrose (J.T.Baker/Avantor Performance Materials S.A. de C.V., Xalostoc, México) for 24 h at 4°C, 10 µm coronal sections were obtained from tissues using a cryostat (Microm HM550; Thermo Scientific, Waltham, MA). For cultured cells, they were fixed with cooled 4% PFA for 20 min and then stored in antifreeze solution. To analyze cells implanted in the adult rat brain, an intracardiac perfusion was performed on the killed animals, first with saline solution (PBS), followed by 4% cooled PFA. Before slicing in frozen conditions, tissues were sequentially dehydrated in 10%, 20%, and 30% sucrose (24 h each). Forty-micrometer slices were obtained from brains and collected in antifreeze solution. After fixation, tissue or cells were subjected to immunolabeling using the protocols described in Maya-Espinosa et al. [15] and Baizabal and Covarrubias [11]. The antibodies used are given in Supplementary Table S1. Processed tissues were analyzed with an epifluorescence or confocal microscope as detailed hereunder.

RNA extraction and quantitative PCR

Total RNA extraction with TRIzol (Invitrogen, Waltham, MA) and complementary DNA (cDNA) synthesis with AMV Reverse Transcriptase (RT; Invitrogen) were carried out following the manufacturer's instructions. Messenger RNA (mRNA) levels were determined by real-time quantitative PCR (qPCR) performed on cDNA produced from total RNA of each sample. The qPCR was carried out using standard protocols with KAPA SYBR® FAST kit (KAPA Biosystems, Wilmington, MA) and Rotor Gene Q thermocycler (Qiagen, Hilden, Germany). To determine relative gene expression levels, a comparative Ct (ΔCt) method was used and the amount of a specific mRNA was normalized based on the estimated amount of Rplp0 or Cyclophilin (Cyc) mRNAs. Primer sequences (forward and reverse) are given in Supplementary Table S2.

Image acquisition and cell counting

For cell quantification in culture, images were captured in a Zeiss AxioVision microscope using AxioVison LE software or direct counting from the microscope eyepieces. We counted at 40× or 60× magnifications in two different fields for each culture. For transplanted cells, images were captured in an Olympus FV1000 multiphoton laser scanning microscope. At least two fields of two slices were analyzed for each transplanted brain (three for each of the three EBC suspensions prepared). Quantifications of double-stained cells were carried out on continuous Z-optical slices. When required, data were statistically analyzed by the Student's *t*-test.

Results

Generation of traceable neural derivatives from ESCs with increased DA differentiation potential

EBCs derived from the R1B5 ESC line, constitutively expressing an *EGFP* transgene, show neural differentiation capacity when transplanted to an adult neurogenic niche, a lesioned striatum or the SNpc; however, in contrast with the specific differentiation observed within the embryonic DA niche [11], their fate was rarely Th^+ neurons [15]. On the contrary, it has been shown that the forced *Lmx1a* expression driven by the chimeric Nestin-enhancer TK-basal promoter (NesE) increases the midbrain DA differentiation capacity of ESCs, as revealed when they are subjected to different DA differentiation protocols [18–20].

To test the capacity of ESCs to carry out DA differentiation in an in vivo context, the *NesE-Lmx1a* transgene was introduced to R1B5 ESCs. Transfected clones were initially selected by the ability to activate the *NesE-Lmx1a* transgene in NPCs (ie, expressing *Nestin*) derived from an unbiased short-term monolayer neural differentiation protocol [9] (Supplementary Fig. S1). From the three ESC clones showing a relatively high *NesE-Lmx1a* transgene expression after 4 days in the neural differentiation medium, two were selected for further analysis (R1B5/NesE-Lmx1a/C3 and R1B5/NesE-Lmx1a/C5) (Supplementary Fig. S1C). Between these two clones, R1B5/NesE-Lmx1a/C3 (referred herein as the R1B5/NesE-Lmx1a) not only had higher *Lmx1a* expression levels but also showed more consistent DA differentiation in culture (see hereunder) and was used for all transplantation experiments.

Overexpression of Lmx1a *leads to DA differentiation in a non-DA embryonic domain*

The capacity of Lmx1a to increase DA differentiation in vitro was previously determined and found that Shh and

INFORME DE LABORES 2019

Fgf8 are still required to lead specific differentiation. To corroborate the increased DA differentiation potential of the selected clones, the five-stage protocol was performed with the R1B5/NesE-Lmx1a line and the DA neuronal differentiation efficiency compared with that obtained with the parental R1B5 line (Fig. 1A). For this, we took advantage of the constitutive presence of GFP to make more evident the changes in cell distribution during the differentiation of live cultures. We did not observe any difference between the two lines in the progress of culture across the differentiation process (Fig. 1B), suggesting that the exogenous Lmx1a or any event during clone selection did not generally affected neural differentiation.

In contrast, a specific effect of exogenous *NesE-Lmx1a* transgene was expected because NPCs derived and expanded from R1B5/NesE-Lmx1a cells showed not only more clusters with Lmx1a but also a greater percentage of $Lmx1a^+/Nes^+$ cells in comparison with that determined for NPCs from R1B5 cells (94.5% vs. 7.8%, $n=3$) (Fig. 1C, D). Accordingly, higher levels of total *Lmx1a* mRNA were detected in samples from R1B5/NesE-Lmx1a cells in comparison with samples at the same stage from R1B5 cells (Fig. 1D).

The DA promoting effect of the exogenous Lmx1a on NPCs was evaluated at the differentiation stage by estimating the number of clusters with Th^+ cells and the proportion of Th^+ cells within each cluster. We found a markedly higher number of cell clusters with Th^+ cells in cultures derived from R1B5/NesE-Lmx1a cells compared with cultures derived from R1B5 cells (94.4%, $n=3$ vs. 38%, $n=2$) (Fig. 1E, F), which correlated very well with the increased number of clusters with Lmx1a at the fourth stage. In addition, the proportion of Th^+ cells in each cluster was also greater for cultures derived from R1B5/NesE-Lmx1a cells than those derived from R1B5 cells (61%, $n=3$ vs. 4%, $n=2$) (Fig. 1F). In agreement with these determinations, differentiated R1B5/NesE-Lmx1a cells showed higher levels of *Th* expression than differentiated R1B5 cells (Fig. 1F). Therefore, Lmx1a in R1B5/NesE-Lmx1a cells can promote DA differentiation at early (estimated by the number of developed Th^+ clusters) and late (estimated by the number of Th^+ neurons within each cluster) stages of differentiation.

The DA promoting function of the *NesE-Lmx1a* transgene was also tested in an in vivo embryonic context. DA neurogenesis in the midbrain occurs from the gestational stage E9.0 to the stage E14.0 [21]. We previously determined that EBCs could be specifically instructed to differentiate into mesencephalic DA neurons by the milieu of the ventral midbrain of E10.5 embryos, passing through a gradual differentiation from NPCs Nes^+ and $Lmx1a^+$ up to becoming neuronal postmitotic Th^+ cells [11]. When donor cells implanted into sites far from the ventral midline, they differentiated in accordance with the implantation site.

EBCs derived from the R1B5 or R1B5/NesE-Lmx1a lines were transplanted to the ventricular surface of E10.5 midbrains and cells analyzed at 4 and 7 days postimplantation (dpi) (Fig. 2). At 4 dpi, as with R1B5 EBCs, implanted cells within the ventral region (the DA domain) acquired Nes and Lmx1a markers in most implantation cases (five of six cases) but no Th^+ cells were detected (zero of six cases) (Fig. 2B, C). In contrast, at this same stage of explant culture, implanted R1B5 EBCs within the dorsal region (non-DA domain) did not develop into $Lmx1a^+$ cells, whereas implanted R1B5/NesE-Lmx1a EBCs within this same region derive into $Lmx1a^+$ cells in some implantation cases (two of four cases) (Fig. 2B, C).

At day 7, R1B5/Nes-Lmx1a EBCs implanted in either the ventral or dorsal region gave rise to cells coexpressing *Lmx1a* and *Th* (6 of 11 cases in the ventral region and 3 of 8 cases in the dorsal region) (Fig. 2B, C), whereas coexpression of these markers was only detected for cells derived from R1B5 EBCs when implanted in the DA domain (3 of 4 cases) (Fig. 2B, C), as previously reported. Because the endogenous *Lmx1a* was only activated when EBCs implanted around the midline, these observations agree with the promotion of DA differentiation by the activation of the *NesE-Lmx1a* transgene upon reaching the NPC differentiation stage. The fact that many NPCs ectopically expressing *Lmx1a* in dorsal regions did not become Th^+ neurons, indicates that additional factors present in the ventral region are required to complete DA differentiation (Fig. 2), as recently reported [22].

Lmx1a overexpression is required for EBCs DA differentiation in the intact SNpc

Although it remains controversial whether the SNpc carries out active neurogenesis for a continuous turnover of DA neurons, we recently propose that, at least, the SNpc holds a silent neurogenic niche that can be detected by EBCs such that they derive into a large number of neurons in this region [15]. Accordingly, R1B5/NesE-Lmx1a EBCs survived in the SNpc and differentiated into a similar proportion of neural cells as transplanted R1B5 EBCs (no significant difference determined). Specifically, transplanted R1B5/NesE-Lmx1a EBCs derived into Nes^+ or Dcx^+ (markers for neural stem cells or neuroblasts, respectively) cells at 6 dpt (Fig. 3). Therefore, exogenous *Lmx1a* does not alter the neurogenic capacity of EBCs in the adult brain.

Strikingly, at 6 dpt many cells expressing *Th* were derived from transplanted R1B5/NesE-Lmx1a EBCs (GFP^+), whereas none was found when R1B5 EBCs were transplanted (Fig. 3) as previously reported [15]. In agreement with the expected effect of Lmx1a in promoting mesencephalic DA neuronal differentiation, several nuclei (at least 16% of total GFP^+ cells) were detected with Pitx3, a transcription factor emerging specifically in the midbrain at an early stage of DA differentiation (Fig. 3E). However, at 15 dpt, the number of GFP^+/Th^+ detected was markedly reduced although the number of Dcx^+ cells was as for R1B5 EBCs ($n=2$) (Fig. 3D) [15]. These observations suggest that Lmx1a can lead EBCs to gain higher DA potential in vivo without the need of exogenous Shh and/or Fgf8, but additional factors seem to be required to complete differentiation and/or increase long-term survival of these putative DA neurons (see Discussion section).

The lesioned SNpc favors DA differentiation of EBCs

In the past, it has been demonstrated that the damaged brain can support neurogenic processes of both endogenous and/or exogenous NPCs or from undifferentiated PSCs [23–25]. To evaluate whether the SNpc can turn into a

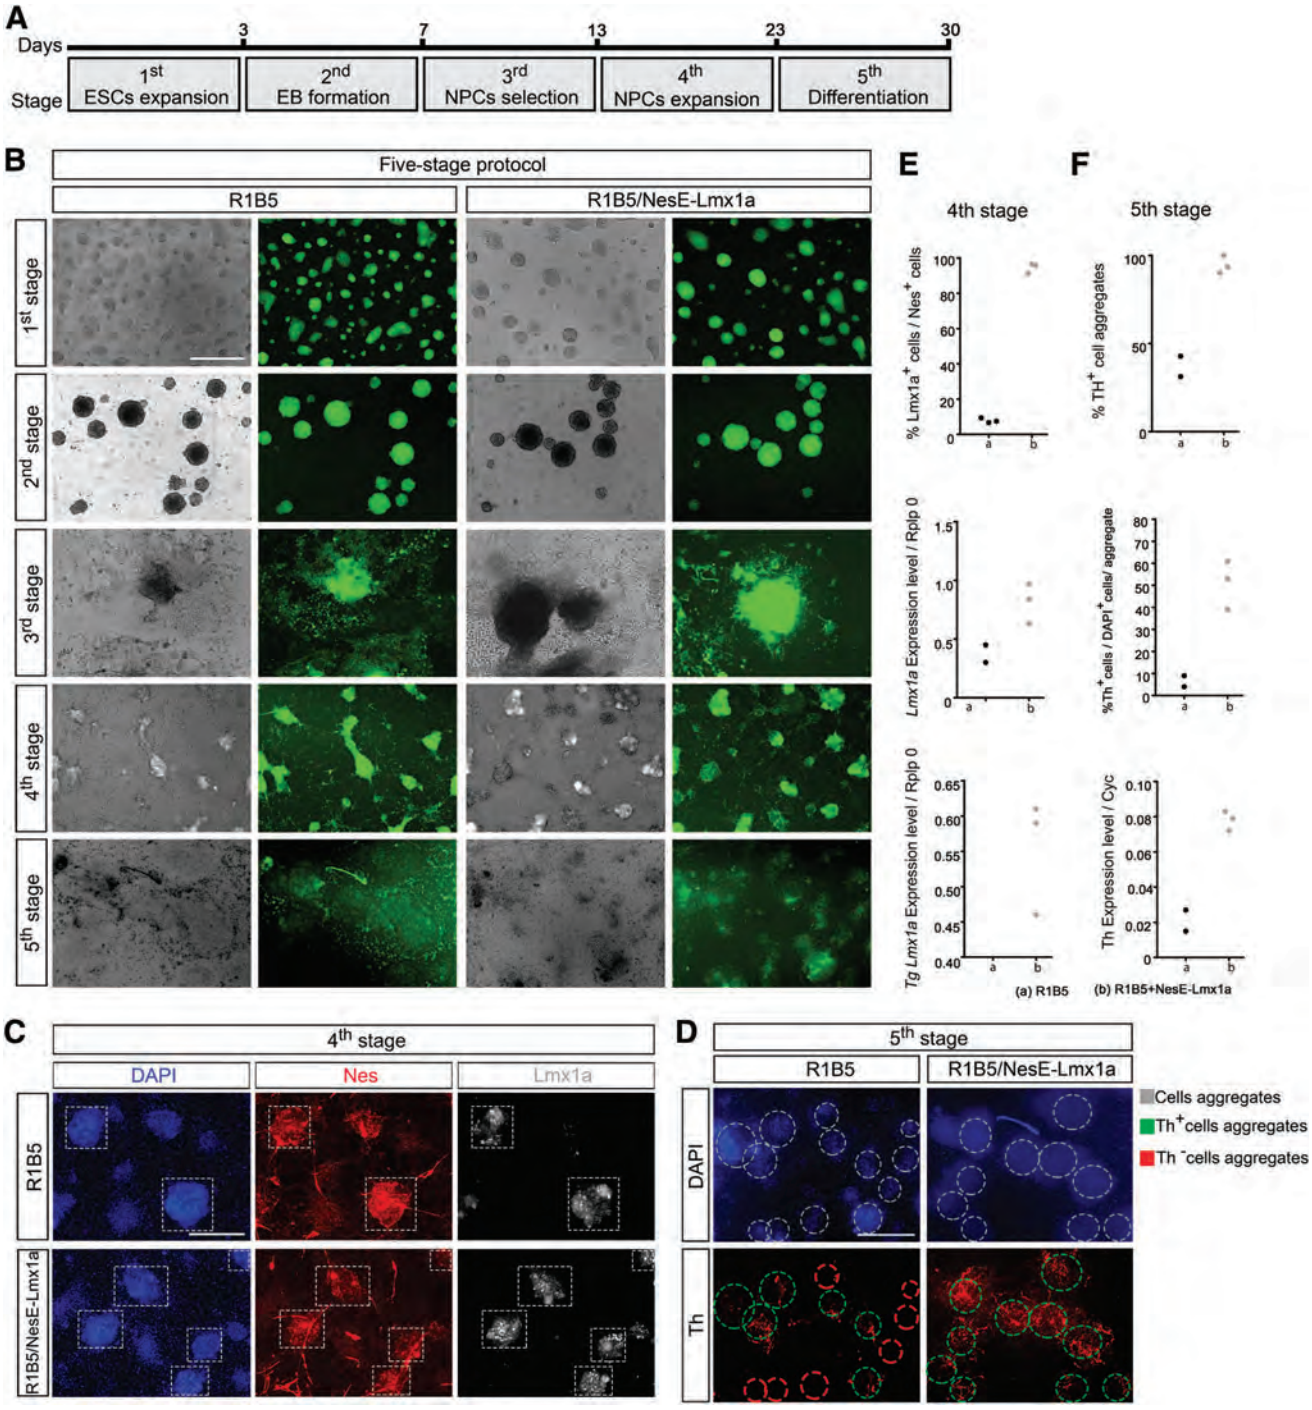

FIG. 1. In vitro DA differentiation of ESCs containing the *NesE-Lmx1a* transgene. **(A)** Scheme of DA neuronal differentiation through the five-stage protocol. R1B5 and R1B5/NesE-Lmx1a ESC were differentiated under the same conditions. **(B)** Bright field and fluorescence (GFP) imaging across each differentiation stage. Low magnification images did not reveal major differences in culture development at any differentiation stage when both cell lines were compared. **(C)** Detection of putative DA NPCs ($Nes^+/Lmx1a^+$). Lmx1a and Nes were detected by specific immunolabeling at the fourth differentiation stage; *dashed squares* indicate $Nes^+/Lmx1a^+$ cell clusters. **(D)** Detection of putative DA neurons (Th^+). Cells immunopositive for Th were found within clusters at the fifth differentiation stage; *dashed circles* delimit distinct cell clusters containing (*green*) or not containing (*red*) Th^+ cells. **(E)** Quantification of the number of putative DA NPCs. Because of the presence of the *Lmx1a* transgene, abundant $Nes^+/Lmx1a^+$ cells were detected at the fourth differentiation stage of R1B5/NesE-Lmx1a differentiation (b, *gray dots*), in contrast with the few found in differentiated R1B5 cells at this same stage (a, *black dots*); determination of *Lmx1a* expression levels by RT-qPCR confirmed this observation. **(F)** Quantification of the number of putative DA neurons. At the fifth differentiation stage, more clusters containing Th^+ cells and more Th^+ cells in each cluster derived from cells of the R1B5/NesE-Lmx1a cell line (b, *gray dots*) than from those of the R1B5 cell line (a, *black dots*); higher *Th* expression levels determined by RT-qPCR confirmed the increased DA differentiation efficiency of R1B5/NesE-Lmx1a cells. Scale bars: 500 µm. DA, dopaminergic; ESCs, embryonic stem cells; NPCs, neural precursors cells; RT-qPCR, reverse transcriptase quantitative PCR. Color images are available online.

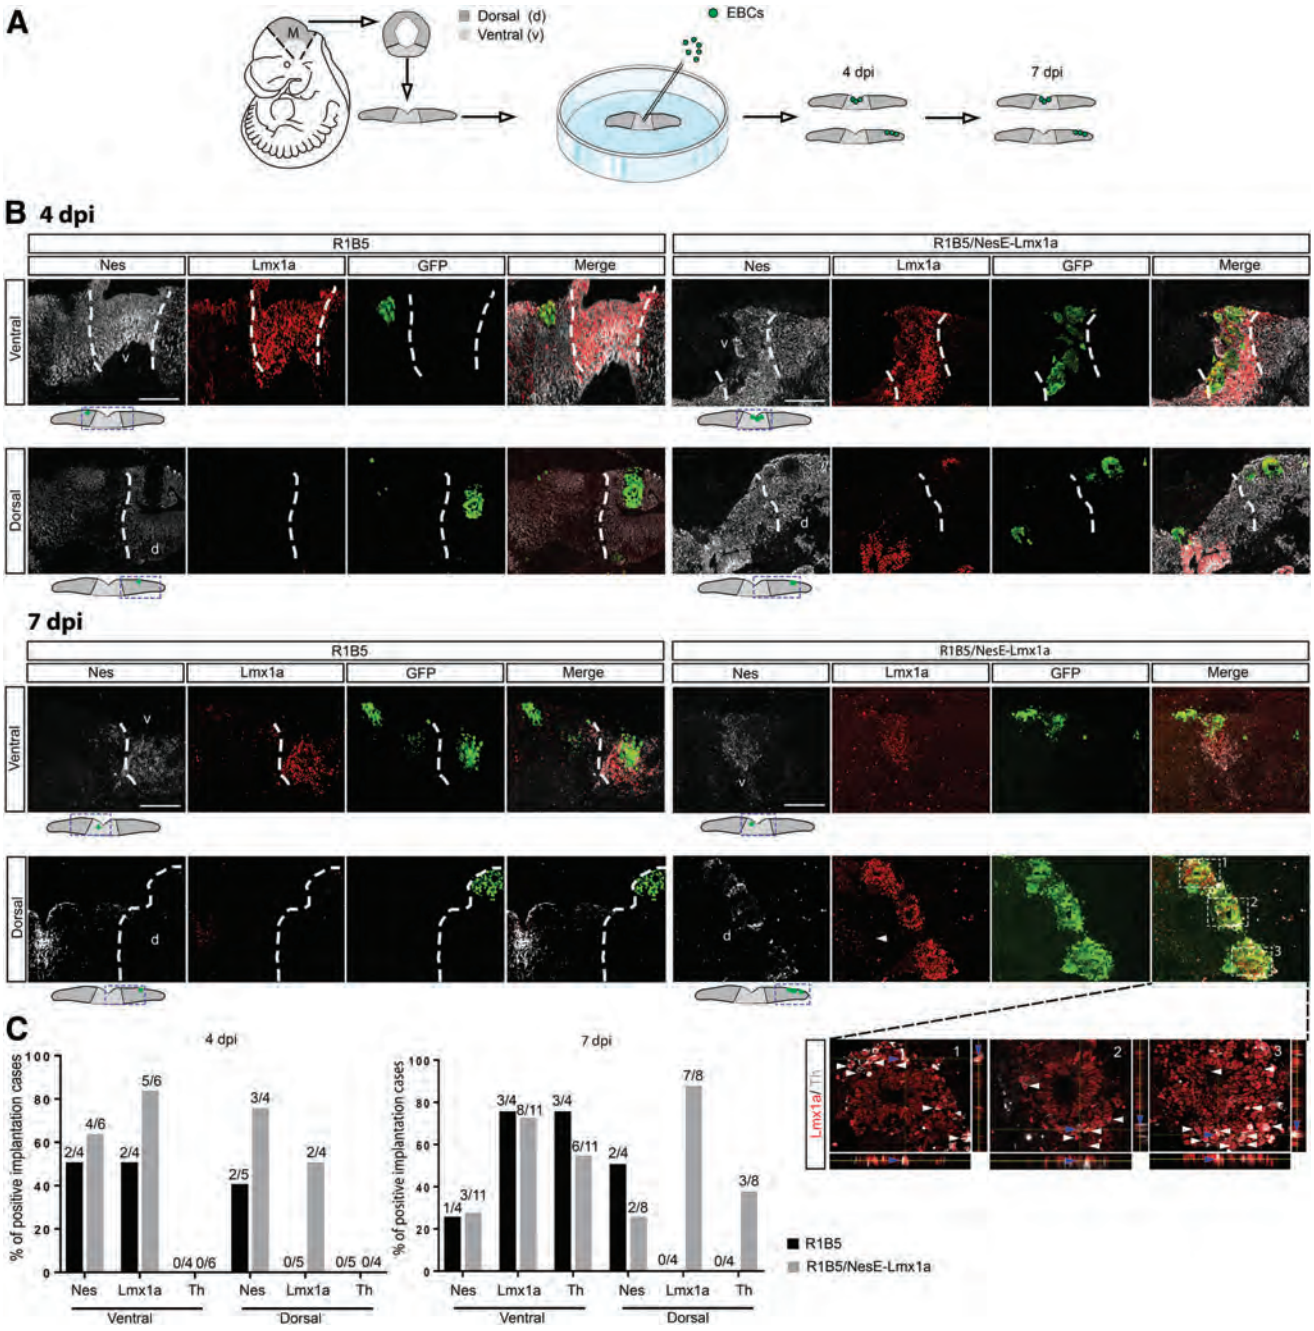

FIG. 2. Evaluation of *Lmx1a* transgene function in the developing midbrain context. **(A)** Schematic representation of the midbrain explant culture and implantation of EBCs into the ventral or dorsal area (DA or non-DA niche, respectively). **(B)** Detection of EBC-derived DA NPCs or neurons in midbrain explants. Nes, Lmx1a and Th were detected by immunolabeling at 4 or 7 days after implanting (dpi) R1B5 or R1B5/NesE-Lmx1a EBCs (GFP^+) into the ventral (4 and 7 dpi, *upper panels*) or dorsal (4 and 7 dpi, *lower panels*) midbrain regions. Magnification of zones are delimited by *dashed squares*; *white arrowheads* indicate implanted cells (GFP^+) coexpressing *Lmx1a* and *Th*, whereas some of these selected for orthogonal analysis are indicated with *blue arrowheads*. **(C)** DA differentiation efficiency of EBCs in the ventral or dorsal midbrain. Number of implantation cases in which implanted cells were positive for Nes, Lmx1a or Th markers at 4 or 7 dpi in ventral or dorsal areas were determined. Note that, whereas EBCs derived from both cell lines behaved similarly once integrated into the ventral region or near to it, only those derived from the R1B5/NesE-Lmx1a cell line gave rise to Nes^+ and/or $Lmx1a^+$ (at 4 dpi) and $Lmx1a^+$ and/or Th^+ (at 7 dpi) cells when implanted in the dorsal region. Scale bars: 200 µm. dpi, days postimplantation; EBC, embryoid body cell. Color images are available online.

stronger neurogenic niche after lesioned with 6-OHDA, the fate of EBCs from R1B5 and R1B5/NesE-Lmx1a lines was determined when transplanted to the lesioned SNpc (Fig. 4). At 6 dpt, a proportion of EBCs implanted at the lesioned area had a neuronal morphology and, unexpectedly, many of those cells were Th^+ (>20%) (Fig. 4 and Supplementary Fig. S2) disregarding whether they derived or not from cells containing the *NesE-Lmx1a* transgene (Fig. 4B–D). A significant proportion of these Th^+ cells coexpressed *Dcx* (>90%) (Fig. 5).

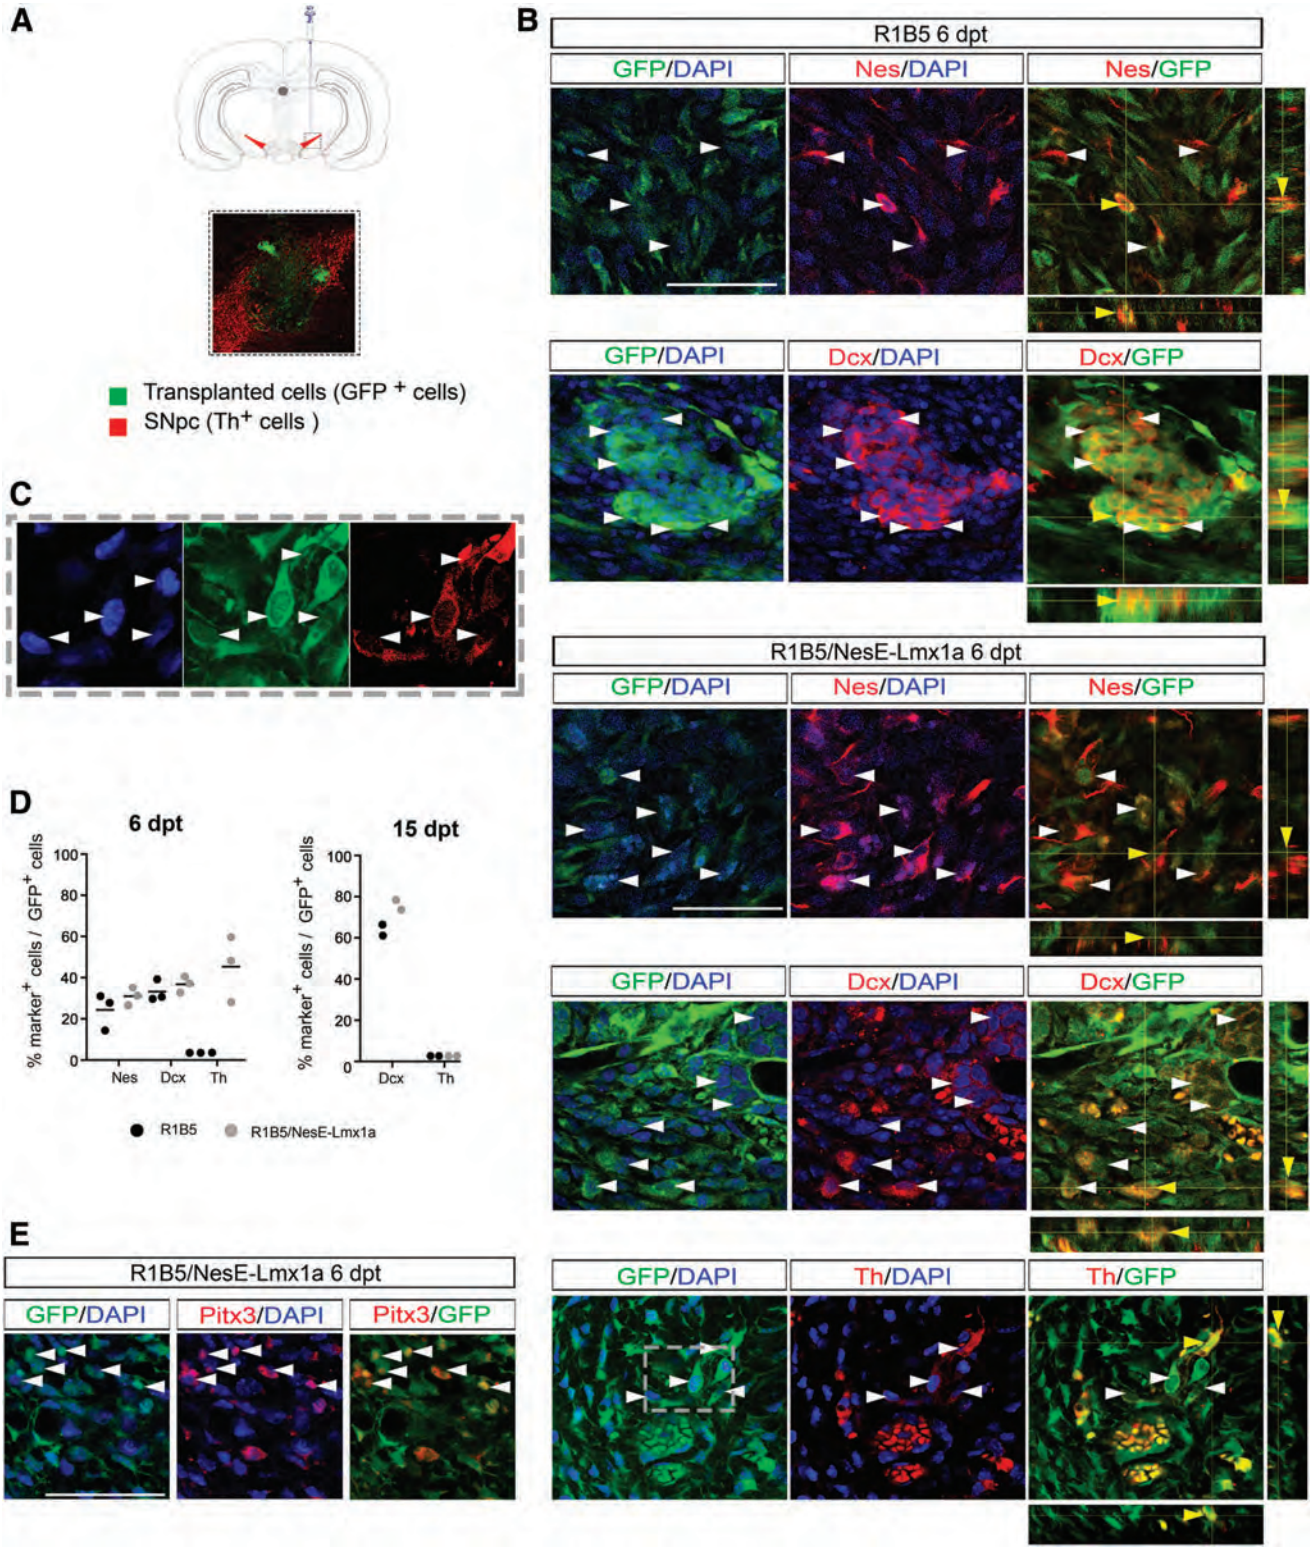

FIG. 3. Effect of *Lmx1a* overexpression on DA differentiation of EBCs in the intact rat SNpc. **(A)** Schematic representation of EBC transplantation to the adult SNpc. A representative image revealing the typical implantation site of EBCs (GFP^+) within the SNpc (Th^+, *red*) is shown. **(B)** DA fate of EBCs in the SNpc at 6 dpt. NPCs (Nes), neuroblast (Dcx), and DA (Th) markers were determined by immunostaining at 6 dpt in cells derived from transplanted R1B5 and R1B5/NesE-Lmx1a EBCs; *white arrowheads* indicate transplanted cells (GFP^+) expressing *Nes*, *Dcx* or *Th*, whereas *yellow arrowheads* indicate those cells selected for orthogonal views. **(C)** A higher magnification of the *dashed square* in *lower panels* of **(B)**. **(D)** Quantification of EBC neural and DA differentiation in the SNpc at 6 and 15 dpt. GFP^+ cells presenting the given marker were manually counted; each point in graph represents the average differentiation efficiency of EBCs derived from an independent culture and transplanted to the brain of three rats. Note that, whereas transplanted EBCs from both lines differentiated into similar number of NPCs and neuroblasts at 6 dpt, only R1B5/pNes-Lmx1a EBCs differentiated into Th^+ cells. **(E)** Detection of the midbrain-specific DA differentiation marker Pitx3. Pitx3 was immunodetected in transplanted cells at 6 dpt; *arrowheads* indicate positive nuclei for this marker. Scale bars: 50 μm. dpt, Days posttransplantation; SNpc, substancia nigra pars compacta. Color images are available online.

INFORME DE LABORES 2019

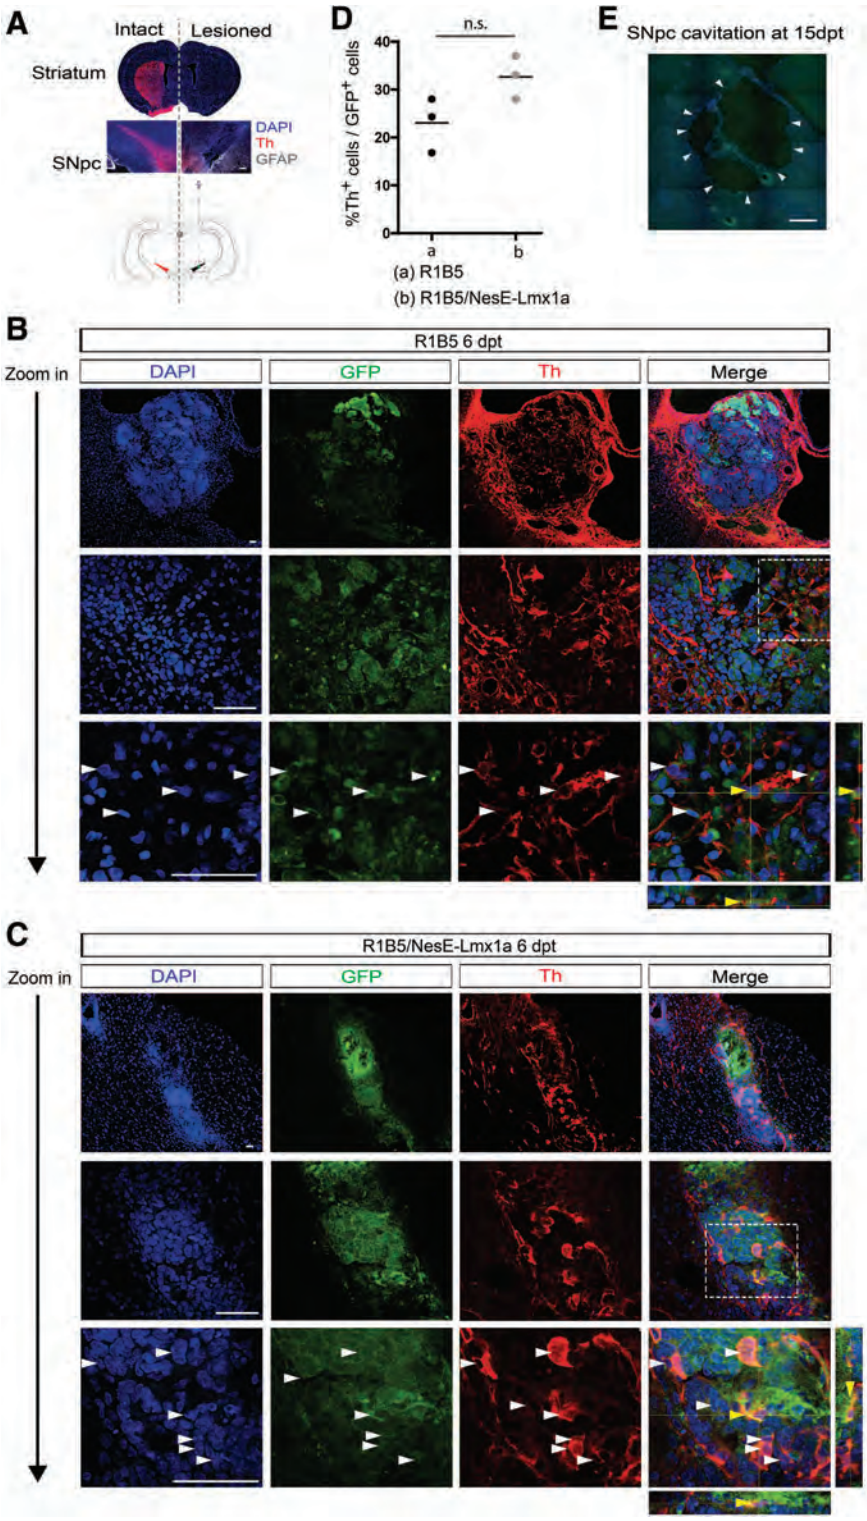

FIG. 4. Effect of lesioned SNpc on EBC DA differentiation. **(A)** Schematic representation of EBC transplantation to the lesioned adult SNpc. Representative images revealing the lack of Th (*red*) in coronal sections containing the SNpc-innervating striatum (*upper image*) or the SNpc (*lower image*) 2 weeks after unilaterally inducing DA neuron depletion are shown; EBCs were transplanted at this stage. Scale bar: 200 μm. **(B, C)** Detection of putative DA EBC-derived cells in the lesioned SNpc. Th was immunodetected at 6 dpt in cells from R1B5 **(B)** and from R1B5/NesE-Lmx1a **(C)** after EBCs were transplanted to lesioned animals. *Dashed squares* delimit the magnified area shown in the *lower panels*; *white arrowheads* indicate Th^+ cells derived from transplanted EBCs, whereas *yellow arrowheads* indicate those cells analyzed in orthogonal views. Scale bars: 50 μm. **(D)** Quantification of EBC DA differentiation in the lesioned SNpc. GFP^+ cells presenting Th were manually counted; each *point* in graph represents the average differentiation efficiency of EBCs derived from an independent culture and transplanted to the brain of three rats; n.s., no significant difference found. Note that, in contrast with the results in the intact SNpc, R1B5 and R1B5/NesE-Lmx1a EBCs differentiated into Th^+ cells in the lesioned region. **(E)** X-Y reconstruction of the lesioned SNpc at 15 dpt. Image is composed of 3 (*x* axis) × 4 (*y* axis) images. *Arrowheads* indicate the cavitated zone. Scale bar: 200 μm. It was apparent that cavitation continued growing after transplantation and no EBCs was found at 15 dpt. Color images are available online.

In contrast with the outcome of transplanted EBCs in the intact SNpc (at least 30 days survival) [15], the lesioned condition did not allow long-term survival of the in vivo-derived EBCs progeny, possibly because of the cavitation of the host tissue resulting from the 6-OHDA-induced neurodegeneration (Fig. 4E). These results suggest that the lesioned SNpc retains a neurogenic environment but, in addition, gains inductive properties that direct differentiation toward a DA phenotype.

Discussion

The common cell transplantation approach to test the dopamine releasing capacity of grafted cells in a PD animal model is to place them within the target striatal region [26]. For successful therapeutic effectiveness, this strategy does not need cells for transplantation with the capacity for nigrostriatal circuit integration; in this case, rather, grafted cells stimulate the host striatum and rescue from dopamine deficiency by

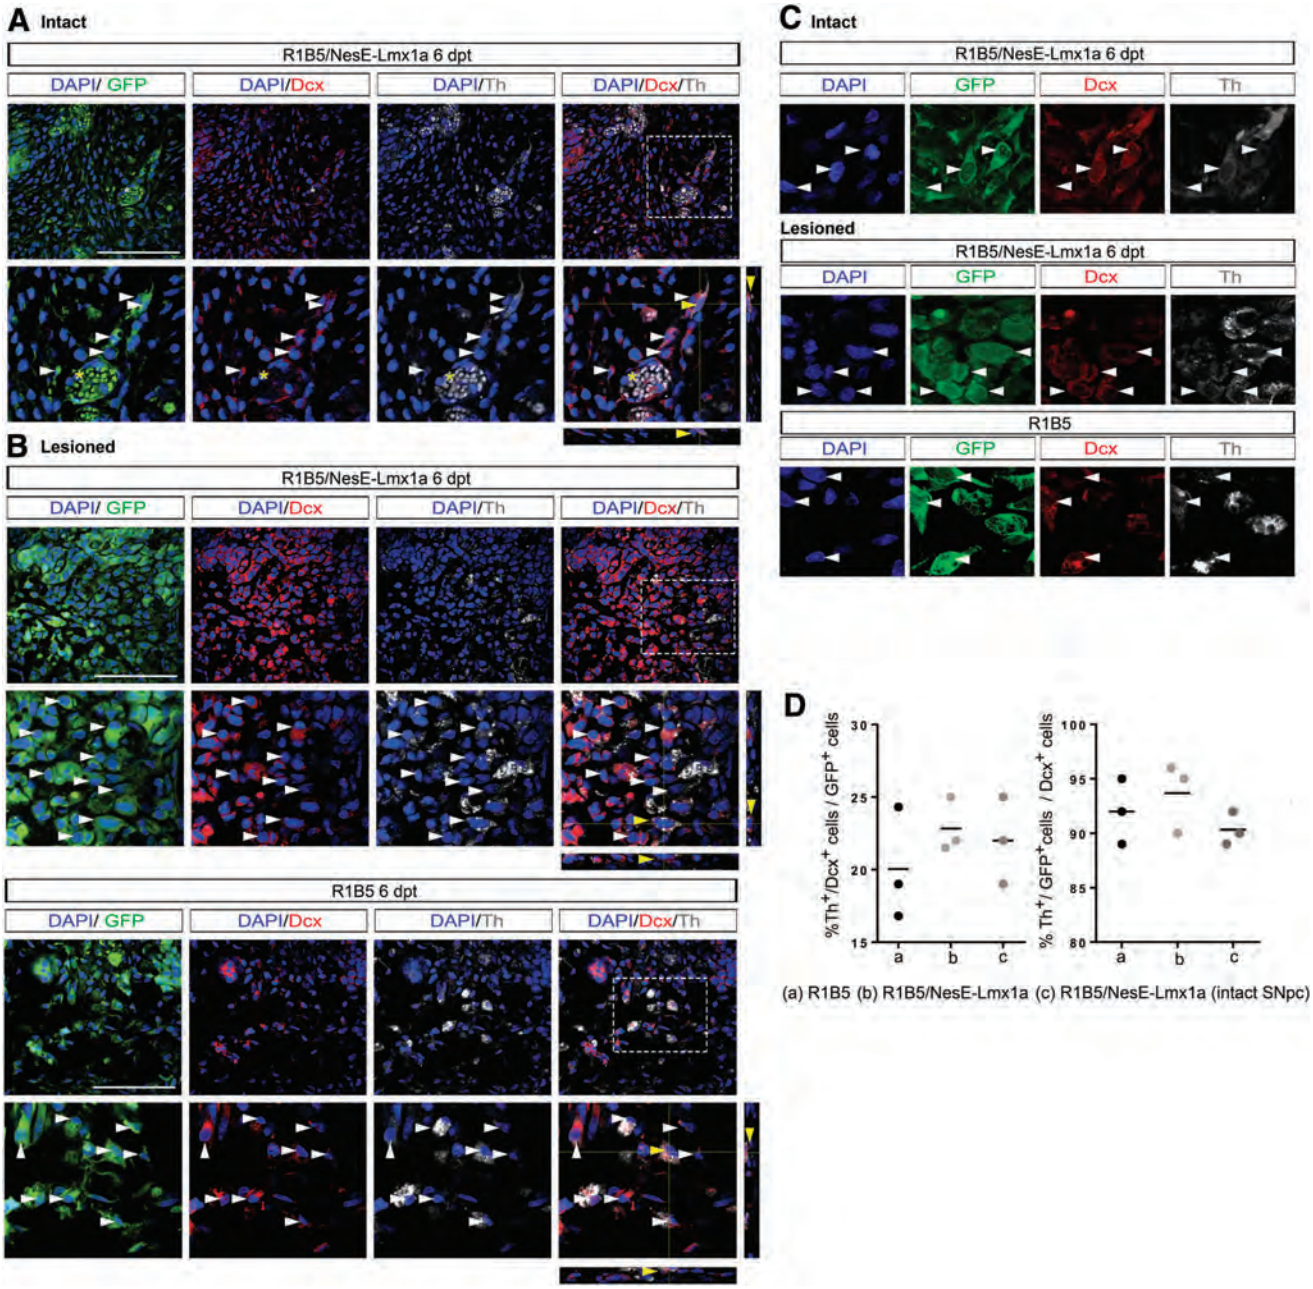

FIG. 5. Differentiation of transplanted EBCs into DA neuroblasts. The Dcx neuroblast marker was immunodetected in Th^+ cells derived from transplanted R1B5 or R1B5/NesE-Lmx1a EBCs in the intact **(A)** or lesioned **(B)** SNpc. *Dashed squares* in *upper panels* delimit the magnified area shown in *lower panels*. *White arrowheads* indicate transplanted cells coexpressing *Th* and *Dcx,* whereas *yellow arrowheads* indicate those cells analyzed in orthogonal views. The *asterisk* indicates a group of Th^+/Dcx^- cells that might represent chromafin-like cells. Scale bars: 100 μm. **(C)** Higher magnifications of transplanted Th^+/Dcx^+ cells (indicated by *white arrowheads*). **(D)** Quantification of EBC-derived DA neuroblasts in the intact and lesioned SNpc. GFP^+ cells positive for Th were manually counted; each *point* in graph represents the average differentiation efficiency of EBCs derived from an independent culture and transplanted to the brain of three rats. Note that most Th^+ cells derived from both lines were neuroblasts as indicated by the presence of Dcx. Color images are available online.

releasing dopamine without requiring the extension of long axons. In contrast, an approach based on transplantation to the SNpc requires cells for transplantation that not only produce dopamine but also are able to direct axons to the specific target neurons in the striatum.

We previously demonstrated that the intact adult SNpc can support efficient neuronal differentiation of non-neuralized EBCs, but DA neurons are not within the EBC-derived neurons [15]. Here we looked to find whether the inability of EBCs to derive DA neurons in the SNpc is limited by the capacity of transplanted cells or by the SNpc host environment that prevents specific differentiation or neuronal survival. For this purpose, we developed a traceable ESC line prompted to differentiate into DA neurons and

evaluate its capacity to derive DA neurons in the intact and 6-OHDA-lesioned SNpc.

We confirmed that the introduction of *pNesE-Lmx1a* transgene into ESCs increases the production of DA neurons following the five-stage differentiation protocol in the presence of Shh and Fgf8 [19]. The analysis of these data allows to propose that Lmx1a increases DA differentiation by acting at two different steps of differentiation. Specifically, the higher number of groups containing Th^+ cells can be considered an indication of Lmx1a contribution to the initial specification of DA NPCs, whereas a larger number of Th^+ cells within a group might imply that, after the initial specification, Lmx1a also contributes to DA differentiation. In the context of the intact adult SNpc, Th^+ neuroblasts emerged only in the presence of exogenous Lmx1a and were detected since 6 dpt, but none remained by 15 dpt. Considering the above DA differentiation capacity of EBCs in vitro, this might indicate that the initial Lmx1a-induced specification is occurring in vivo but differentiation could not continue and neuroblasts lose DA identity or died.

Undifferentiated EBCs own the capacity to differentiate into neurons within certain regions of the adult brain. This neuronal differentiation capacity, rather than being a preferred default fate, is likely because of the presence of a permissive or an inductive neurogenic environment [15]. Accordingly, differentiation into neurons was poor in the striatum, although other neural cells (ie, astrocytes) were still among the major cell types derived. In particular, efficient neuronal differentiation of EBCs occurred in the adult SNpc, but DA neurons were not detected. Because EBCs are responsive to DA specification signals, these data are in agreement with the expected absence of specification signals in the intact adult SNpc, a deficit that was at least partially overcome by EBCs expressing an exogenous *Lmx1a* (ie, those derived from the R1B5/NesE-Lmx1a ESC line).

Brain damage creates a local condition that can critically determine the incorporation of new neurons into specific neuronal circuits. When NPCs are transplanted, not only it is necessary that they survive within the damaged area but also that the environment is proper for specific neurogenesis. Neurogenesis or a neurogenic environment sometimes arises upon damage [22–24]. In the 6-OHDA-lesioned SNpc, EBCs can still detect the preexisting neurogenic environment, but in contrast with the observations in the intact SNpc, exogenous Lmx1a for DA specification appeared superfluous and DA neuroblasts were also derived from wild-type EBCs. These data suggest that the lesion by 6-OHDA did not affect the neurogenic capacity of the SNpc and, rather generates a condition that favors DA differentiation. The possible specification molecules involved remain to be identified.

In contrast with the results presented here, significant survival and/or integration of DA neurons in the lesioned SNpc has been previously achieved with differentiating DA NPCs. For example, NPCs from mouse E12.5 developing mesencephalons transplanted to the lesioned SNpc produce a large number of DA neurons, in some cases showing the ability to project to the striatum [12,13]. However, it is relevant to mention that the NPCs transplanted in these cases include many NPCs already committed to differentiate into DA neurons, such that specific differentiation factors are no longer required. Accordingly, in a study in which NPCs at different stages of differentiation were selected and transplanted to the nonlesioned SNpc or lesioned striatum, DA neurons derived mainly from $Neurog2^+$ NPCs which, in the ventral mesencephalon, represent neuroblasts committed to become DA neurons [22,27].

Committed DA NPCs derived from human ESC in vitro might also be the source of projecting DA neurons emerging in the lesioned SNpc after transplantation [14]. Therefore, the inefficient differentiation and/or survival of DA neuroblasts in our study may be because of the inability of EBC-derived NPCs to reach the committed stage. In the lesioned SNpc this could not be determined because of the few cells surviving after 6 dpt, probably because of the adverse conditions within the damaged area. It will be interesting, however, to determine whether the addition of factors, such as Shh and Fgf8, needed for the progression of DA differentiation and absent in the unlesioned or lesioned SNpc can increase the differentiation efficiency of EBC into DA neurons after transplantation.

To increase the grafting efficiency, allotransplants and xenotransplants are commonly performed with immunosuppressed host animals. Here mouse EBCs were transplanted to the brain of immunocompetent rats, and the use of immunosuppressors such as cyclosporine and tacrolimus was avoided. This latter condition was taken because we noted that EBC growth and neurogenesis is reduced in the presence of these immunosuppressors (unpublished data), an effect that appears to be related to their antiangiogenic activity [28,29]. Although active immune response could affect grafting, this did not appear to be evident up to 15 dpt in the intact SNpc [15]. At 15 dpt, although DA neuroblasts were not detected, many neuroblasts derived from transplanted EBCs remained (Fig. 3D). Therefore, it is unlikely that a specific immune rejection is the cause of lack of EBC-derived DA neurons and, rather factors required for the establishment of committed DA NPC are missing in the SNpc, as mentioned previously.

Transplantation of undifferentiated NPCs for cell replacement therapies may favor their integration into specific neuronal circuits. Although the SNpc holds a strong neurogenic environment that, as shown here, was retained after 6-OHDA lesion, this was not sufficient to direct DA neuronal differentiation. Lmx1a and the 6-OHDA lesion contributed to promote the early DA specification stage of EBCs, but according to the observations presented, additional factors were required to reach terminal differentiation. Optimization of in vivo DA neuronal differentiation from non-neuralized EBCs will require the addition of intrinsic factors (eg, Foxa2) and/or extrinsic factors (eg, Shh and Fgf8), a protocol that needs to ponder also the tumorigenic potential of remaining undifferentiated EBCs.

Abstract

Objectives

To study the differences in the levels of nitrogen metabolites, such as ammonia and nitric oxide and the correlations existing among them in both red blood cells (RBCs) and serum, as well as the possible differences by gender in healthy subjects and patients with type 2 Diabetes Mellitus (DM).

Design and methods

This cross-sectional study included 80 patients diagnosed with type 2 DM (40 female and 40 male patients) and their corresponding controls paired by gender (40 female and 40 male). We separated serum and RBC and determined metabolites mainly through colorimetric and spectrophotometric assays. We evaluated changes in the levels of the main catabolic by-products of blood nitrogen metabolism, nitric oxide (NO), and malondialdehyde (MDA).

Results

Healthy female and male controls showed a differential distribution of blood metabolites involved in NO metabolism and arginine metabolism for the ornithine and urea formation. Patients with DM had increased ammonia, citrulline, urea, uric acid, and ornithine, mainly in the RBCs, whereas the level of arginine was significantly lower in men with type 2 DM. These findings were associated with hyperglycemia, glycosylated hemoglobin (Hb A_{1C}), and levels of RBC's MDA. Furthermore, most of the DM-induced alterations in nitrogen-related metabolites appear to be associated with a difference in the RBC capacity for the

analysis, decision to publish, or preparation of the manuscript.

Competing interests: The authors have declared that no competing interests exist.

release of these metabolites, thereby causing an abrogation of the gender-related differential management of nitrogen metabolites in healthy subjects.

Conclusions

We found evidence of a putative role of RBC as an extra-hepatic mechanism for controlling serum levels of nitrogen-related metabolites, which differs according to gender in healthy subjects. Type 2 DM promotes higher ammonia, citrulline, and MDA blood levels, which culminate in a loss of the differential management of nitrogen-related metabolites seen in healthy women and men.

Introduction

Diabetes mellitus (DM) is a worldwide disease frequently associated with a high risk of atherosclerosis and renal, nervous system, and ocular damage [1]. Reactive oxygen species (ROS) have been implicated in the pathogenesis of DM [2], as well as in its complications [3,4]. Patients with type 2 DM frequently have vascular endothelium dysfunction, which is related to hypercholesterolemia, and nitric oxide (NO) deficiency, a major factor that contributes to endothelial dysfunction [5].

Another source of possible complications in DM patients could be derived from an altered nitrogen metabolism, even in the absence of evident liver disease and/or nephropathy. Certainly, experimentally induced diabetic rats have lower gut amino acids utilization, which can diminish alanine and ammonia release into the portal circulation [6]. Therefore, this type of experiments could provide a background for the understanding of why DM patients with hepatic encephalopathy have a lower liver glucose absorption and utilization [7]. Indeed, it has been reported that DM patients have severe hepatic encephalopathy at early stages of chronic liver disease, when compared with non-diabetic patients with hepatic dysfunction [8].

The red blood cells (RBC) play an important role in vascular function, delivering oxygen, minimizing NO scavenging, and further delivering NO bioactivity in hypoxia, through the compartmentalization of hemoglobin (Hb); therefore, RBC promote hemostasis through a well-regulated delivery of oxygen [9]. In fact, reduced levels of NO derived from arginine has been implicated in the vascular dysfunction of diabetic patients. This pathological process is characterized by an impaired endothelial cell production of the vasodilator and an anti-platelet adhesion factor, and/or a decreased NO bioavailability [10].

An increased activity and expression of arginase I is associated with diabetes-induced increase in oxidative stress. It also initiates the feed-forward cycle of diminished NO levels and oxidative stress [11]. Moreover, citrulline could promote NO production and endothelial function and improve peripheral insulin sensitivity [12], improving organ perfusion and the endothelial metabolism, which might involve an antioxidant property [13].

In this context, we have found that type 2 DM alters the metabolite distribution between serum and RBC. Results demonstrate that RBC regulate serum levels of nitrogen-related metabolites, not only by their transport but also by metabolizing amino acids such as arginine, probably through several enzyme-mediated metabolic pathways [14]. In fact, this extra-hepatic nitrogen metabolism, mediated by blood cells, could have a role in the specific physiopathology of type 2 DM. These findings indeed agree with proteomic profiling studies which showed that the mature human RBC have a lot of proteins related to metabolic function, which reveals

an unexpected level of complexity in the functional capabilities of human RBC metabolism [15].

Moreover, it has been reported that there are differences in the nitrogen metabolism in human subjects according to gender. Changes in vascular NO activity may contribute to changes in cardiovascular risk associated mainly with males, probably related to the α-adrenoceptor responsiveness, among other mechanisms [16]. The renal vasculature of men becomes more dependent on NO with age compared with that of women, suggesting that renal diseases progress could be related to gender [17]. Despite the fact that there is little information regarding the management of ammonia according to gender, it is noteworthy that hepatic myelopathy and blood ammonia elevation were found mainly among middle-aged Japanese men with chronic liver disease [18].

Based on the evidence above, we argue that patients with type 2 DM have an aggravated dysregulation of nitrogen metabolism and, therefore, the disturbed intermediary metabolism has more detrimental consequences in several organs. This altered nitrogen metabolism is influenced by gender and oxidant status. Consequently, this study improves our understanding of the relation between the disturbances in several metabolites reflecting nitrogen and nitric oxide (NO) metabolism, and abnormal levels of blood ammonia in the absence of evident nephropathy and liver disease.

Subjects and methods

Study population

We recruited patients with type 2 DM at different stages of the disease, from the outpatient clinics, mostly directly depending on the Ministry of Public Health (SSA, México), mainly from the Xoco General Hospital. The study group consisted of 40 female and 40 male patients with type 2 (non-insulin-dependent) DM. The patients were selected based upon the following criteria: All patients were not active alcoholics, non-smokers, and were on regular treatment for diabetes (with hypoglycemic agents). Patients were apparently free from any important secondary complications such as nephropathy or liver dysfunction. We studied in parallel a control group of healthy 40 female and 40 male who were non-smokers and non-alcoholics. Following a 12 h overnight fast, all individuals were subjected to blood sampling and all patients omitted their morning medication. This study was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association and approved by the Ethics Committee of the General Hospital of Mexico (Ministry of Public Health), after written informed consent.

Clinical tests

We measured in serum, through standardized procedures with kits from SPINREACT (Spain), the following metabolites: glucose, cholesterol, triacylglycerols (TG), and the activities of "marker enzymes" of liver damage, namely alanine (ALT-GPT) and aspartate (AST-GOT) aminotransferases. Insulin level was measured with a kit from Ray Bio (USA) and Hb A_{1C} was measured with a kit from BioSys-Kovalent (Brasil) (Table 1).

Biochemical measurements

Whole blood was poured directly into ice-cold perchloric acid (8% w/v, final concentration). After centrifugation, we obtained acid-extracts of serum and RBC. We determined, using enzymatic methods, levels of ammonia [19] and free urea [20] in the neutralized perchloric extracts and assessed the uric acid using a commercial kit (SpinReact, Spain). In addition, we

Table 1. Clinical parameters in control subjects and in female and male patients with type 2 DM.

Subjects	Healthy volunteers		Patients with type 2 DM	
Parameter	Females	Males	Females	Males
BMI	25.6	24.8	27.1	26.5
Glucose (mg %)	88	94	149	142
Insulin (μUnits/ml)	6.4	4.6	8.34	10.1
HOMA-IR	1.7	1.5	3.6	3.5
Hb A_{1C} (%)	4.6	5.0	8.8	8.4
Hb A_{1C} (mmols/mol)	27	29	73	70
TG (mg/dL)	141	148	185	175
Cholesterol (mg/dL)	150	138	185	179
ALT-GPT (IU/L)	18	21	22	23
AST-GOT (IU/L)	19	17	22	25

The results are expressed as medians. Abbreviations: BMI, body mass index; TG, triacylglycerols; ALT, alanine aminotransferase, and AST, aspartate aminotransferase. Most of the distributions were best described by skewed distributions, thus the mean is no longer a good measure of central tendency. Consequently, we relied on the median to compare between sets of data (S1 and S2 Files).

https://doi.org/10.1371/journal.pone.0219481.t001

measured arginine, citrulline, ornithine, nitrites, and malondialdehyde (MDA), with the methods previously described in detail [14]. (dx.doi.org/10.17504/protocols.io.q5qdy5w).

Preparation of RBC for metabolites release assays

Another set of anti-coagulated blood samples was obtained from healthy subjects (40 female and 40 male) and diabetic patients (40 female and 40 male). The serum was rapidly separated and removed after centrifugation at 900 g and 4˚C for 5 min, the buffy coat was removed, and the erythrocyte pellet was washed four times with two volumes of cold (4˚C) buffered solution of 20 mmol/L HEPES (pH = 7.42) and containing 0.9% NaCl. Thereafter, RBC were gently suspended to a 33% hematocrit (Hct) with the same buffered solution and stored at 4˚C overnight, completing 24 h after washing. We obtained acid extracts from aliquots taken from all the washes, the overnight stored solution, and the remaining total RBC pellet. Then, we measured all the metabolites described above from them.

Arginase activity in RBC

The activity of arginase (EC 3.5.3.1) was determined in RBC lysates with 20 mmol/L arginine at pH = 9.5, essentially as described by Colombo and Konarska [21]. The results are expressed as nmol of ornithine • min^{-1} • mg^{-1} of Hb.

Calculations and statistical analysis

We calculated the concentration of serum and RBC metabolites as μmol • ml^{-1} or nmol • ml^{-1}, and the results are expressed as the mean ± SD for levels of metabolites showed. **Statistical analysis**. We have a total of 84 determinations according to metabolite, blood compartment, group, and gender. Each of these data sets has 40 values. We took several blood samples for each patient and each person in the control group, and we obtained determinations from clusters of samples (pooled samples for each individual). Consequently, all results and conclusions drawn out from the analysis should consider that results correspond to the clusters and not to individual patient's data. All data sets are available at the Data sets section of the open science

INFORME DE LABORES 2019

framework project (see https://osf.io/a6cd3/?view_only=90dfd426c06648f5bbb96470c689d106).

The statistical analysis described in this section was performed in the Python 2.7 language using the numpy and scipy libraries (see Statistical analysis code in open science framework project: https://osf.io/a6cd3/?view_only=90dfd426c06648f5bbb96470c689d106). We computed the following descriptive statistics for each set of data: mean, standard deviation, skewness, and medians (**S1 File**). To study differences according to gender we focused on comparing medians since most of the data is best described by skewed distributions and are not normally distributed. In this situation, medians are a better measure of central tendency than means.

Furthermore, to analyze statistical differences according to gender, we first fitted the data to different distributions of continuous variables using maximum likelihood estimation and then obtained estimators for shape, location, and scale parameters for the distributions. We fitted the data to the following distributions: beta, exponential, exponential-weibull, exponential-power law, Gilbrat, logistic, lognormal, normal, Pareto, power law, weibull minimum, and weibull maximum. Then with the maximum likelihood estimators (MLEs), we performed the Kolmogorov-Smirnov (KS) goodness of fit test to obtain the distribution that best described the data for each determination. We chose the best approximation as the distribution which had the smallest D-statistic among all distributions. The KS test for goodness of fit performs a test of the distribution of an observed random variable against a given distribution under the null hypothesis that the two distributions are identical. We report D-statistics and p-values of the KS tests, and MLEs for each determination (**S2 File**).

Finally, we computed Spearman correlation coefficients and their p-values. We use the Spearman correlation because it assesses monotonic relations and it does not assume a linear relation between two sets of data. With the Spearman correlations, we constructed a correlation matrix for all 84 determinations (see **S3 File**). Each row and each column corresponds to a data set of one determination. The cells of the matrix are the Spearman correlation coefficient between two sets of data and the p-value. The Spearman correlation coefficient can take values between -1 and 1, where 0 means no correlation.

Results

Clinical parameters

Most of the distributions were best described by skewed distributions, thus the mean is no longer a good measure of central tendency. Consequently, we relied on the median to compare between sets of data. The medians obtained for the values of the distributions for some clinical parameters (**S1 File**, **Table 1**). The medians for blood glucose, insulin, HbA_{1C} and HOMA-IR, obtained for the control subjects are within the established "normal ranges". In fact, insulin was lower in men, when compared to female healthy subjects. In the case of DM type 2 patients we observed a pronounced post fasting hyperglycemia (> 100 mg/dl), increased levels of Hb A_{1C} (>7%), and hyperinsulinemia (>8 μU/ml). These values are those expected for the two groups under study.

We performed the statistical analysis for each of these sets of values and compared the results. When comparing results for glucose between genders in the control subjects, we found that the best approximation shows different distributions (see **S2 File**, **Table 1**). The Spearman correlation coefficient was weak **S3 File**, **Table 1**).

In the case of patients with type 2 DM, the best approximation for glucose showed the same distribution in both genders, and interestingly, the same as in control men (logistic; **S2 File**, **Table 1**). Nevertheless, the Spearman correlation coefficient between genders for glucose in

diabetic patients indicate that the correlation between male and female is low (0.1581; p-value 0.3296; S3 File, Table 1). Indeed, the comparison between Spearman correlation coefficient of glucose levels in control subjects and in diabetic patients, strongly suggest that together with the difference in glucose management between genders, there is a significant difference between the control subjects and the diabetic patients.

When we compared the values for insulin in the control groups of men and women, the Spearman correlation coefficient suggested a low weak negative correlation according to gender (-0.219; p- value 0.1742) (S3 File, Table 1). In the case of DM type 2 patients, the distributions of insulin were also different according to gender; these distributions were as well different compared to those observed for glucose in the same group. When comparing the Spearman correlation coefficient for insulin in the same gender, between control subjects and diabetics, we found that for both men and women, there is a null correlation, but in the case of women, the distribution is in the opposite direction (S3 File, Table 1). These differences may indicate that the mechanisms involved are connected to other systems that work differently between genders.

With respect to triglycerides, the best approximation for men and women, both for control subjects and for diabetic patients, shows different distributions (see S2 File, Table 1), but the Spearman correlation coefficients (S3 File, Table 1), indicate a low correlation between genders. These differences in distributions suggest differences in the production and regulation of triglyceride synthesis between genders and also between both study groups. As to cholesterol, the best approximation of values in both genders of control subjects and in diabetic men, showed the same distribution (see S2 File, Table 1). Here, the Spearman correlation coefficient indicated a low correlation in the distribution of cholesterol between women and men in control subjects (S3 File, Table 1). The distribution in diabetic women was different and the Spearman correlation coefficient between genders of diabetic patients was close to zero, indicating a null correlation (See S3 File, Table 1).

When comparing the Spearman correlation coefficient for cholesterol in the same gender, between control subjects and diabetic patients, we found that, for both men and women, there is a low correlation between the groups studied (S3 File, Table 1). In the case of women, the distribution is in the opposite direction compared with men, in a manner similar to the distribution of insulin, which suggests important differences in the interconnections between genders.

Results of the statistical analysis of the data obtained for the transaminases enzymes ALT and AST indicated that best approximation for both determinations was different between men and women in control subjects as well as in DM type 2 patients (see S2 File, Table 1). In control subjects the Spearman correlation coefficient suggests a weak and positive correlation according to gender for ALT and AST (S3 File, Table 1), whereas in the case of DM type 2 patients, the relation between genders is null for ALT and weak negative for AST. These results suggest a change in the behavior of activities of both enzymes as a result of pathology. The analysis of the results of the clinical parameters in DM type 2 patients could indicate differences in their production or utilization according to gender. In general, results maintain the differences between genders and also show different effects in the handling of glucose and cholesterol between control subjects and DM type 2 patients.

Blood levels of ammonia, uric acid and urea in patients with type 2 DM

Ammonia, uric acid, and urea are products of the metabolism of proteins (nitrogen metabolism). The median values obtained for our control groups are those shown in the Fig 1. In the control groups, the "free" ammonia clearly predominated in the RBC over serum. Statistically,

The results are expressed as the medians for levels of ammonia, urea, and uric acid, in healthy control female (n = 40) and male volunteers (n = 40), as well as in female patients with type 2 DM (n = 40) and male patients with type 2 DM (n = 40). Symbols for experimental groups at the top. Descriptive statistics: Most of the distributions were best described by skewed distributions, thus the mean is no longer a good measure of central tendency. Consequently, we relied on the median to compare between sets of data.

https://doi.org/10.1371/journal.pone.0219481.g001

we found that the ammonia values for the control subjects are best described by different distributions according to gender and blood compartment (see S2 File, Fig 1). The Spearman correlation coefficients for RBC-ammonia of the control subjects indicated a null correlation between genders (S3 File, Fig 1).

We found an accumulation of ammonia in RBC as well as a drastic enhancement of serum ammonia, in female and male patients with type 2 DM. Nevertheless, the RBC/serum ratio for ammonia was similar in the four groups (Fig 1A). The Spearman correlation coefficients indicate a low positive correlation between diabetic female and male ammonia levels in RBC (S3 File, Fig 1). These results give evidence in support of the differential regulation of ammonia according to gender.

The blood urea levels, in all subjects were within normal values (< 3.33 μmol• ml^{-1}). Urea predominated in the RBC fraction in a similar way to the ammonia levels. We noted that serum urea was lower in the male control group than the female control group, which led to an increased RBC/serum ratio of urea in the male control group (Fig 1B). The data obtained for the blood urea levels in the control groups showed different distributions depending on genders and blood compartment (S2 File, Fig 1). Here, we found a null correlation in RBC and a low positive correlation in serum levels (see S3 File, Fig 1), suggesting gender differences in blood urea levels in control subjects (Fig 1B).

The type 2DM patients had a drastic increase of urea in both blood compartments except for serum in women, also indicating clear gender differences for blood urea levels. Women patients had a significantly higher RBC/serum ratio for urea than the female controls, while DM male patients showed an opposite behavior (Fig 1B). These results show that in diabetic patients, RBCs accumulate both ammonia and urea, possibly to keep these metabolites in serum within normal levels, without gender differences. The statistical analysis pointed out of the data obtained for the urea in the DM type 2 patients (see S2 File, Fig 1). The Spearman correlation coefficient indicates a positive weak correlation between genders for urea levels in RBC and serum (see S3 File, Fig 1). These results, together with the above, provide strong evidence in favor of the differences in metabolic regulation according to gender.

The type 2 DM patients showed significantly lower serum levels for uric acid when compared to their respective controls, without modifying those in the RBC fraction. This resulted in higher RBC/serum ratios of uric acid in both genders with type 2 DM (Fig 1C). The statistical analysis for the uric acid determinations shows differences between genders. Nevertheless, uric acid in serum of control and diabetic males, and in RBC and serum of diabetic females, show the same distribution (see S2 File, Fig 1). The Spearman correlation coefficients indicate a positive low correlation between RBC values of control female and males, but a strong positive correlation between the control male and female serum values for uric acid (0.6439, p-value 0.0007). For DM type 2 patients the correlation was significant and positive in RBC (0.6247, p-value 0.0001) and positive but weak in serum (0.2407, p-value 0.1344) (S3 File, Fig 1).

We also measured arginase activity in RBC from control subjects and patients with type 2 DM. We did not find differences by gender in control subjects (2.17 vs. 2.62 nmol • min^{-1} • mg^{-1} of Hb, in women and men, respectively). On the contrary, in the DM type 2 patients indeed increased this enzyme activity. The female patients showed an activity of 3.84 nmol •

min-1 • mg-1 of Hb, which was even higher in diabetic men (6.06 nmol • min-1 • mg-1 of Hb). These significant increases of arginase activity in RBC from patients with type 2 DM could be explain the increased RBC urea amount in these patients (Fig 1B).

Upon comparing the Spearman correlation coefficients between arginase in RBC and urea in serum, we observed that for both genders in DM type 2 patients, the Spearman correlation coefficients indicate a moderate correlation between arginase in RBC and serum urea, although in inverse senses (S3 File, Fig 1).

Metabolites involved in the generation of NO in patients with type 2 DM

The arginine metabolism involving nitric oxide synthetase (NOS) results in the production of citrulline and NO [5]. We have shown that the human RBC in healthy subjects is capable to metabolize arginine into nitrites, citrulline, ornithine, and urea [14], we analyzed these metabolites in DM type 2 patients and compared the results. In the control group we observed that blood arginine was mostly present in RBC, compared to serum (Table 2). The statistical analysis of RBC-arginine values from control subjects showed that the behavior for both genders was best described by the same distribution (S2 File, Table 2), giving an evidence of a positive and significant relation between the values according to gender. Serum arginine levels in the same subjects were around 0.2 mmol • L^{-1} for both genders, and the Spearman correlation coefficient showed a positive and weak correlation (S3 File, Table 2), indicating differences according to gender and blood compartment.

We found an arginine RBC/serum ratio of 4.3 for control male subjects and 2.9 for control female subjects (Table 2). In male patients with type 2 DM, there were not significant differences in serum arginine levels compared to RBC (Table 2). On the opposite, women with DM had higher levels of RBC-arginine than male patients, with congruently higher RBC/serum ratio for this amino acid, when compared to the control group (Table 2).

The medians of the nitrites determinations show that levels in RBC in control subjects and diabetic patients were higher than in serum. We also found that nitrites determinations in RBC and serum of control male subjects were higher than those of control female. On the contrary in patients with DM type 2, the women showed an upper levels of RBC-nitrites (S1 File, Table 2). These results give evidence that type 2 DM reverted gender differences found for the nitrites blood distribution observed in the control groups (Table 2).

The statistical analysis of the nitrites determinations in control subjects shows that in the case of serum, the same distributions were obtained for control women and diabetic men. The distributions of the nitrites levels from RBC in control men and RBC and serum of diabetic women were also the same (S2 File, Table 2). There were positive weak and low correlations of values in RBC and in serum, respectively, between the both gender in control subjects. However, whereas that the Spearman correlation coefficients indicate a low correlation between levels of nitrites in RBC from female and male DM type 2 patients, (S3 File, Table 2), importantly a strong and positive correlation was obtained between levels of nitrites for diabetic men and women in serum (S3 File, Table 2). As previously found for other metabolites, the statistical distributions and the Spearman correlation coefficients indicate differences in nitrites levels according to gender and blood compartments.

Arginine is synthesized from citrulline by the sequential activities of the cytosolic enzymes argininosuccinate synthetase (ASS) and argininosuccinate lyase (ASL), and these proteins have already been identified in RBC [22]. While serum levels of ornithine showed no differences according to gender, the male control group showed higher RBC-ornithine than the control females (see S1 File, Table 2). Type 2 DM promoted higher ornithine content in RBC of female patients but not of men. This led to a significant increase the RBC/serum ratio for

INFORME DE LABORES 2019

Table 2. RBC and serum levels of nitrogen-related metabolites and their ratios in female and male patients with type 2 DM.

Subjects	Healthy volunteers		Patients with type 2 DM	
Parameter	Females	Males	Females	Males

RBC-Citrulline	0.179	0.151	0.364	0.311
RBC/serum ratio	0.77	0.62	0.60	0.54

The results are expressed as medians of the metabolites in μmol • ml^{-1}. Most of the distributions were best described by skewed distributions, thus the mean is no longer a good measure of central tendency. Consequently, we relied on the median to compare between sets of data (S1 and S2 Files).

https://doi.org/10.1371/journal.pone.0219481.t002

ornithine in the female patients, in contrast to the gender differences found in healthy subjects (Table 2).

On the contrary, blood citrulline was mainly found in serum, resulting in an RBC/serum ratio for citrulline below one. Here, control men presented a significantly lower level of RBC-citrulline than the healthy female group (Table 2). The onset of type 2 DM elicited an increase of citrulline in both blood compartments but maintained the RBC/serum ratios for this amino acid. Consequently, this pathology also annulled gender differences in the citrulline blood levels observed in control subjects (Table 2).

Relations between blood metabolites in serum and RBC in patients with type 2 DM

The aforementioned results allowed us to shed light on the possible metabolic paths followed in serum and RBC. The arginine/nitrites and citrulline/nitrites relations in serum were higher in healthy women compared to men (Table 3). However, the group of female patients with type 2 DM showed altered relations of these nitrogen compounds when compared to healthy women. The relations in serum of ammonia/urea, arginine/urea, and citrulline/ornithine were significantly higher, while that of arginine/ornithine did not change. On the contrary, the other relationships shown in Table 3 were found significantly lower in women with type 2 DM, when compared to the healthy female group. With respect to men, although the ammonia/urea was lower in men with type 2 DM, the other serum relationships among nitrogen compounds had the same pattern of behavior as that of type 2 DM women. However, the differences were even larger in men (Table 3).

The relations in RBC were significantly different according to the gender (Table 3). In this blood compartment, the relations arginine/ammonia, arginine/nitrites, and arginine/citrulline, were also higher in control men than those found in the healthy female group. On the contrary, the citrulline/nitrites as well as the citrulline/ornithine relations were lower in the male control group than in the healthy women (Table 3). These results, when related to the pattern of relationships in serum of control subjects, argue in favor of gender differences in the "management" of ammonia and nitrogen-related compound (Table 3). In addition, with the

Descriptive statistics. We computed the arithmetic mean, the variance, the skewness, and median for each determination. Most of the distributions were best described by skewed distributions, thus the mean is no longer a good measure of central tendency. Consequently, we relied on the median to compare between sets of data.

https://doi.org/10.1371/journal.pone.0219481.t003

exception of the relationships of ammonia/urea and arginine/ammonia, the onset of type 2 DM in male patients readily neutralized gender differences in the blood distribution of these metabolites, seen in the healthy volunteers (Table 3).

Release of ammonia, urea, and arginine from RBC of patients with type 2 DM after washing and storage

Gender differences in amino acid concentrations in serum have been recorded in normal healthy Japanese people [23]. Therefore, to make an effort to explain the gender differences in healthy subjects and patients with DM we measured the metabolite "release" from the RBC of both experimental groups. The RBC from control female and male subjects showed an efflux of ammonia of 38.2% and 44.5% of total RBC content, respectively, after blood cells washing and storage (Fig 2A). In this context, patients with DM released even more ammonia (56.9% and 47.6% in women and men, respectively), which resulted in having a similar amount of ammonia, when compared to healthy subjects (Fig 2A).

Interestingly, RBC from healthy subjects had an efflux of urea of 58.4% and 47.7% of total RBC content in women and men, respectively. The patients with type 2 DM released a quite similar amount of urea than healthy subjects (63.0% and 53.9% in women and men, respectively, of the total RBC content) (Fig 2B). The RBC content of arginine showed a very small release of 11.5% and 11.1% of total RBC content in control women and men, respectively (Fig 2C). RBC from the patients with DM almost doubled the release of arginine (19.4 and 20.8% of total RBC content in women and men, respectively), even though the remaining RBC levels for arginine (Fig 2C) were almost the same as those found in non-washed blood cells, mainly in control preparations (Table 2).

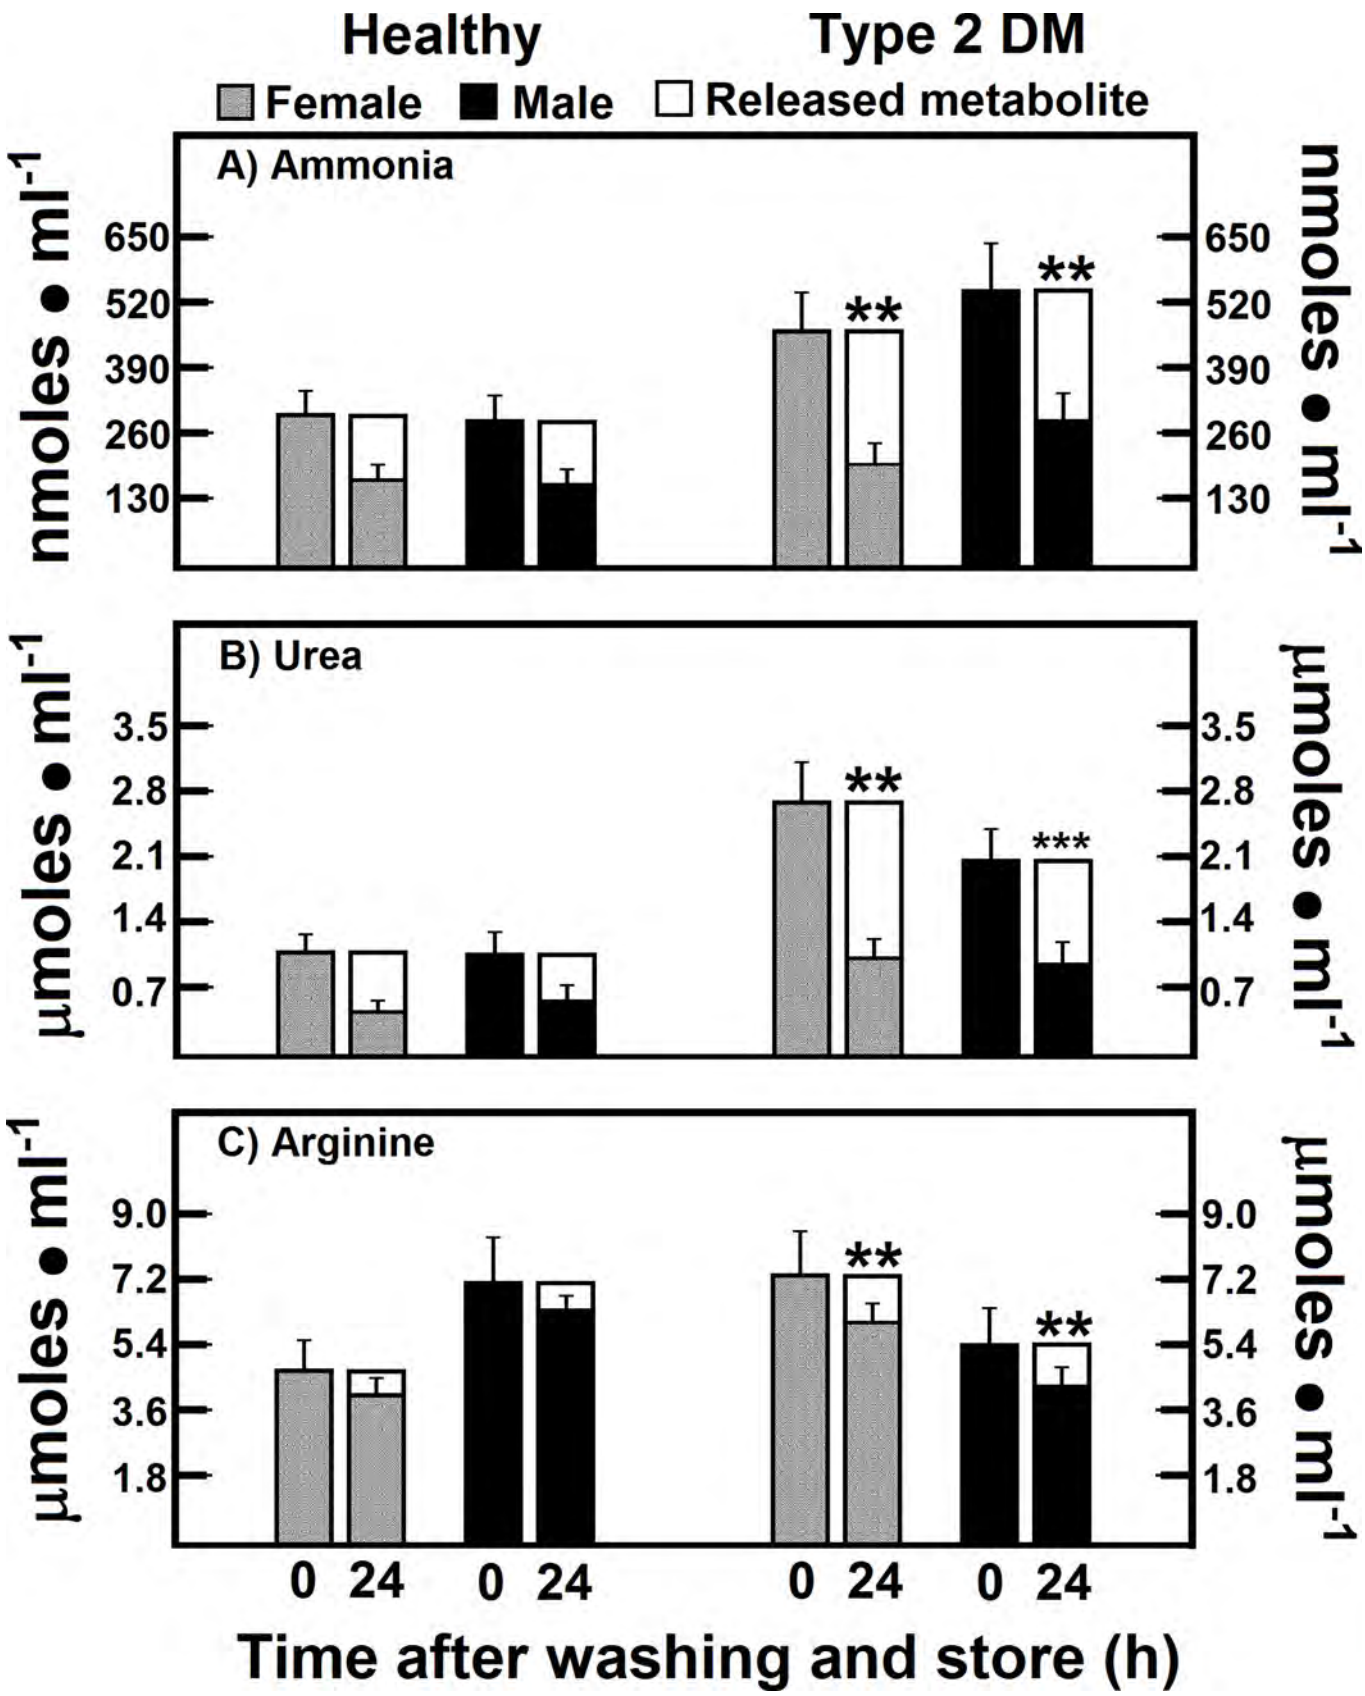

Fig 2. Release of ammonia, urea, and arginine from RBC of patients with type 2 DM after washing and storage. The results are expressed as the mean ± SD for levels of RBC ammonia, urea, and arginine, in healthy control female (n = 40) and male volunteers (n = 40), as well as in female (n = 40) and male DM type 2

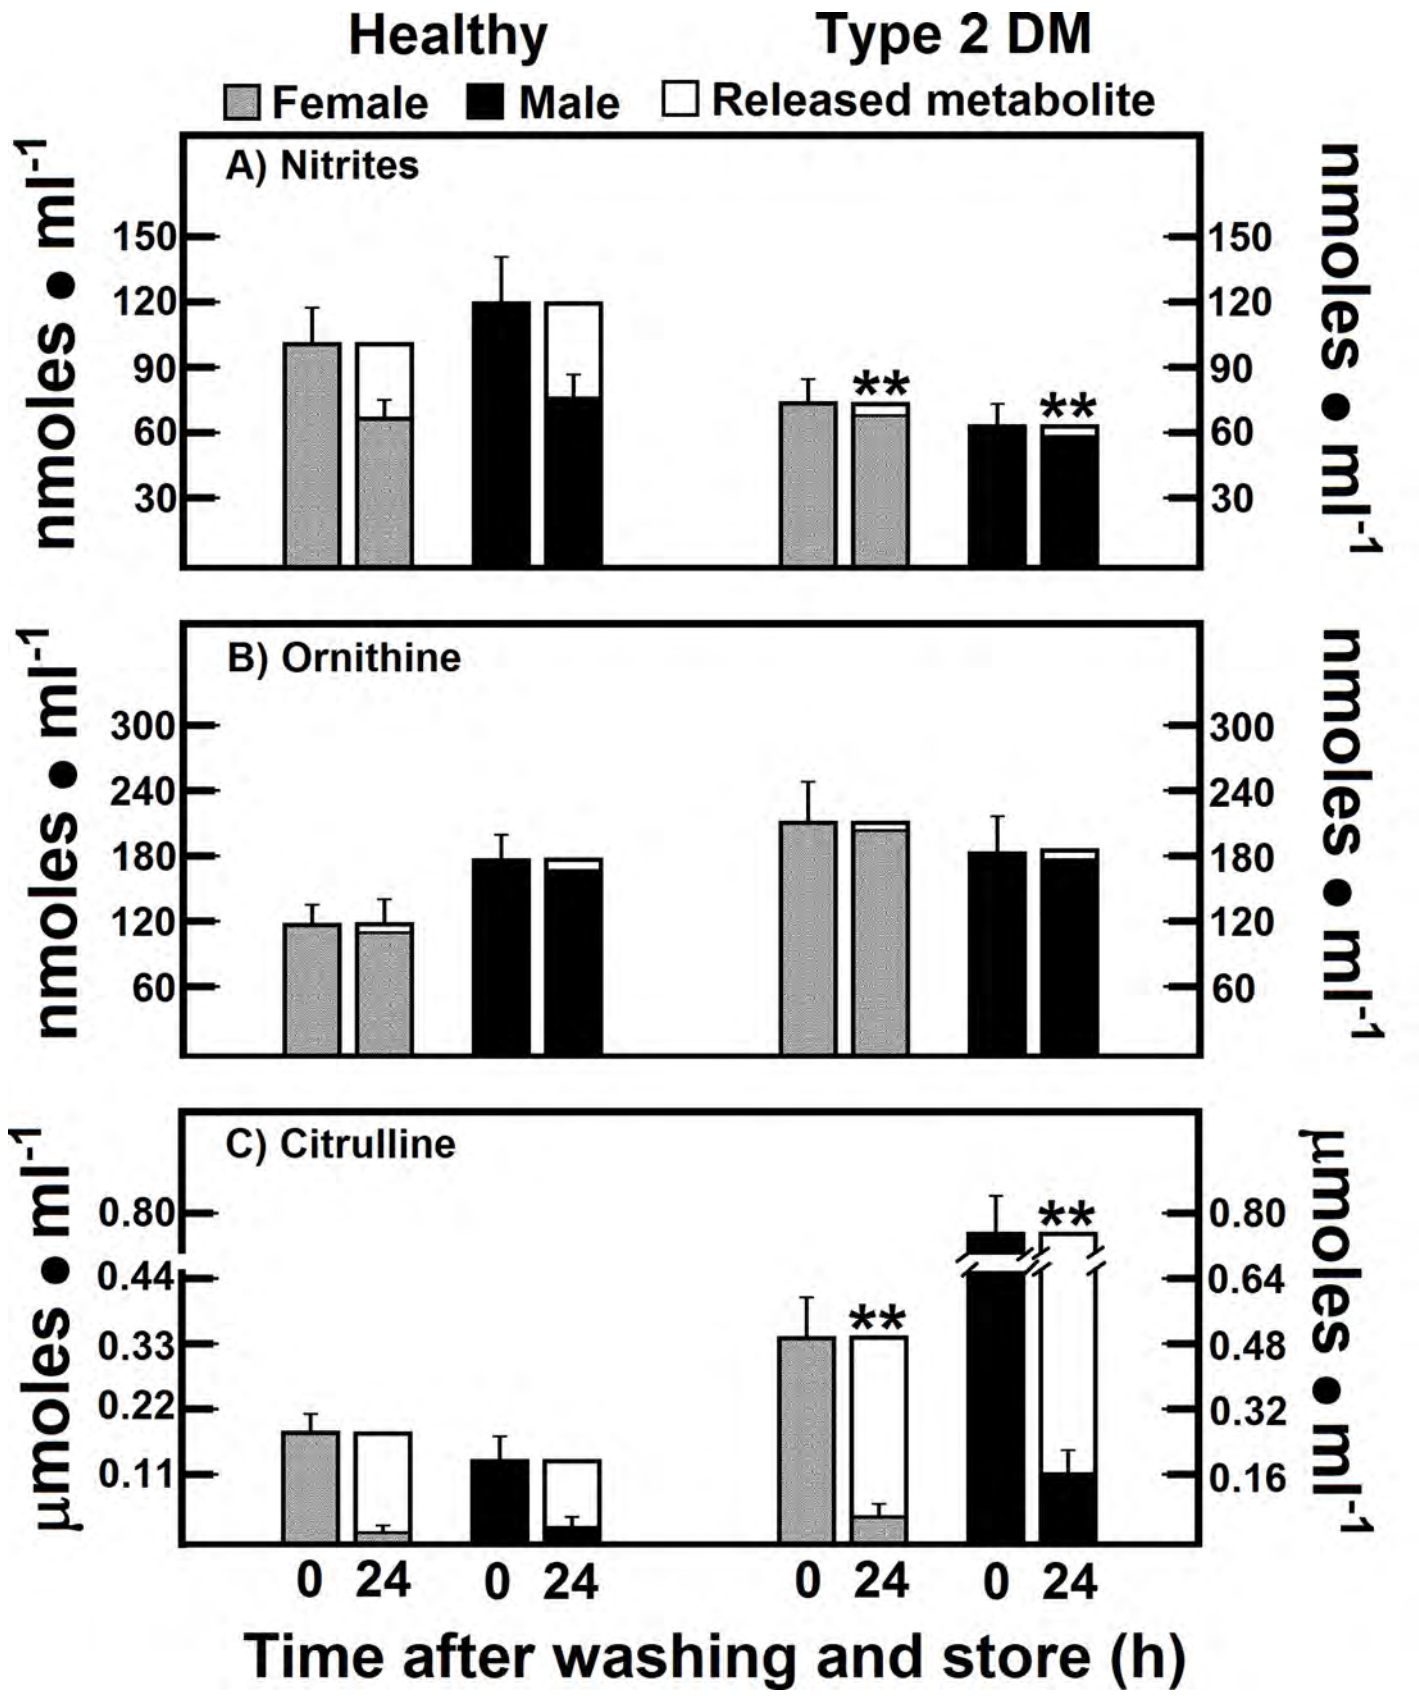
patients (n = 40), at time 0. Empty bars represent the release rate for each metabolite 24 h after washing and storage (time 24). Symbols for experimental groups at the top. Statistical significance: *$p < 0.01$ against the control female group, and **$p < 0.01$ vs. the corresponding gender control group.

https://doi.org/10.1371/journal.pone.0219481.g002

Release of nitrites, ornithine, and citrulline from RBC of patients with type 2 DM after washing and store

The RBC content of nitrites, which are NO oxidation products, also showed changes after washing and storing the blood cells (Fig 3A). The efflux of nitrites from RBC in controls after washing and storing was 34.3% and 37.9% of total RBC content in women and men, respectively. On the contrary, RBC in patients with type 2 DM showed a lower release of nitrites (less than 10% of total RBC content) in both experimental groups (Fig 3A), which contrasted with the high levels of serum nitrites found in both, women and men DM patients (Table 2).

The efflux of ornithine in the RBC from DM patients, was closely similar to that of control cells after washing and storage (Fig 3B). We conclude that RBC do not release ornithine, since the rate of release of this amino acid was lower than 6% (Fig 3B). Interestingly, the citrulline that differs very little chemically from ornithine was readily released after washing and storage (more than 90% of the initial value) in female or male control subjects (Fig 3C). RBC-citrulline in type 2 DM patients also showed a reliable efflux under our experimental conditions; however, this release was proportionally lower in type 2 DM patients. Nevertheless, we also observed a gender difference, as men with type 2 DM retained more citrulline in their RBC than women (Fig 3C). Indeed, present data confirm the existence of a net efflux of by-products of RBC arginine metabolism in RBC of control and patients with type 2 DM, determined by radio-labeled tracing as previously reported under these experimental conditions [14].



Correlation between levels of ammonia and MDA and their release from RBC in patients with type 2 DM

For this section, we used the Pearson correlation coefficient and the mean and standard deviations to report results. When we calculated the area under the curve (AUC) for the progressive release of this ammonia from RBC of female subjects (6.4 ± 1.9 nmol • h^{-1} • ml^{-1} of RBC), this value was not statistically different when compared to male volunteers (AUC = 5.2 ± 1.6 nmol • h^{-1} • ml^{-1} of RBC; Fig 4A and 4B). Female patients with type 2 DM showed a significant increase of RBC ammonia release (AUC = 9.9 ± 2.5 nmol • h^{-1} • ml^{-1} of RBC) when compared with healthy women (Fig 4A and 4B). Interestingly, we also found a larger liberation of ammonia by RBC from diabetic male patients (AUC = 10.5 ± 2.9 nmol • h^{-1} • ml^{-1} of RBC), which is twice that of found in normal male subjects.

In women with type 2 DM the released RBC amount of MDA, a byproduct of membrane's lipid peroxidation (AUC = 0.55 ± 0.15 nmol • h^{-1} • ml^{-1} of RBC) was not significantly different from that found in healthy women (AUC = 0.58 ± 0.17 nmol • h^{-1} • ml^{-1} of RBC; Fig 4C). On the contrary, male patients with type 2 DM released more MDA from their isolated RBC when compared with healthy men (AUC = 0.60 ± 0.16 vs. 0.86 ± 0.25 nmol • h^{-1} • ml^{-1} of RBC, in diabetic patients; Fig 4D).

Correlations among nitrogen metabolites with serum glucose in patients with type 2 DM

In an attempt to define the specificity of the changes in blood nitrogen metabolism as a consequence of the alterations found in patients with type 2 DM, we investigated correlations among the different metabolites included in our experiments.

INFORME DE LABORES 2019

Fig 3. Release of nitrites, ornithine, and citrulline from RBC of patients with type 2 DM after washing and storage. The results are expressed as the mean ± SD for levels of RBC nitrites, ornithine, and citrulline, in healthy control female (n = 40) and male volunteers (n = 40), as well as in females (n = 40) and males (n = 40) with type 2 DM at time 0. Empty bars represent the release rate for each metabolite 24 h after washing and store (Time 24). Symbols for experimental groups at the top. Statistical significance as pointed out in the Fig 2.

https://doi.org/10.1371/journal.pone.0219481.g003

There was a null Spearman correlation coefficient between RBC-arginine and glucose in male diabetics, indicating that these metabolites are not related in this blood compartment. When analyzing the correlations between arginine and glucose in serum we observed otherwise, the diabetic women have a null correlation coefficient (0.0146, p-value 0.9286), whereas

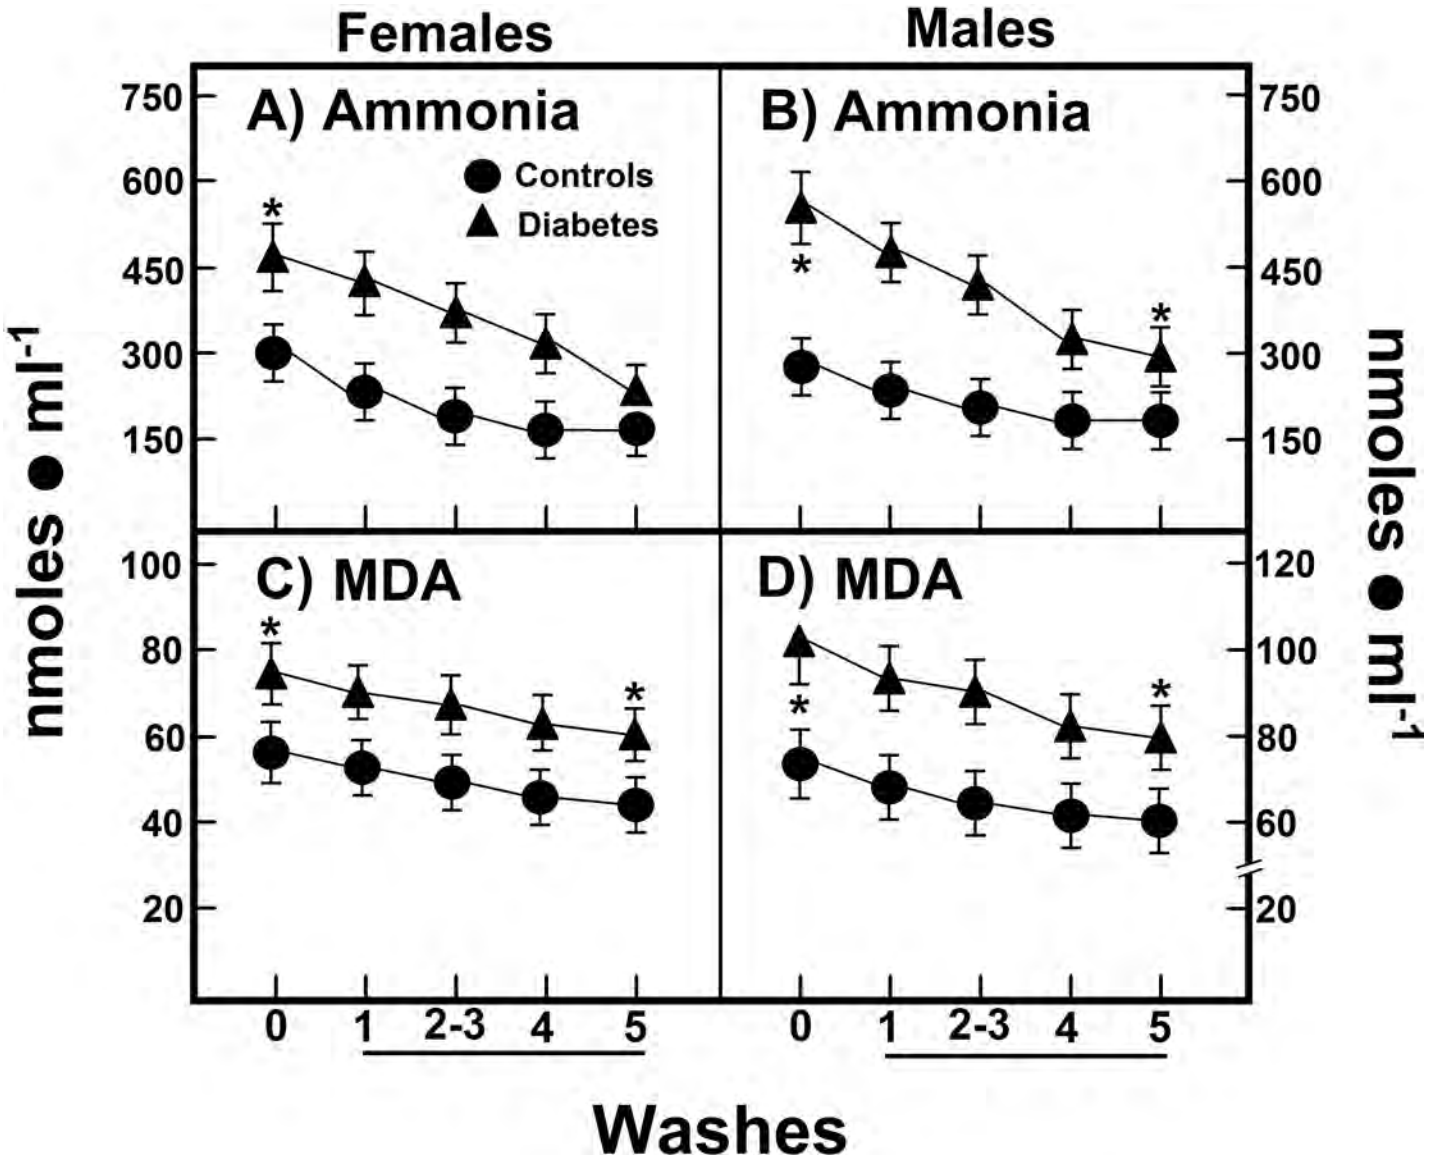

Fig 4. RBC amount and curves of release of ammonia and MDA from RBC of patients with type 2 DM after washing and storage. The results are expressed as the mean ± SD for levels of RBC ammonia (panels A and B), as well as of malondialdehyde (MDA; panels C and D), in healthy control female (n = 40) and male volunteers (n = 40), as well as in females (n = 40) and males (n = 40) with type 2 DM. The wash numbers 5 correspond to storage of RBC in the washing solution for 24 h. Symbols for experimental groups at the top of the figure, and statistical significance as indicated in the Fig 2.

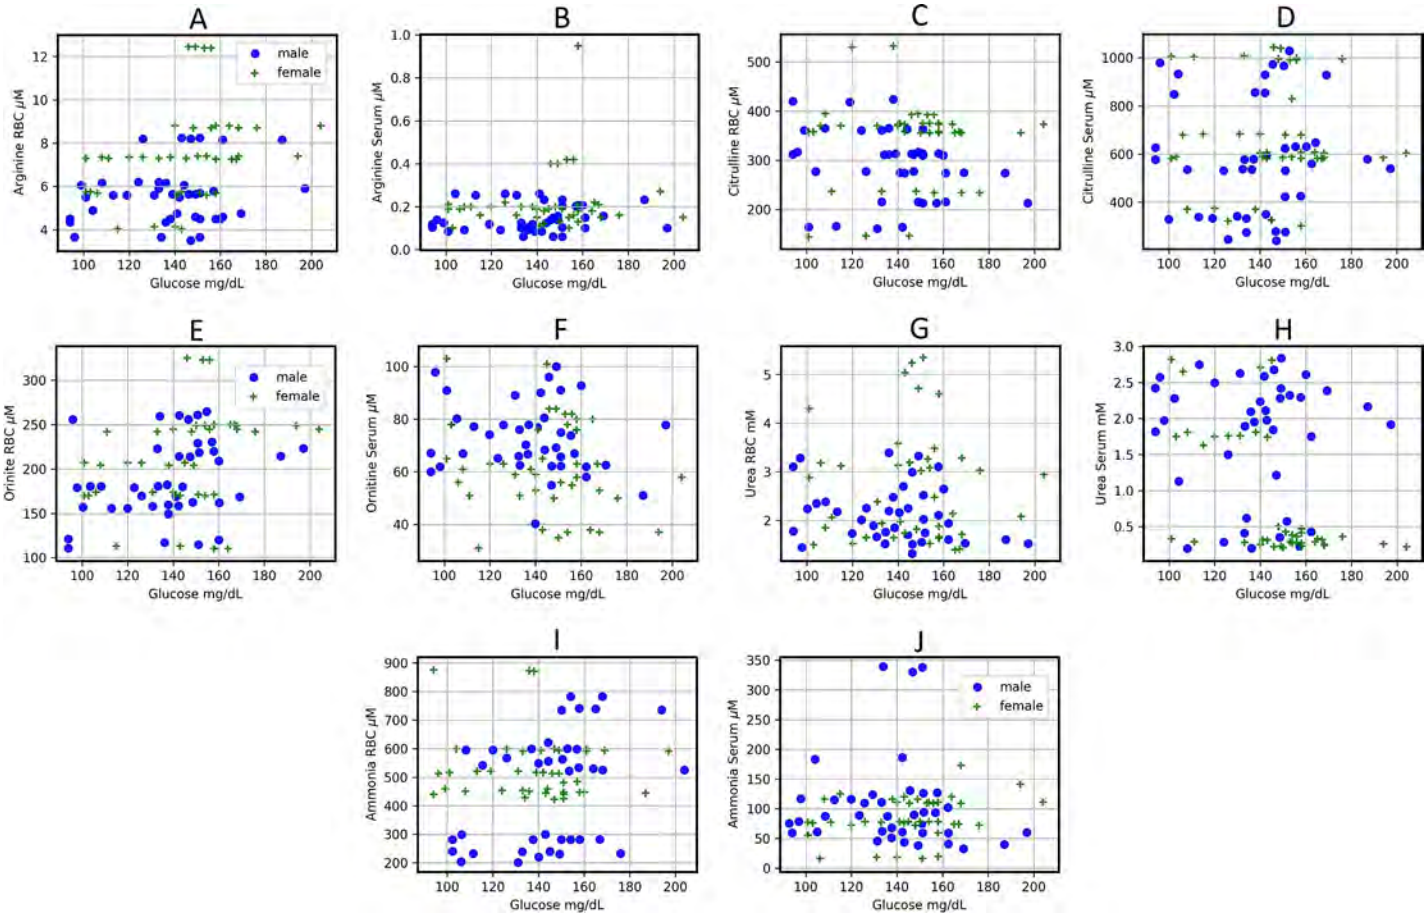

Fig 5. Scatter plots for different determinations according to gender (males are circles and females are stars) and RBC (A,C,E,G and I) or serum (B,D,F,H, and J) in DM type 2 patients. Scatter plots show the relation between two sets of data. This relation is summarized in the Spearman correlation coefficient (r) for each relation in each scatter plot:: A (rM = 0.08, rF = 0.39), B (rM = 0.14, rF = -0.014), C (rM = -0.301, rF = -0.086), D (rM = 0.113, rF = -0.044), E (rM = 0.299, rF = 0.425), F (rM = -0.133, rF = -0.163), G (rM = -0.227, rF = -0.04), H (rM = -0.013, rF = -0.559), I (rM = -0.132, rF = 0.322), and J (rM = -0.257, rF = 0.235). To see the p-values for each correlation, see the correlation matrix (S3 File).

https://doi.org/10.1371/journal.pone.0219481.g005

the diabetic men show a positive and low Spearman correlation coefficient (0.1420, p-value 0.3818; Fig 5B).

In diabetic males, the RBC-citrulline is inversely related with glucose, as evident from a weak negative Spearman correlation coefficient (Fig 5C). Also interestingly, serum levels of citrulline correlated directly with those of glucose in this patients with a low positive correlation for serum citrulline and glucose (Fig 5D). However, these correlations are lost in the case of diabetic women (Fig 5C and 5D).

The RBC levels of ornithine correlated weakly positive with serum glucose in both diabetic genders, although the Spearman correlation coefficient is higher in diabetic women (S3 File, Fig 5E). Conversely, Spearman correlation coefficient suggests a low negative relation between serum ornithine and glycaemia in both diabetic genders (S3 File, Fig 5F).

We found that when the glucose serum levels increase, the levels of urea decrease in RBC and serum in both genders. The Spearman correlation coefficient between urea in RBC and glucose in serum is low from diabetic men and females (Fig 5G). Interestingly, the comportment is opposite when we compared according to gender both compounds in serum (S3 File, Fig 5H). The RBC and serum levels of ammonia had a low and inverse correlation with serum

glucose in diabetic males (RBC: -0.132, p-value 0.1783; serum: -0.257, 0.1081. S3 File, Fig 5), while RBC and serum-ammonia had also a low but direct correlated with hyperglycemia in female patients with type 2 DM (S3 File, Fig 5I and 5J).

Correlations between serum nitrites with ammonia and urea in patients with type 2 DM

It has been speculated that facultative anaerobic bacteria might reduce nitrite to NO and possibly further to form ammonia [24]. Therefore, we searched relationships among the circulating amounts of nitrites, arginine, urea, and ammonia.

In relation to gender, the Spearman correlations coefficients show that the correlations between arginine and nitrites have an opposite behavior in control subjects, both in RBC and in serum. A weak negative correlation can be observed between arginine and nitrites in RBC of control men), whereas in RBC of control women the Spearman correlation coefficient indicates a weak positive correlation (S3 File). In the case of serum, correlation between nitrites and arginine showed an opposite pattern (S3 File, Fig 6A and 6B).

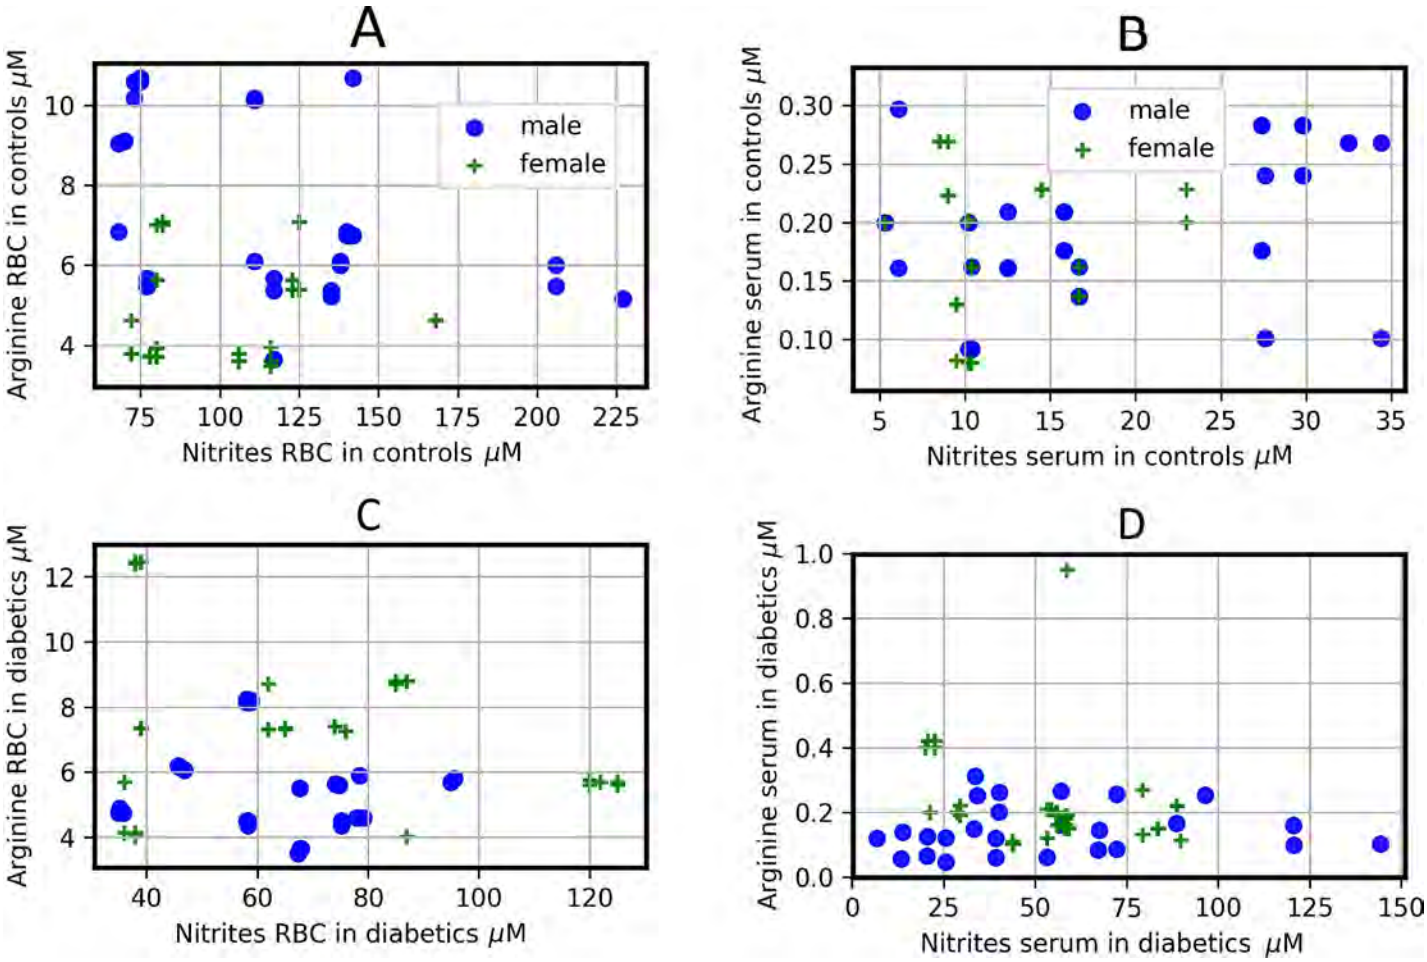

Fig 6. Scatter plots for different determinations for controls and diabetic patients according to gender (males are circles and females are stars) and RBC (left column) or serum (right column). Scatter plots show the relation between two sets of data; this relation is summarized in the Spearman correlation coefficients. These correlations are: A (rM = -0.439, rF = 0.269), B (rM = 0.276, rF = -0.22), C (rM = -0.2578, rF = -0.179), D (rM = 0.229, rF = -0.361). To see the p-values for each correlation, see the correlation matrix (S3 File).

https://doi.org/10.1371/journal.pone.0219481.g006

In serum of patients with DM type 2, the Spearman correlations coefficients between arginine and nitrites, showed a weak and inverse correlation pattern, while in RBC both correlations are weak and negative (S3 File, Fig 6C and 6D). If we compare the Spearman correlations coefficients between the levels of arginine and nitrites in both genders of control subjects with those of patients with type 2 DM, we observed that the pathology does not change the behavior of the correlations, neither in serum nor in RBC, with the exception of RBC of women, where the Spearman correlation coefficient goes from weak positive in control females to low negative in diabetics females (S3 File, Fig 6). Regarding the correlations between ammonia and nitrite, when comparing the Spearman correlations coefficients between RBC of control subjects and patients with type 2 DM of both genders, the pathology does not change the way in which they correlate (Fig 7A and 7C). Importantly, in serum the Spearman correlations coefficients between ammonia and nitrites change from null in control men to weak negative in diabetic men, whereas an inverse behavior is observed in women (Fig 7B and 7D). Control women have a weak positive correlation between ammonium and nitrites (S3 File, Fig 7), while DM type 2 women have a null correlation in this relation. Once again, the comparison of the Spearman correlations coefficients between genders shows us a different behavior in the correlations in both the groups studied.

Whereas we find null correlations between RBC or serum levels of nitrites and urea in control subjects (S3 File, Fig 7E and 7F), patients with DM type 2 exhibit different parameters. For instance, female patients had a low negative correlation between RBC-nitrites and those levels for urea (S3 File, Fig 7G), while in serum, the levels of nitrites and urea, both in male and in female patients with type 2 DM, showed weak correlation in these metabolites (Fig 7H). Therefore, results from **Figs 5, 6 and 7** strongly support the existence of a differential blood metabolism for nitrogen-related compounds by gender, which is largely disturbed by the presence of type 2 DM.

Discussion

The RBC are the most abundant cell in humans and their alterations are deeply involved in health and disease. Indeed, as a result of the metabolomic and proteomic analysis, it has been understood that they are very important in the physiology of the body; close to 2000 gene products have been reported [25]. Moreover, to our knowledge, this study provides the first documented evidence of a putative role of blood cells (mainly attributed to RBC) in the control of serum levels of diverse metabolites, such as those related to the nitrogen metabolism in humans, which is largely altered by pathologies such as type 2 DM. We highlight two main findings. Firstly, the distribution of these metabolites in human blood compartments (serum and RBC) is influenced by gender, probably affecting bi-directional transport through RBC membranes and its metabolism [14]. Secondly, onset of type 2 DM abrogates many of the gender-related differences found in healthy subjects.

The hyperglycemia and the increase in levels of HbA_{1C} found in patients with DM were closely associated with blood levels for either, ammonia or urea (Fig 5). These results suggested that abnormal levels of blood glucose might induce alterations in the nitrogen metabolism. The latter can be related to the fact that RBC may undergo suicidal death or eryptosis, which is characterized by cell shrinkage and cell membrane alterations triggered by oxidative stress [26]. Exposure of normal erythrocytes to high glucose concentrations *in vitro* intensified lipid peroxidation (LP) and the loss of RBC enzyme activities [27]. Moreover, high levels of HbA_{1c} are closely related to LP in RBC, which are also associated to a significant reduction in membrane Na+/K+-ATPase activity [28,29].

Type 2 DM is characterized by low-grade, chronic inflammation and an increased activity of IkB/NFkB seems to provide a molecular mechanism responsible for inflammation and

https://doi.org/10.1371/journal.pone.0219481.g007

insulin resistance in type 2 DM, associated with increased risk of cardiovascular diseases [30]. In endothelial cells, excess free fatty acids activate the pro-inflammatory IKKβ–NF-κB pathway causing cellular insulin resistance and impaired NO production [31]. In this scenario, structural and/or functional alterations of RBC could be playing a role in the endothelial dysfunction noticed in patients with type 2 DM.

Studies have suggested that when the liver capacity for removing ammonia is reduced, other organs interact to maintain ammonia levels [32]. Glutamine functions as a "trapper" for excess ammonia, through the reaction of glutamine synthetase, and this occurs in the skeletal muscle [33]. Indeed, blood patterns for these amino acids should be altered in patients with chronic liver damage [34]; but, what about the alterations in the nitrogen metabolism found in female and male patients in absence of liver failure?

The end-products of the nitrogen metabolism, ammonia and urea, were greatly elevated in blood in diabetic patients (**Fig 1**, **Table 2**). Urea drastically augmented in RBC, which could be accounted for by the blood cells capacity to uptake and transport these metabolites (**Fig 1**, **Table 2**). Despite the apparent high production of urea by the liver of DM patients, ammonia definitively increased. Increased serum ammonia and glutamic acid levels found in patients with type 2 DM could be associated with delayed gastrointestinal transit [35], as well as with the increased activity of monoamine oxidase DB [36]. Since the presence of high blood levels for ammonia was not related to liver dysfunction, this could indicate that other extra-hepatic cells, such as RBC, are participating in the control of nitrogen metabolism [25].

Ammonia toxicity may induce cell damage, as it occurs during neuro-degeneration in aging, and Alzheimer disease [37] and, in diabetic rats there was a marked increase in the Na +-dependent component of the L-glutamate transport, causing a higher intracellular concentration of glutamate [38]. Whether the same occurs within blood cells remains to be studied; however, our findings provide evidence that RBC from the patients with type 2 DM can transport potential toxic nitrogen-related molecules (ammonia, urea, glutamic acid), which constitutes an unexplored risk factor for further complications. In experimental models for DM, a differential susceptibility for the harmful effects of ammonia on female or male animals has been reported. A porta-caval shunt reduces growth and spontaneous motor activity in male but not in female rats [39].

On the other hand, an intra-portal load of L-glutamine in rat with experimentally-induced type 1 DM generates increased glucose output, accompanied by enhanced urea and ammonia production [40]. These might be providing a background to explain the enhanced blood levels for ammonia and urea found in our patients with type 2 DM (**Figs 1**, **2**, **4 and 5**). In this context, we have recently shown an association between oxidant stress and elevated levels of ammonia [41], where increased systemic free ammonia concentration was capable of mediating the deleterious effects of AZT on partial hepactectomy-Induced rat liver regeneration. Indeed, the AZT significantly increased blood levels of ammonia and of MDA; despite this nucleoside did not reduce the amount of urea in the whole blood, but rather did change its distribution in the blood compartments [41].

Hyperglycemia is associated with increasing levels of six amino acids (alanine, isoleucine, leucine, valine, phenylalanine, and tyrosine) and with decreasing levels of histidine and glutamine; these associations were explained by insulin sensitivity [42]. Plasma branched chain and

aromatic amino acids have been also associated with incident diabetes and underlying metabolic abnormalities [43], which could be a focus for identifying novel etiological mechanisms and treatment targets for DM.

An excess of ammonia can alter NO production; type 2 DM patients showed increased serum nitrites levels, as well as those of citrulline in both blood compartments, associated with a decreased blood arginine level, mainly observed in men with type 2 DM (**Table 2**). Interestingly, the existence of gender differences in the NO metabolism is currently known. Systemic NO production is higher in healthy premenopausal women than in men, paired by age, under ambulatory conditions. This variance could explain the differences in endothelial production of NO, and the differential vascular function observed in men and women [16,44]. Indeed, estrogens can play a role in modifying NO response in women. Estrogens can inhibit Ca^{2+} influx mediated by L-type Ca^{2+} channels, representing one way through which estrogen protects ischemic hearts [45].

The present study gives evidence that in healthy subjects exist significant gender differences in NO production and, for the first time, in arginine metabolism (**Tables 2 and 3, S2 and S3 Files**). The arginine/nitrites and arginine/citrulline ratios were bigger in RBC of healthy men than in women, suggesting a lower flow of arginine through putative nitric oxide synthase in men, and healthy men also seemed to use less arginine as substrate for arginase, i.e., the arginine/urea ratio (**Table 3**). These data agree with the aforementioned speculation that women seem to have a more active NO metabolism than men. Interestingly, serum arginine levels were maintained within a normal range in patients with DM; hence, the importance of maintaining normal serum arginine levels could be is related to its metabolic role as the ammonia detoxification product, and to production of L-citrulline and NO [5,46], improving RBC function and extending cell life span in old RBC [47]. So, it was noteworthy to find that onset of type 2 DM practically abrogates gender differences in nitrogen-related metabolites which are observed in controls (**S2 and S3 Files, Tables 2 and 3**).

We found significant relationships between serum nitrites levels with those of ammonia and urea, indicating the participation of NO metabolism in the management of blood ammonia and of urea (**Fig 6**). As to citrulline, what could cause its elevation in blood of patients with type 2 DM? Citrulline has beneficial effects such as the increased NO production and endothelial function through its conversion to arginine [48]. Therefore, it is attractive to speculate whether the massive outflow of citrulline from RBC is an attempt to reestablish NO metabolism, functioning as an antioxidant in RBC of type 2 DM patients.

Which mechanism is most probably involved in these unexpected results is left to be answered in future research. One possible explanation could be given by the role of RBC in handling molecules participating in the nitrogen metabolic pathways and the fact that these blood cells are altered by the occurrence of DM [14]. Indeed, we have shown that the RBC capacity for metabolizing arginine depends on the oxidant status and the lipid composition of RBC membranes, which are altered in patients with type 2 DM [49], and high glucose concentrations altered the content and distributions of three tubulin isotypes, reducing RBC deformability and osmotic resistance [50]. Moreover, the RBC abnormalities in the membrane lipid composition, associated with some perturbations, can significantly affect RBC receptor binding and enzyme activities, as it occurs in the diabetic retinopathy, where higher amounts of phosphatidyl-choline species have been found in RBC [51].

In conclusion, this study provides the first documented findings giving strong evidence of a putative role of RBC as an extra-hepatic mechanism for controlling serum levels of nitrogen-related metabolites, which differs according to gender in healthy subjects. Type 2 DM promotes a characteristic pattern of metabolic disturbances that culminates in a loss of the differential management of nitrogen-related metabolites seen in healthy women and men.

Therefore, it is not unlikely that these characteristic patterns of blood metabolites elicited by type 2 DM might be involved in the specific physiopathology of this disease, and changes in the oxidative status, i.e., increased lipid peroxidation in RBC membranes of diabetic patients, are playing a role in the metabolic alterations found in these blood cells.

S1 File. Descriptive statistics.
(XLS)

S2 File. Best fit distributions for all determinations. The table reports D-statistics and p-values of the KS goodness of fit test for each of the 84 data sets. The KS test for goodness of fit performs a test of the distribution of an observed random variable against a given distribution under the null hypothesis that the two distributions are identical. The table also reports the MLEs for shape, location and scale parameters obtained from the maximum likelihood estimation needed to perform the KS tests. We fitted the data to the following distributions: beta, exponential, exponential-Weibull, exponential-power law, Gilbrat, logistic, lognormal, normal, Pareto, power law, Weibull minimum, and Weibull maximum.

SAGE

ABSTRACT: Enhancers play a central role in the transcriptional regulation of metazoans. Almost a decade ago, the discovery of their pervasive transcription into noncoding RNAs, termed enhancer RNAs (eRNAs), opened a whole new field of study. The presence of eRNAs correlates with enhancer activity; however, whether they act as functional molecules remains controversial. Here we review direct experimental evidence supporting a functional role of eRNAs in transcription and provide a general pipeline that could help in the design of experimental approaches to investigate the function of eRNAs. We propose that induction of transcriptional activity at enhancers promotes an increase in its activity by an RNA-mediated titration of regulatory proteins that can impact different processes like chromatin accessibility or chromatin looping. In a few cases, transcripts originating from enhancers have acquired specific molecular functions to regulate gene expression. We speculate that these transcripts are either nonannotated long noncoding RNAs (lncRNAs) or are evolving toward functional lncRNAs. Further work will be needed to comprehend better the biological activity of these transcripts.

KEYWORDS: Enhancer, eRNAs, lncRNAs, chromatin loop, gene expression, chromatin

General Features and Dynamics of eRNAs

One of the most intriguing questions in biology is how cells achieve transcriptional regulation. In the case of multicellular organisms, development and response to external stimuli are complex processes that require fine regulation of gene expression. At the heart of metazoan transcriptional regulation are found the enhancers,[1] which are DNA elements bound by cofactors and transcription factors (TFs) that are able to increase the transcription levels of their target genes by direct stimulation of their promoters often through chromatin looping.[2] At the chromatin level, enhancers are characterized by prominent accessibility to DNase I and high levels of histone H3K4me1,[3] as well as high levels of histone H3K27ac when active.[4] An interesting discovery in the biology of enhancers came in 2010 when 2 groups independently found that enhancers were transcribed genome-wide into noncoding RNAs termed enhancer RNAs (eRNAs).[5,6] This finding raised the question of the potential role that eRNAs could play in the regulation of gene expression, as several long noncoding RNAs (lncRNAs) have been shown to be functional molecules.[7]

eRNAs have been identified in diverse organisms like *Caenorhabditis elegans, Drosophila melanogaster*, and mouse, and in human cell lines, which suggest that transcription at enhancers is of ancient origin and might have an important role in enhancer activity.[8–11] eRNAs have been described as usually bidirectional, on average separated by 180 base pairs and transcribed at equal levels into nonpoly(A), unspliced molecules.[9] Most eRNAs are transcribed at lower levels than mRNAs and other noncoding RNAs such as lncRNAs and are rapidly degraded by the exosome.[9,12] Interestingly, it has been observed that eRNAs can be subject to methylation.[13,14] Recent single-cell genome-wide data of nascent transcription challenges some of the typical characteristics of eRNAs as it was shown that enhancer transcription is unidirectional, and therefore within a cellular population, some cells transcribe the sense strand and others the antisense strand.[15] In the cases where both strands of eRNAs were detected in the same cell, single-molecule fluorescence in situ hybridization (FISH) experiments showed that colocalization of both RNA molecules was rare. Because typical RNA expression methodologies show an average for total cells, that would explain why eRNAs have been described as bidirectional. Importantly, eRNAs were expressed at similar levels compared with gene promoters in single cells and were detected in just a subset of cells, ie, displaying transcriptional bursting.[15] More single-cell measurements of nascent transcription in different conditions are needed to clarify the real nature of transcripts originating from enhancers.

Active enhancers are the main source of eRNAs, and the transcription of enhancers into eRNAs has been correlated with increased transcription of nearby genes,[5,9,16] suggesting that transcription, the eRNAs themselves, or both, might be important for enhancer activity. In support of this, time course experiments evaluating the response of cells to different stimuli have provided strong evidence of specific timing of transcription of enhancers into eRNAs.[10,16] For example, in mammalian cells, upon stimulation with growth factors and exposure to pathogens, the eRNAs from active enhancers are transcribed first, then mRNAs that code for TFs, and finally non-TFs mRNAs. This suggests that upon stimuli, a concerted transcriptional response is established during which responsive enhancers are transcribed into eRNAs first and then genes coding for TFs which could ultimately lead to genome-wide changes in

BOX 1. A toolbox to work with eRNAs.

Cap analysis gene expression (CAGE) and global nuclear run-on sequencing (GRO-seq)-based methods as well as other recently developed experimental strategies that target nascent unstable transcripts are the best approaches to start characterizing eRNAs.[9,19–22] The transcriptomic data can then be compared against ChIP-seq data for enhancer chromatin marks, as well as DNase I, and more recently, ATAC-seq data to annotate enhancers and in this way assign eRNAs to those genomic regions.

After identification of transcribed enhancers, the next desirable step is to assign enhancers to target genes. This can be done by assigning an enhancer to the closest gene; however, we find this undesirable and strongly suggest to use genome-wide 3C-based techniques like Hi-C,[23] Capture Hi-C,[24] ChIA-PET,[25] or HiChIP.[26] Alternative, expression has also been used to link enhancers with promoters,[9] and recent computational approaches have been developed to predict enhancer-promoter interactions.[27] Once enhancer-promoter relationships have been established, the next step is to characterize either both the enhancer and its eRNAs or just the function of the eRNAs in this case when the enhancer has already been tested for function. In the former scenario, genome editing tools such as CRISPR-Cas9 can be used to assess the importance of a given transcribed enhancer by direct deletion of the genomic sequence. Evaluation of the expression levels of its target gene by quantitative reverse transcription polymerase chain reaction (RT-qPCR) will inform on the transcriptional effect the enhancer has on that promoter while 3C or 4C-seq can inform on the contribution of that enhancer element on the topology of that locus.

To evaluate the functional contribution of eRNAs to enhancer activity and the regulation of the target promoter, several considerations should be taken. First, validate eRNAs presence by strand-specific RT-qPCR. If possible, perform a Northern blot analysis to identify large RNA molecules derived from the enhancer element. The data from CAGE, GRO-seq, strand-specific RT-qPCR, and Northern blot should provide critical information on the abundance of RNA species, if there is a strand that is particularly more abundant and on the size of the molecules. This information will be fundamental to design knockdown strategies to determine whether the RNA molecule itself is regulating expression. In this case, small interfering RNAs (siRNAs) or locked nucleic acid antisense oligonucleotides (LNAs) can be used to deplete eRNAs and should be preferentially designed against the most abundant RNA specie. However, it is important to notice that RNA interference machinery is found mainly in the cytoplasm, so techniques based on the use of antisense oligonucleotides might be better for loss of function assays to study eRNAs. In this regard, the efficiency of transfection can greatly affect the resulting knockdown efficiency and because of that a careful selection of a cell system remains fundamental.

To evaluate the effect of eRNA knockdown, we advise to measure transcription of target genes as well as possible changes in long-range interactions if it is the case. To further support a function of the mature eRNA, a dead-Cas9–based strategy can be used to bring an eRNA to an enhancer element and evaluate different features like changes in the chromatin organization, histone marks, DNA accessibility, and potency to increase transcription. Finally, to study the potential association of an eRNA with specific regulatory proteins, it is advisable to perform RNA immunoprecipitation against the protein of interest and evaluate enrichment of the eRNA. If there is no a priori knowledge of the involvement of a protein, pull down of the eRNA with nuclear or cytoplasmic extracts, protein purification, and mass-spectrometry of eluted proteins should inform on potential protein partners.

In some cases, it has been shown that the act of transcription rather than the RNA molecule itself can be important and therefore inserting early termination sites as poly(A) signals into the enhancer sequence could be useful to study the role of productive transcription on enhancer activity.

transcription by directly regulating transcription at target genes. A possibility is that early responsive enhancers might produce eRNAs that contribute to a robust transcriptional induction of TF coding genes. It would be interesting to knockdown eRNAs from active enhancers contacting early inducible TF-genes and to characterize if they are actually playing a functional role in transcriptional activation as it might be suggested by their timing of transcription. An intriguing observation in B-lymphocytes during an innate antiviral immune response is that a subset of active enhancers continues to be transcribed despite loss of expression of its target genes.[16] This is in contrast with the majority of cases where enhancer-promoter pairs are concordant in their transcriptional status, ie, enhancer is transcribed first, then its target gene and then loss of enhancer transcription correlates with loss of transcription of its target gene.[16]

Overall, these observations suggest that eRNA transcription at enhancers is a regulated and dynamic process. In many scenarios, stimulus-dependent transcription at enhancers precedes the transcription of associated genes. However, these are mostly correlative observations, and still little is known about the molecular function of eRNAs and how they can impact transcription.

Mechanisms of Action

In the past decade, loss and gain of function assays have been critical to characterize the function of many ncRNAs like the lncRNAs. Most of the described mechanisms involve the interaction of lncRNAs with key regulatory proteins, like Polycomb and Trithorax.[17,18] In many of these cases, the RNA acted as a decoy, a scaffold, a guide, or even as an enhancer.[7] In contrast to lncRNAs, assigning a molecular mechanism of action to eRNAs has been challenging mainly due to their unstable nature as well as their very low abundance (Box 1). However, over the past decade the function of some of these eRNAs, in very specific scenarios, has been characterized. We proceed to describe these examples and discuss their implications for eRNA functions and their impact in the control of transcription.

Stimulation of enzymatic activity

The strongest evidence for a common function of many eRNAs was the finding that eRNAs interact with CREB binding protein (CBP), an acetyltransferase that, alongside with p300, deposits the histone H3K27ac mark in chromatin.[28] Native RNA immunoprecipitation and PAR-CLIP (photoactivatable ribonucleoside-enhanced cross-linking and immunoprecipitation) experiments demonstrated a CBP-eRNAs interaction in vivo.[28] In vitro assays showed that CBP-eRNAs interactions were independent of sequence, which suggest that a particular secondary structure of these RNAs may influence binding to CBP, as has been suggested for lncRNAs interacting with other regulatory proteins.[29] Of note, CBP-eRNAs interactions are already detected at actively transcribed enhancers where CBP is already bound.[28] This could mean that the interaction between CBP and eRNAs is not required for CBP recruitment. In line

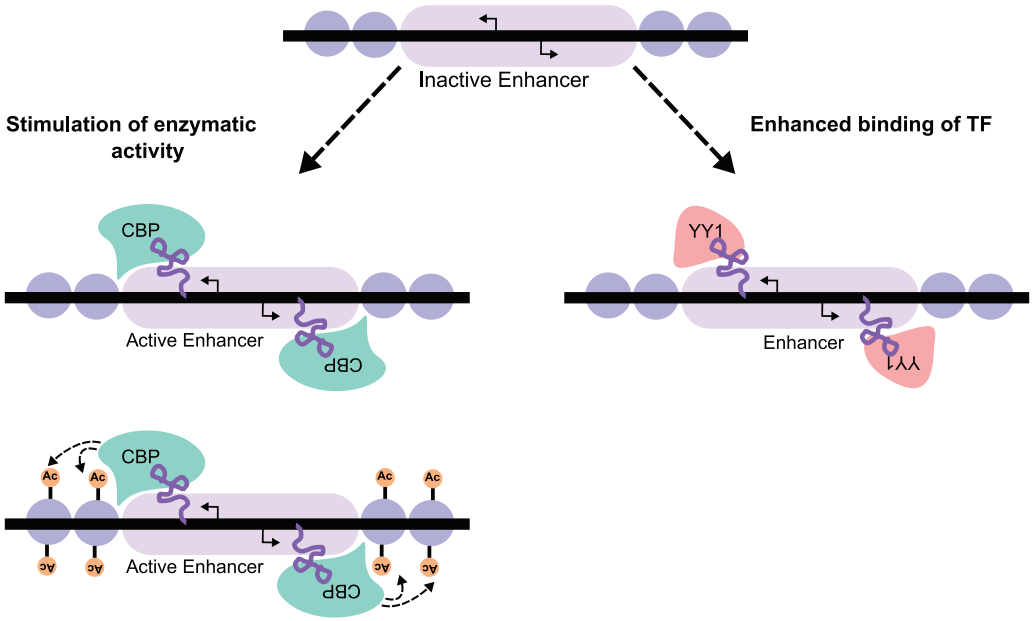

Figure 1. Enhancer RNAs (eRNAs) can influence catalytic activity of chromatin modifier proteins or act as traps for transcription factors. *Left*, eRNAs can directly interact with CBP, a histone acetyltransferase, and stimulate its enzymatic activity which results in a eRNA concentration dependent increase of H3K27ac as well acetylation in other amino acid residues of histones. *Right*, eRNAs at enhancers can trap transcription factors, like YY1, which results in an increase of signal for YY1 as evaluated by ChIP. This could mean that association with eRNAs increases residency time of TFs. CBP indicates CREB binding protein; TF, transcription factors.

with this, CBP-eRNA's interaction stimulates the histone acetyltransferase activity of CBP by increasing its affinity for a histone substrate which results in higher deposition of H3K27ac as well as H4K5ac histone marks[28] (Figure 1, *Left*). Knockdown of different eRNAs using antisense oligonucleotides resulted in a decrease in the histone H3K27ac level at the corresponding enhancer of origin and at the adjacent gene promoter with a concomitant reduction in the mRNA levels for target genes.[28] These data suggest that transcription of enhancers into eRNAs could enhance CBP acetyltransferase activity, which in turn might promote the acquisition of a chromatin environment permissive for enhancer function. In line with this, it has been shown that depletion of eRNAs during myogenesis results in a decrease in DNase I accessibility,[30] although the chromatin remodeling complex responsible for this effect remains elusive.

TFs trapping

lncRNAs can interact with different proteins involved in chromatin modification or organization, such as PRC2, MLL1, and CTCF.[17,18,31] Because enhancers are platforms for the binding of a variety of TFs, and Zinc Finger Domains of different TFs can interact with RNA[31–33]; therefore, eRNAs could interact with TFs, possibly influencing their residency time at enhancer elements. In line with this, YY1, a ubiquitously expressed TF in mammals, can interact in vivo with RNA when bound both at promoters and enhancers.[33] Inhibiting transcription or the exosome resulted in a decrease of YY1 recruitment at enhancers. This suggests that it is the nascent transcription of the eRNAs that is important for YY1 binding at enhancers. In line with this, tethering a specific eRNA in the vicinity of six enhancers bound by YY1 resulted in an increase in the binding of YY1 to those sites[33] (Figure 1, *Right*). Although the increase of YY1 binding to enhancers after eRNA tethering was modest, it supports a model where eRNAs might help to increase binding or residency time of YY1 at enhancers.

eRNAs can also interact with bromodomain-containing protein 4 (BRD4),[34] which is a member of the bromodomain and extraterminal domain (BET) family of proteins. It can bind to acetylated histones and stimulates elongation of protein-coding and noncoding RNAs. The interaction between eRNAs and BRD4 increases BRD4 binding to acetylated histones in vitro and to its target enhancers in vivo.[34] Knockdown of BRD4 interacting eRNAs results in loss of BRD4 and RNA polymerase II (RNA Pol II) binding at enhancer as well as loss of transcription of the target gene.[34]

Because other TFs have been shown to specifically interact with mRNAs and lncRNAs, like CTCF,[31] it remains to be determined if they can also interact with eRNAs as well. In addition, it is currently unclear what could be the effect of increasing the residency time of a TF at enhancer elements. An attractive possibility is that eRNAs could increase the binding of TFs to low affinity sites at enhancers; however, this remains to be elucidated.

Chromatin loop formation

Enhancer-promoter interactions through chromatin looping are important for tight control of gene expression either during development or cell differentiation, or in response to specific stimuli.[35,23] Defects in these interactions can have profound

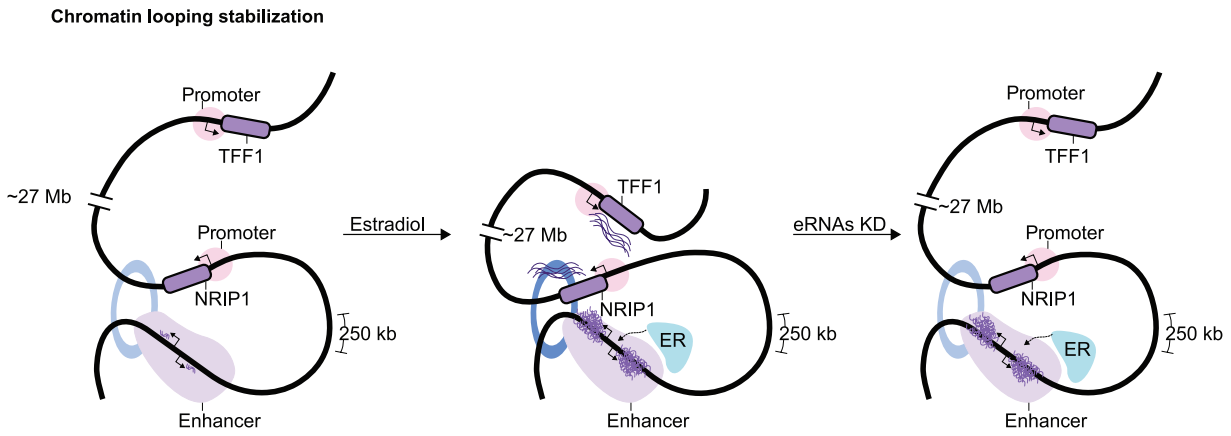

Figure 2. eRNAs can stabilize chromatin long-range interactions between transcribing enhancers and target promoters. The *NRIP1* promoter is in close proximity with an enhancer located ~250 kb upstream. Upon stimulation with estradiol, the transcription of both the enhancer and *NRIP1* is induced. This transcriptional effect is accompanied by increased deposition of the cohesin subunits Rad21 and SMC3 at the enhancer, as well as an increased frequency of interaction between the enhancer and the *NRIP1* promoter gene. This local reorganization is also accompanied by the gain of a novel interaction with *TFF1*, located 27 Mb away from *NRIP1* gene that is also transcriptionally induced during estradiol treatment. Depletion of *NRIP1*-associated eRNAs results in loss of *NRIP1* transcription, decreased deposition of cohesin subunits at the enhancer, and importantly, a decreased frequency of long-range interactions between the enhancer and the *NRIP1* promoter gene as evaluated by 3C and the loss of the 27 Mb interaction as evaluated by fluorescence in situ hybridization. Of note, eRNAs can directly interact with cohesin subunits. eRNA indicates enhancer RNAs; KD, knockdown; ER, Estrogen Receptor.

implications in development and disease generally due to changes in gene expression.[36–38] Different architectural proteins have shown to be important for promoting chromatin looping between regulatory elements, among them CTCF, YY1, and cohesin, as well as proteins involved in the general machinery of transcription like Mediator, RNA Pol II, Integrator, and cell-type-specific TFs.[23,39–44] These proteins can bind, for example, at enhancers and promoters and induce the establishment or the stability of long-range interactions. Because enhancers can be transcribed into eRNAs, it has been tempting to speculate that they might influence looping interactions between enhancers and promoters, which could ultimately result in regulated changes in gene expression. In line with this, several studies have reported a contribution of eRNAs to chromatin looping between selected activated enhancers and promoter elements.[12,16,40,45,46] In most of these studies, knockdown of eRNAs from selected enhancers either by small interfering RNAs (siRNAs) or locked nucleic acid antisense oligonucleotides (LNAs) results in quantitative and qualitative changes in looping contacts between transcribed enhancers and promoters which correlates with decreased transcription of their target genes.

In some cases, it has been shown that eRNAs can directly recruit architectural proteins like cohesin to their enhancer elements and this could directly contribute to changes in long-range interactions.[46] For example, in breast cancer cells the promoter of the *NRIP1* locus interacts in cis through chromatin looping with and enhancer located ~250 kb away. Upon stimulation with estradiol, the estrogen receptor binds to the enhancer. This results in strong transcription into eRNAs, increased binding of cohesin subunits, and higher frequency of long-range interaction with the *NRIP1* promoter which correlates with upregulation of the *NRIP1 mRNA* levels.[46] Importantly, reduction of eRNAs by the use of LNAs leads to the loss of looping interactions and transcription at *NRIP1* locus. These changes are also accompanied by decreased recruitment of cohesin subunits to the enhancer element. For this locus, the changes in long-range interactions are not just restricted to its enhancer element because depletion of eRNAs also results in loss of a ~27 Mb long-range interaction with the *TFF1* locus, which itself has an inducible enhancer transcribed upon estrogen stimulation (Figure 2).

Other proteins like Mediator, an important regulator of RNA Pol II activity, have been documented to play a role in promoting looping interactions between enhancers and promoters.[39,45,47] In regard to eRNAs, some reports have suggested that eRNAs interact with Mediator to promote long-range interactions between transcriptionally active enhancers and their target promoters.[45,47] However, a careful examination of current annotations for those locus suggest that those eRNAs are in fact lncRNAs that act in cis to regulate neighboring genes through direct interaction with Mediator and cell-type -specific TFs. Therefore, the role of Mediator in eRNA function requires further clarification.

The proper biogenesis of eRNAs is also important for stimulus-dependent enhancer activity and the establishment of long-range interaction between such enhancers and their target promoters. In this regard, it has been documented that Integrator, a multisubunit complex associated with RNA Pol II, is recruited to enhancers in a stimulus-dependent manner and is necessary for release of eRNA transcripts for elongating

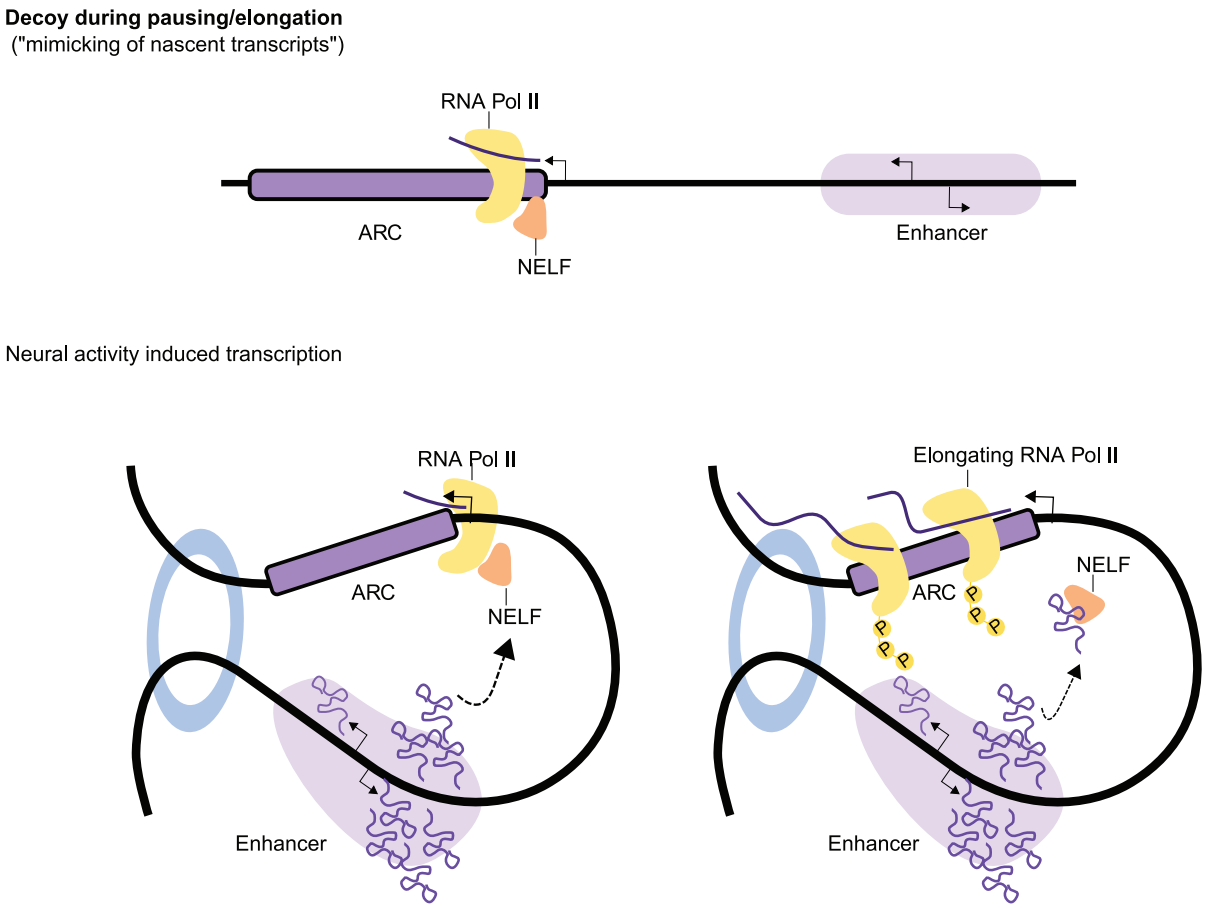

Figure 3. Enhancer RNAs (eRNAs) can promote exit of RNA Pol II pausing at promoters by mimicking nascent transcripts and interacting with NELF. The *ARC* locus is in physical proximity with an enhancer element throughout chromatin looping. Upon neuron stimulation, the transcription of both the enhancer and *ARC* gene is induced. Interestingly, transcription of one of the enhancer strands is more abundant. This eRNA can directly interact with NELF acting as a decoy for that protein. This results in loss of NELF at *ARC* promoter and the release of the paused RNA Pol II which engages in productive elongation. NELF indicates negative elongation factor; RNA Pol II, RNA polymerase II.

RNA Pol II.[40] Loss of Integrator results in accumulation of eRNAs primary transcripts. This effect compromises enhancer function, resulting in loss of chromatin looping between selected responsive enhancers and their target promoters with a corresponding loss of transcriptional induction. These data suggest that mature eRNAs, but not the transcription of enhancers, are required for long-range interactions between enhancers and promoters.

In this regard, it may be tempting to speculate that at stimulus-dependent enhancers, the induction of transcription by binding of specific TFs results in the generation of mature eRNAs by the Integrator complex. Then, these eRNAs in conjunction with boundary proteins like CTCF or YY1, could promote the stalling of loop-extrusion factors, like cohesin, through direct RNA-protein interactions.[48] Therefore, depletion of eRNAs could result in the loss of an RNA-dependent boundary that results in a decrease of specific long-range interactions between pairs of enhancer-promoter sequences. Interestingly, an RNA-dependent function of CTCF for chromatin looping has been recently reported.[49–51]

RNA Pol II productive elongation

eRNAs can regulate RNA Pol II elongation by interacting with proteins that either promote or inhibit elongation.[52,53] For example, eRNAs can promote exit of RNA Pol II pausing at activity-dependent neuronal promoters throughout direct interaction with the negative elongation factor (NELF), which promotes RNA Pol II pausing.[52] Knockdown of eRNAs associated with the enhancers of the neuronal genes *ARC* and *GADD45B* did not affect long-range interactions between the enhancers and promoters but resulted in an increase of the NELF at their promoters, which was accompanied by a decrease of the corresponding mRNA[52] (Figure 3). Because these eRNAs can interact with NELF via an RNA-binding domain, it was suggested that eRNAs could trap NELF, mimicking nascent transcription at target promoters. Therefore, eRNAs could promote RNA Pol II productive elongation by acting as a decoy for NELF, which in turn might be facilitated by the close physical proximity between the enhancers and promoters by means of chromatin looping.

eRNAs can also promote elongation by interaction with the positive transcription elongation factor b (p-TEFb) complex

which promotes RNA Pol II elongation by phosphorylation of different targets including NELF and Pol II-Ser2.[53–55] An eRNA transcribed from an enhancer that increases the expression of the target gene *PSA* can directly interact with the kinase CYCLIN T1 which is part of the p-TEFb complex.[53] Loss of this interaction correlates with a diminishment of Pol II-Ser2 phosphorylation and *PSA* expression. Interestingly, the interaction between CYCLIN T1 was achieved via an HIV-1 TAR RNA-like motif found in the eRNA. The motif present in the eRNA is also similar to the one found in the 7SK small nuclear RNA which can inhibit p-TEFb function. Therefore, this eRNA could favor elongation by RNA Pol II by competing with 7SK for the interaction with the p-TEFb complex thought CYCLIN T1. This is an example of a functional embedded structure in an eRNA and opens up the possibility that a subset of eRNAs act through specific sequence motifs. However, as we know that enhancers poorly conserved, this case might rather be an exception.

Concluding Remarks

The discovery of the pervasive transcription of the genome into ncRNAs has opened a whole new field of study. Enhancer transcription is of interest as these regulatory elements are at the heart of transcriptional regulation in processes as diverse as development, cell differentiation, and response to stimuli. One of the most important questions in the field is if eRNAs have a function. Even though it has been suggested that most eRNAs might be transcriptional noise,[56] for over almost a decade, different mechanisms of action have been characterized by which eRNAs could influence gene expression. Overall, eRNAs seem to exert their function by interacting with different regulatory proteins, similar to what has been discovered for lncRNAs. eRNAs can affect the chromatin environment of their enhancer, either by promoting chromatin accessibility, stimulating the histone acetyltransferase activity of CBP or enhancing the binding of TFs.

eRNAs can also stabilize chromatin looping contacts between enhancers and promoters by the recruitment of cohesin and can affect the transcriptional machinery already poised at promoters. In those cases, eRNAs can act as decoys for proteins like NELF, promoting elongation or influence the catalytic activity of other proteins associated with RNA Pol II.

Although progress has been made over the past years to uncover the potential molecular function of eRNAs, it should be pointed out that most of the examples covered here are restricted to a few loci. In many cases, although transcription of both strands of the enhancer is detected, one strand is prominently transcribed into an ncRNA that has a molecular function important for enhancer activity or gene transcription. This rise the concern of whether the molecular functions already reported for this subset of eRNAs could be a general feature of eRNAs or in fact they represent specific cases were eRNAs have acquired functions similar to lncRNAs or have been misannotated as eRNAs.[57] In this regard, a clear working definition that helps to distinguish eRNAs from lncRNAs might be of great help.

Based on current evidence, we propose that transcription of enhancers into eRNAs could be an RNA-based mechanism to trap proteins relevant for enhancer activity. In support of this, an increasing number of proteins with key regulatory functions like CTCF, YY1, and CBP have been shown to interact with RNA, and this association can have important consequences for their activity. In this regard, transcription at enhancers could be a means to increase the residency time of both DNA-binding proteins and cofactors.

For example, upon cell stimulation, specific TFs could bind to already CBP-bound enhancers and potentiate transcription. Those eRNAs could further stimulate the histone acetyltransferase activity of CBP which in turn could trigger BRD4 binding. Because eRNAs can also interact directly with BRD4 and increase the binding of this protein to the enhancer element, and BRD4 can promote elongation by recruitment of p-TEFb, Mediator, and RNA Pol II, these could lead to increased transcription of the enhancer into eRNAs.[34] All these can result in a net increase of RNA species at the enhancer that could lead to the establishment of a feed-forward loop where increasing eRNA molecules keep on promoting elongation at enhancer as well as acetylation of histones resulting in a chromatin structure that could boost enhancer activity over target promoters. Therefore, based on current evidence, we envision a general mechanism by which eRNAs favor the maintenance or reinforcement of a chromatin environment optimal for enhancer function. In some cases, these eRNAs could have evolved to acquire a specific molecular function and might be in a path toward becoming lncRNAs. Further work is needed, particularly on developing high-throughput genome-wide tools, to assess the functional role of eRNAs and clarify their relevance on transcriptional regulation.

Human mesenchymal stem cells (MSCs) are good candidates for brain cell replacement strategies and have already been used as adjuvant treatments in neurological disorders. MSCs can be obtained from many different sources, and the present study compares the potential of neuronal transdifferentiation in MSCs from adult and neonatal sources (Wharton's jelly (WhJ), dental pulp (DP), periodontal ligament (PDL), gingival tissue (GT), dermis (SK), placenta (PLAC), and umbilical cord blood (UCB)) with a protocol previously tested in bone marrow- (BM-) MSCs consisting of a cocktail of six small molecules: I-BET151, CHIR99021, forskolin, RepSox, Y-27632, and dbcAMP (ICFRYA). Neuronal morphology and the presence of cells positive for neuronal markers (TUJ1 and MAP2) were considered attributes of neuronal induction. The ICFRYA cocktail did not induce neuronal features in WhJ-MSCs, and these features were only partial in the MSCs from dental tissues, SK-MSCs, and PLAC-MSCs. The best response was found in UCB-MSCs, which was comparable to the response of BM-MSCs. The addition of neurotrophic factors to the ICFRYA cocktail significantly increased the number of cells with complex neuron-like morphology and increased the number of cells positive for mature neuronal markers in BM- and UCB-MSCs. The neuronal cells generated from UCB-MSCs and BM-MSCs showed increased reactivity of the neuronal genes TUJ1, MAP2, NF-H, NCAM, ND1, TAU, ENO2, GABA, and NeuN as well as down- and upregulation of MSC and neuronal genes, respectively. The present study showed marked differences between the MSCs from different sources in response to the transdifferentiation protocol used here. These results may contribute to identifying the best source of MSCs for potential cell replacement therapies.

1. Introduction

The *in vitro* generation of neuronal cells from neural (NSCs), embryonic (ESCs), and induced pluripotent stem cells (iPSCs), or by neuronal transdifferentiation of somatic cells by transcription factors (TF) has emerged as a useful strategy for cell replacement therapies in neurological disorders [1–3]; however, technical limitations, graft rejection, ethical issues, and/or tumorigenic risk are associated with the neurons derived from such processes [4–6]. Therefore, recent efforts have been focused on finding more suitable cell types or avoiding genetic manipulation for the generation of neurons [4, 7–11]. In this respect, mesenchymal stem cells (MSCs) offer some advantages over other cell types. MSCs are potentially able to differentiate into various cell lineages (including neurons), are easy to isolate and expand, have a low tumorigenic risk and low grafting rejection, and lack ethical issues [12–15]. These properties point to MSCs as suitable sources for cell replacement therapy in neurological disorders [16–19]; however, an optimal protocol to induce their conversion into neurons remains unestablished.

Chemical compounds known as small molecules have been shown to replace exogenous TF during cell reprogramming [7–9, 11]. Recent reports demonstrated the neuronal transdifferentiation of fibroblasts and astrocytes by small molecule cocktails [20–23]. These molecules act by modulating signaling pathways and epigenetic mechanisms implicated in cell reprogramming, neuronal specification, or neuronal survival [21], representing a convenient strategy to avoid the risks of genetic manipulation in the generation of induced neurons. In our previous report, after a small molecule screening assay, we found that a cocktail containing I-BET151, CHIR99021, forskolin, RepSox, Y-27632, and cAMP (ICFRYA) induced the formation of cells with neuron-like morphology and positive for TUJ1 and MAP2 from bone marrow- (BM-) MSCs [10].

MSCs can be isolated from many adult and neonatal tissues. However, comparative studies indicate that the MSCs from different tissues present differences in the efficiency of trilineage differentiation and other functional abilities, even though they meet the properties to be considered MSCs [24–27]. The present study is aimed at comparing the neuronal transdifferentiation potential of adult and neonatal MSCs obtained from different sources. To this end, we evaluated the neuronal-like morphology and neuronal markers induced by the ICFRYA cocktail in MSCs obtained from bone marrow (BM), skin (SK), dental pulp (DP), periodontal ligament (PDL), gingival tissue (GT), Wharton jelly (WhJ), placenta (PLAC), and umbilical cord blood (UCB). Neuronal induction was successful in the MSCs from some but not all sources. Strategies were selected to improve the induction of the MSC sources that showed neuronal properties. The presence of mature neuron markers, changes in global gene expression, and electrophysiological activity were examined in cells in which neuronal transdifferentiation was presumed.

2. Materials and Methods

2.1. Reagents and Antibodies. Neurobasal medium, α-MEM, RPMI medium, DMEM low glucose (DMEM-lg), DMEM/F-12, fetal bovine serum (FBS), L-glutamine, dispase II, Glutamax, antibiotics, trypsin/EDTA, human neurotrophic factors, N2, and B27 were all purchased from Gibco™ Thermo Fisher Scientific Inc. (MA, USA). Fibronectin, heparin, gelatin, nonessential amino acids, Hoechst 33258, and normal goat serum (NGT) were acquired from Sigma-Aldrich, Merck (St. Louis, MO, USA). The following primary antibodies were used: mouse anti-TUJ1 (SC-80016) and rabbit anti-MAP2 (SC-20172) obtained from Santa Cruz Biotechnology (CA, USA); rabbit anti-GABAB (SC-376282), ENO2 (GTX113428), TAU (GTX116044), and mouse anti-NF-H (GTX27795) from GeneTex Inc. (CA, USA); and rabbit anti-NeuN (MAB377) from Merck-Millipore (Darmstadt, Germany). Secondary antibodies against goat anti-mouse IgG conjugated to Alexa Fluor 488 and goat anti-rabbit IgG conjugated to Alexa Fluor 568 were obtained from Molecular Probes, Thermo Fisher Scientific Inc. (MA, USA). Small molecules I-BET151, CHIR99021, forskolin, RepSox, Y-27632, and dibutyryl cAMP were purchased from Sigma-Aldrich, Merck (St. Louis, MO, USA).

2.2. MSC Isolation and Characterization. All samples were isolated from healthy donors according to the Declaration of Helsinki. The bone marrow samples were obtained according to the Local Ethics Committee of the Villa Coapa Hospital, Mexican Institute for Social Security (IMSS, Mexico). The umbilical cord blood and placenta samples were collected according to the Local Ethics Committee of the Troncoso Hospital (IMSS, Mexico). The dental tissue samples were obtained according to the local Ethics Committee of the Orthodontics Clinic and the Faculty of Dentistry, National Autonomous University of Mexico. The skin samples were collected according to the Local Ethics Committee of the Dermatology Hospital, Health Secretary, Mexico City (SS, Mexico).

Mononuclear cells were isolated from bone marrow and umbilical cord blood samples by a Ficoll gradient, and cells from the internal area of the central placenta lobules were obtained using an enzymatic digestion procedure (Trypsin-EDTA). These cell samples were cultured in DMEM-lg plus 4 mM L-glutamine, 50 U/mL of penicillin, 50 μg/mL of streptomycin, and 50 μg/mL of gentamicin (DMEM-lg) and supplemented with FBS-10% [28]. The Wharton's jelly (membrane), gingival tissue, periodontal ligament, and dental pulp tissue samples were cut into small pieces and cultured as explants in α-MEM supplemented with FBS-15%. Finally, the skin samples were placed overnight in RPMI medium and dispase II, and then, the dermis was mechanically separated from the epidermis. Cells from the dermis were isolated by allowing them to migrate from the dermal segments placed in culture (DMEM-lg supplemented with FBS-10%). For all samples, the medium was changed every two days. The adherent cells were subcultured using trypsin/EDTA at 2×10^2 cells/cm^2 in DMEM-lg supplemented with FBS-10%. All experiments

were performed with MSCs between the fourth and sixth passages.

MSCs were characterized based on morphological, phenotypic, and differentiation parameters [28, 29]. FITC, PE, or APC-conjugated monoclonal antibodies against CD73, CD90, CD45 (BD Biosciences, San Diego, CA, USA), CD105, CD13, CD14, (Caltag, Buckingham, UK), HLA-ABC, HLA-DR, CD31, and CD34 (Invitrogen, Carlsbad, CA, USA) were used for immunophenotypic characterizations and analyzed on a FACSCanto II flow cytometer (BD Biosciences, Fullerton CA, USA). Adipogenic differentiation was determined by visualizing the presence of Oil Red O-stained (Sigma-Aldrich, Merck) lipid vacuoles. Osteogenic differentiation was assessed by alkaline phosphatase staining (FAST BCIP/NBT; Sigma-Aldrich, Merck). Chondrogenic differentiation was induced over 28 days with 10 ng/mL TGF-β (PeproTech). The resulting micromasses were fixed, embedded, and sliced, and cross-sections were stained with Alcian blue dye (Sigma-Aldrich, Merck).

2.3. Neuronal Induction by the ICFRYA Cocktail. Adult and neonatal MSCs were seeded onto fibronectin ($2\,\mu g/cm^2$)/0.1% gelatin-coated plates at a density of 2×10^4 cells/cm^2 and cultured in MSC growth medium for one day. For chemical induction, the cells were washed with serum-free medium and then cultured with neuronal induction medium (50% neurobasal medium, 50% DMEM/F12 with 1 × N2 and 1 × B27 with vitamin A, 1 × Glutamax, 1 × nonessential amino acids, and 20 ng/mL FGF2 plus 5 μg/mL heparin) plus the defined chemical cocktails for 8 or 4 days (as appropriate) at 37°C and 5% CO_2. The concentrations of the molecules in the ICFRYA cocktail were 1 μM I-BET151, 20 μM CHIR99021, 50 μM forskolin, 1 μM RepSox, 5 μM Y-27632, and 100 μM dbcAMP [10]. The neuronal induction medium was replaced on day 4. When indicated, the neuronal induction medium plus the ICFRYA cocktail was supplemented with human brain-derived neurotrophic factor (hBDNF), human glial cell-derived neurotrophic factor (hGDNF), and neurotrophin-3 (NT-3) at 20 ng/mL each.

2.4. In Situ Analysis of Cell Viability. Cells were incubated for 10 min with 1 μg/mL propidium iodide. Microphotographs were obtained using a direct epifluorescence microscope Olympus 1X71 with 10x magnification and the QCapture Pro 6.0 software.

2.5. Immunocytochemistry. After culture, the cells were fixed/permeabilized with cold methanol for 10 min and washed three times with PBS. The cells were blocked using PBS/0.1% BSA + 10% GS (goat serum) for 1 h. Then, the cells were incubated overnight at 4°C with primary antibodies: mouse anti-TUJ1 (1 : 1000), anti-NF-H (1 : 250), and anti-NeuN (1 : 200) and rabbit anti-MAP2 (1 : 500), anti-TAU (1 : 1000), anti-GABAB (1 : 250), and anti-ENO2 (1 : 250). Then, the cells were incubated for 1 h with goat anti-mouse Alexa 488 or goat anti-rabbit Alexa 568 as appropriate. The nuclei were counterstained with 1 μg/mL Hoechst 33258 diluted in PBS. Microphotographs were obtained by the direct epifluorescence microscope Olympus IX71 using the QCapture Pro 6.0 software, and data were analyzed with ImageJ software. At least 500 nuclei from five randomly selected fields were counted to calculate the percentage of positive cells.

2.6. Real-Time Quantitative PCR (qPCR). RNA samples from cultures were extracted with the GenElute Mammalian Total RNA Miniprep Kit (RTN70 Sigma-Aldrich, St. Louis, MO, USA) according to the manufacturer's instructions. The concentration of RNA samples was quantified by a NanoDrop spectrophotometer (Thermo Scientific). Complementary DNA (cDNA) was synthesized from 1 μg RNA with the iScript cDNA Synthesis Kit (Bio-Rad Laboratories Inc., CA, USA) and a Veriti® 96-Well Thermal Cycler (Applied Biosystems). PCR primers were designed using the last reference sequence (RefSeq) version of each gene with the PrimerBlast software; Supplementary Table 5 includes a list of primers used in this study. The qPCR reactions were conducted using a QuantiFast SYBR Green PCR Kit (Qiagen, MD, USA), according to the manufacturer's instructions, and run on a StepOnePlus Real-Time PCR system (Applied Biosystems). After amplification, the melting curves of the RT-PCR products were determined to demonstrate product specificity. PCR efficiency was optimal and ranged from 90% to 100% in the different target gene qPCR assays. For the selection of the best reference gene, a comparison of the transcriptional variation of different housekeeping genes in response to the conditions was performed. The gene with the least CT variation between treatments and control cultures was selected. Thus, gene expression was normalized to TATA-Box binding protein (TBP) mRNA. The relative quantification of mRNA levels was performed using the Pfaffl method [30].

2.7. Microarray Assay. Cells were incubated as described in the neuronal maturation protocol. The samples were then processed for RNA extraction. Total RNA (10 μg) was used for cDNA synthesis incorporating dUTP-Alexa 555 or dUTP-Alexa 647 and employing the CyScribe First-Strand cDNA labeling kit (Amersham). Equal quantities of labeled cDNA were hybridized using the hybridization solution HybIT2 (TeleChem International Inc.) on the collection of human arrays (10 K) for 14 h at 42°C. The acquisition and quantification of array images were performed in the ScanArray 4000 with its accompanying software from Packard BioChips. For each spot, the mean density, mean background, and mean normalized signal values were calculated with the Array-Pro Analyzer software from Media Cybernetics. Microarray data analysis was performed with the free software genArise, which was developed in the Computing Unit of the UNAM Cellular Physiology Institute (http://www.ifc.unam.mx/genarise/). The microarray data were deposited in the Gene Expression Omnibus database repository (GSE120681). The functional annotation gene analysis analyzed the up- and downregulated genes derived from the microarray assay using DAVID 2.0 (https://david.ncifcrf.gov/tools.jsp) and bioinformatics resources to obtain

the Gene Ontology functional annotation classification of the genes.

2.8. Electrophysiological Activity Recording. Whole-cell ion currents were experimentally recorded with an arrangement of Axopatch 200B/Digidata 1550/pCamp10 (amplifier/analog-digital converter/software, all from Molecular Devices, Sunnyvale, CA), analog filtered at 5 kHz and digitally sampled at 10 kHz. Patch-clamp pipettes were made of borosilicate glass (World Precision Instrument) using a P-97 puller (Sutter Instruments, Novato, CA). The intracellular pipette filling solution was composed of (in mM) 10 NaCl, 40 KCl, 10 HEPES, 5 EGTA, 3 $MgCl_2$, 95 K-gluconate, and 10 glucose (pH 7.2 adjusted with KOH). The extracellular solution contained (in mM) 140 NaCl, 4 KCl, 1 $MgCl_2$, 2 $CaCl_2$, 10 HEPES, and 5 glucose (pH 7.4 adjusted with NaOH). All solutions were perfused using a custom-made gravity-based perfusion system. The voltage-clamp protocol used in all experiments was 200 ms step pulses from -120 to +50 mV in 10 mV increments from a holding voltage of -70 mV.

2.9. Statistical Analysis. The results were expressed as the mean ± standard error (SEM) from three independent experiments of three biological samples or 4-6 independent experiments from one biological sample as indicated. The statistical analyses were performed using Student's t-test for between-group comparisons and a one-way ANOVA and the Tukey test for multiple comparisons. GraphPad Prism software for Windows version 6 (La Jolla, CA, USA) was used for all statistical procedures. Differences with $p < 0.05$ were considered statistically significant.

3. Results

3.1. MSC Characterization. Mesenchymal stem cells (MSCs) were isolated from human adult or neonatal sources (Supplementary Table 1) and characterized according to the criteria defining human MSCs proposed by the International Society for Cellular Therapy [31]. For all MSC samples, the cells adhered to the plastic exhibited fibroblastic morphology (Supplementary Figure 1), were positive for MSC markers (CD105, CD90, and CD73), were negative for hematopoietic markers and HLA-DR surface molecules (Supplementary Table 2), and were capable of differentiating into adipocytes, osteoblasts, and chondrocytes (Supplementary Table 3). The neuronal medium per se (NM: N2/B27/hFGF) did not induce neuronal morphology or reactivity to neuronal markers (Supplementary Figure 3); however, a weak reactivity against TUJ1 was observed in all MSC sources (Figures 1(b)–1(h) left picture).

3.2. Neuronal Induction by the ICFRYA Cocktail of Adult and Neonatal MSC Sources. Neuronal induction of all MSC sources was conducted using the ICFRYA small molecule cocktail protocol (Figure 1(a)) as previously reported for BM-MSCs [10]. In addition to neuronal properties, necrotic cell death was evaluated by propidium iodide staining. The neuronal induction effects of the ICFRYA cocktail on MSCs from different sources varied. Neuron-like cells with reactivity to TUJ1 were induced in DP-MSCs (50 ± 7.7%), PDL-MSCs (42 ± 7.1%), GT-MSCs (32 ± 1.9%), SK-MSCs (34 ± 9.1%), and PLAC-MSCs (67 ± 2.3%); however, very low percentages of $MAP2^+$ cells were found (0.7% to 5.9%) (Figures 1(b)–1(f), right pictures and graphs). In these MSC sources, the cocktail produced 48%-68% necrosis. In WhJ-MSCs, the chemical cocktail did not evoke cells with neuronal properties, but high levels of necrosis were present (Figure 1(g) right picture and graph). In UCB-MSCs, the ICFRYA cocktail induced neuronal properties, i.e., bipolar morphology with a high percentage of $TUJ1^+$ cells (57 ± 3.3%) and coexpression of MAP2 in 27 ± 3.9%; however, a very high rate of necrosis (84 ± 6.8%) was observed (Figure 1(h) right picture and graph). The removal of I-BET151 from the chemical cocktail reduced the necrotic cell death strongly in all MSC sources and also reduced the expression of neuronal properties (Figures 1(b)–1(h), no I-BET bars; Supplementary Table 4). It is noteworthy that I-BET alone did not exhibit any effects on the MSCs from any tissue (data not shown). I-BET151 and forskolin are considered key molecules for chemical-based neuronal transdifferentiation; in other reports, high concentrations of these molecules have been used for neuronal transdifferentiation [22]. However, increasing the concentration of I-BET151 (1 μM to 2 μM) and/or forskolin (50 μM to 75 μM) did not improve the expression of neuronal properties on WhJ-, DP-, PDL-, GT-, SK-, or PLAC-MSCs but did increase necrosis (Supplementary Table 4 and Supplementary Figure 2). As illustrated in Figures 2(a) and 2(e), very few cells from WhJ-MSCs presented a bipolar morphology and reactivity to TUJ1. In PDL-MSCs, although MAP2 reactivity was increased, the signal was not associated with cell protrusions, and almost all cells maintained the bipolar morphology (Figures 2(b) and (e)). On the other hand, in UCB-MSCs incubated with ICFRYA containing 2 μM I-BET151, neuronal morphology was observed after two days of induction (Figure 2(c)), notably reducing the induction time from 8 to 4 days. At this time, UCB-MSCs exhibited proper neuron-like induction with 77.6 ± 10.7% $TUJ1^+$ cells, protrusions with secondary ramifications, MAP2 reactivity associated with the branches, and only 25% necrotic death (Figures 2(c) and 2(d) and Supplementary Table 4). In our previous report, the ICFRYA cocktail containing 1 μM I-BET and 50 μM forskolin induced neuron-like cells from BM-MSCs with reactivity to TUJ1 and MAP2. BM-MSCs were added as the gold standard to compare neuronal induction with the other sources. Using different concentrations of the molecules, neuronal morphology was evident after 4 days (Figure 2(d)), and the original ICFRYA molecule concentration showed the best induction in BM-MSCs (Figures 2(d) and 2(e) and Supplementary Table 4).

3.3. Neurotrophic Factors Improve Neuronal Induction of BM- and UCB-MSCs by ICFRYA. To examine a possible effect of neurotrophic factors on the improvement of neuronal induction by the ICFRYA cocktail, BM- and UCB-MSCs were cocultured with astrocytes and/or in the presence of neurotrophic factors (BDNF, GDNF, and neurotrophin-3) and fetal bovine serum (FBS) 1%. Coculturing with astrocytes

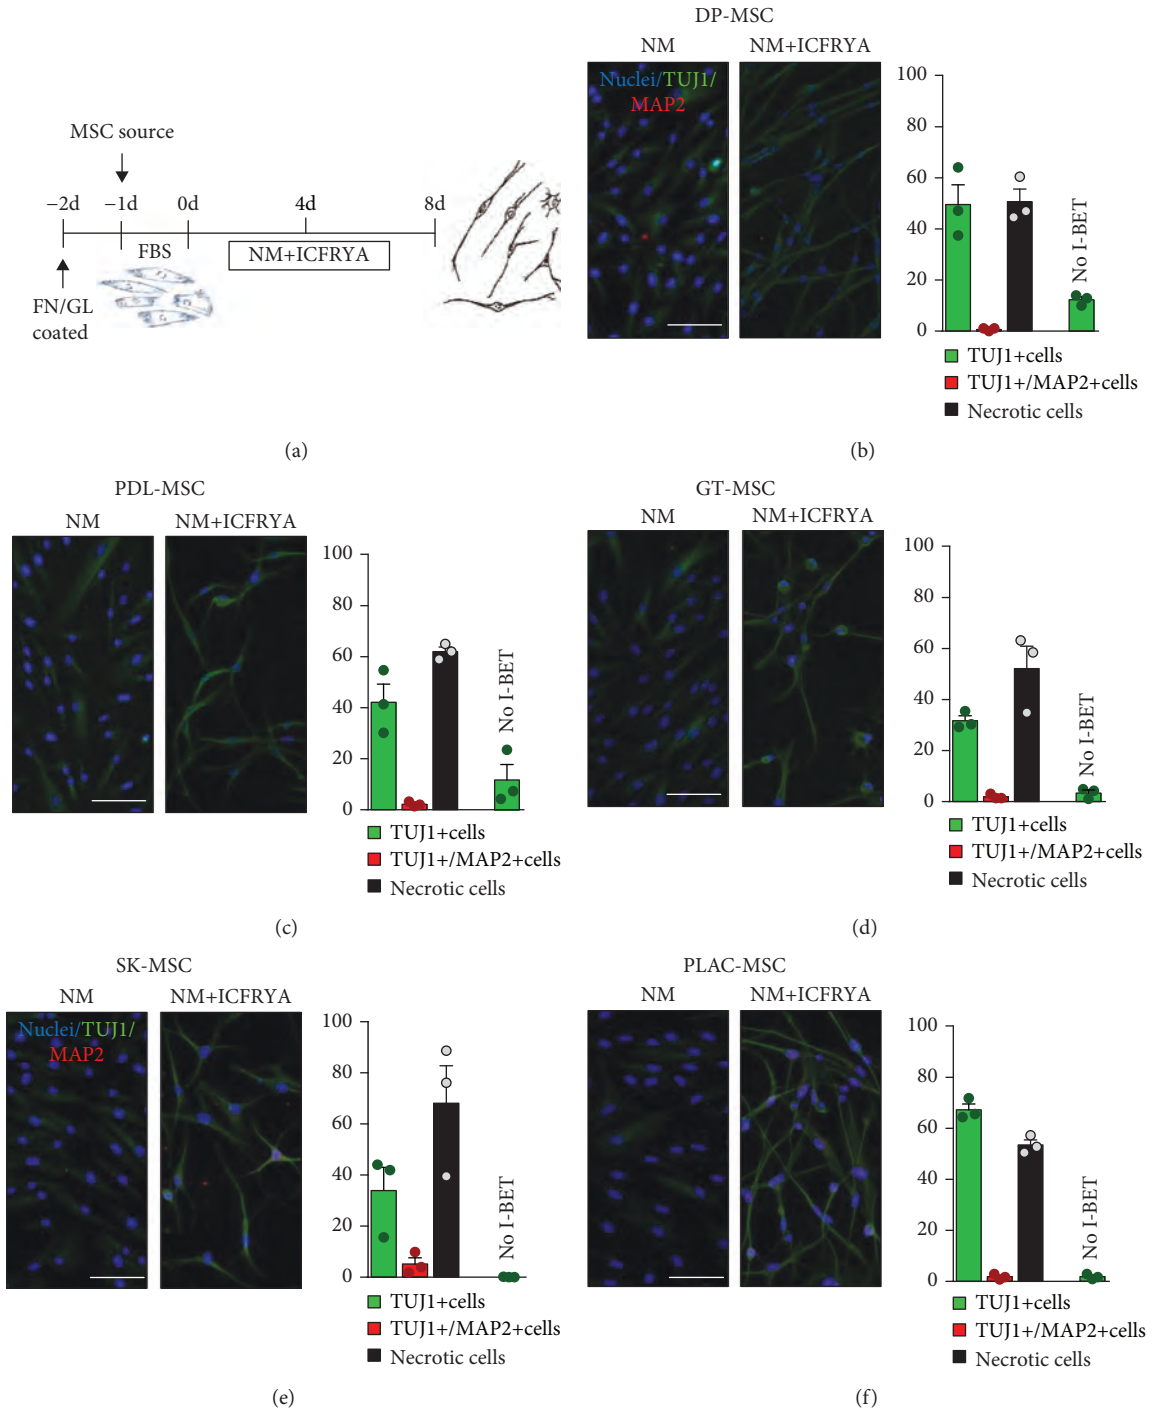

Figure 1: Continued.

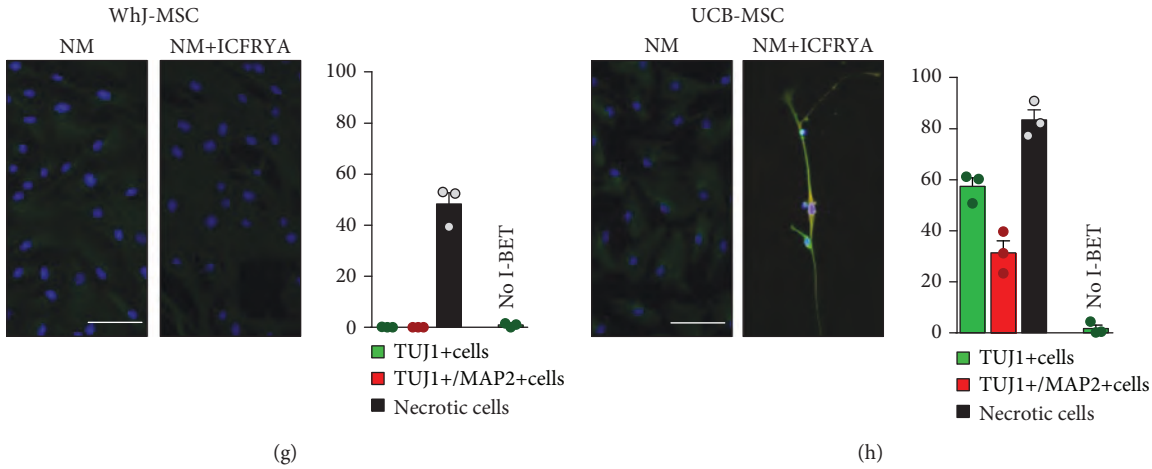

Figure 1: Neuronal properties induced by the ICFRYA small molecule cocktail in different sources of human mesenchymal stem cells (hMSCs). (a) Schematic diagram of the neuronal induction protocol. One day prior to the neuronal induction, MSCs were seeded on FN/GL-treated plates, and the medium was replaced with neuronal medium (NM: N2/B27/FGF/EGF) or NM containing the ICFRYA small molecule cocktail: I: I-BET151; C: CHIR99021; F: forskolin; R: RepSox; Y: Y27632; A: cAMP. NM or NM plus the ICFRYA cocktail was changed at day 4, and the neuronal properties and necrosis were evaluated on day 8. (b–h) Representative images and percentages of neuron-like morphology cells positive for TUJ1 (green bars), TUJ1/MAP2 (red bars), and necrotic cells (black bars). MSCs cultured with NM maintained fibroblastic morphology (panels (b–h) left picture) and acquired neuron-like morphology only under small molecule stimulation (panels (b–h) right picture). The presence of neuronal markers was estimated by immunostaining, and necrosis was evaluated in situ using propidium iodide (PI). In addition to marker reactivity, neuronal-like morphology was considered to define $TUJ1^+$ cells and $TUJ1^+/MAP2^+$ cells. The data are presented as the mean ± SEM of $n = 8$ from three biological replicates in three independent experiments. Scale bars represent 100 μm. FN/GL: fibronectin-gelatin; FBS: fetal bovine serum; NM: neuronal medium; ICFRYA: I-BET151, CHIR99021, forskolin, RepSox, Y27632, cAMP.

during chemical induction strongly decreased cell viability and did not improve the neuronal properties (data not shown). The ICFRYA cocktail plus neurotrophic factors and FBS was the best neuronal induction condition. In both BM- and UCB-MSCs, this condition generated neuron-like cells with multiple arborizing dendritic-like structures and high percentages of cells positive for MAP2, NF-H, TAU, and other mature neuron markers such as ENO2, GABA, and NeuN (Figures 3(a) and 3(b)). No significant differences were found between the positive neuron-like cells induced from BM- or UCB-MSCs (Figure 3(c)). BM-MSCs and UCB-MSCs in control conditions did not show reactivity to the neuronal markers, and no cells positive for the glial marker GFAP were detected in the control or induced cultures (Supplementary Figure 3).

Changes in the gene expression of neuronal, glial, and MSC markers as detected by qRT-PCR were analyzed after the induction process. The neuron-like cells derived from UCB-MSCs and BM-MSCs showed increased expression of neuronal genes, such as TUJ1, MAP2, NF-H, DCX, NCAM, ND1, NCAM, TAU, ENO2, GABA, and NeuN, and downregulated expression of the MSC markers CD90 and CD105 (Figure 4(a)). The fold change in expression of CD90, CD105, DCX, and ND1 was significantly higher in the cultures generated from UCB-MSCs than from BM-MSC cells.

To evaluate the transdifferentiation process, we conducted a global RNA expression analysis. In the presence of the ICFRYA cocktail, both UCB- and BM-MSC cells upregulated the expression of neuronal regulators and other genes associated with neurodevelopment and functional properties (Figure 4(b)). Among the genes implicated in functional differentiation, the potassium voltage-gated gene KCNC1 was upregulated in BMs, and the KCNC1 and KCNJ16 genes were upregulated in UCB-MSCs. The glial genes GFAP and S100B remained unchanged, and positive regulators of the cell cycle and genes associated with mesenchymal and fibroblastic lineages were downregulated (Figure 4(b)). Gene Ontology term analysis indicated enrichment in the genes related to processes such as small molecule metabolism, cell signal, cell differentiation, positive regulation of neurogenesis, neuronal differentiation, functional neuron activities, dendritic spine development, and action potentials (Figure 4(c)). Altogether, the results indicate that the neuron-like cells obtained can be considered induced neurons (iNs) generated from UCB-MSCs (UCB-iNs) or iNs generated from BM-MSCs (BM-iNs). Although the UCB-iNs and BM-iNs have similar neuronal features, there was a higher number of genes regulated in each Gene Ontology process and a higher p value in the UCB-iNs (Figure 4(c)).

3.4. Ion Currents in BM-iNs and UCB-iNs. Whole-cell ion currents were evaluated in control cells (UCB-MSCs and BM-MSCs) and in cells with complex neuron-like morphology from UCB-iNs and BM-iNs (Figures 5(a) and 5(b)). Fast inward sodium-like currents were not detected in the control nor treated conditions. Outward noninactivating ion potassium-like currents were also evaluated. Slight and irregular potassium-like currents were recorded in BM-iNs and no different to those in control BM-MSCs (Figures 5(c) and 5(d)). Potassium-like currents of high

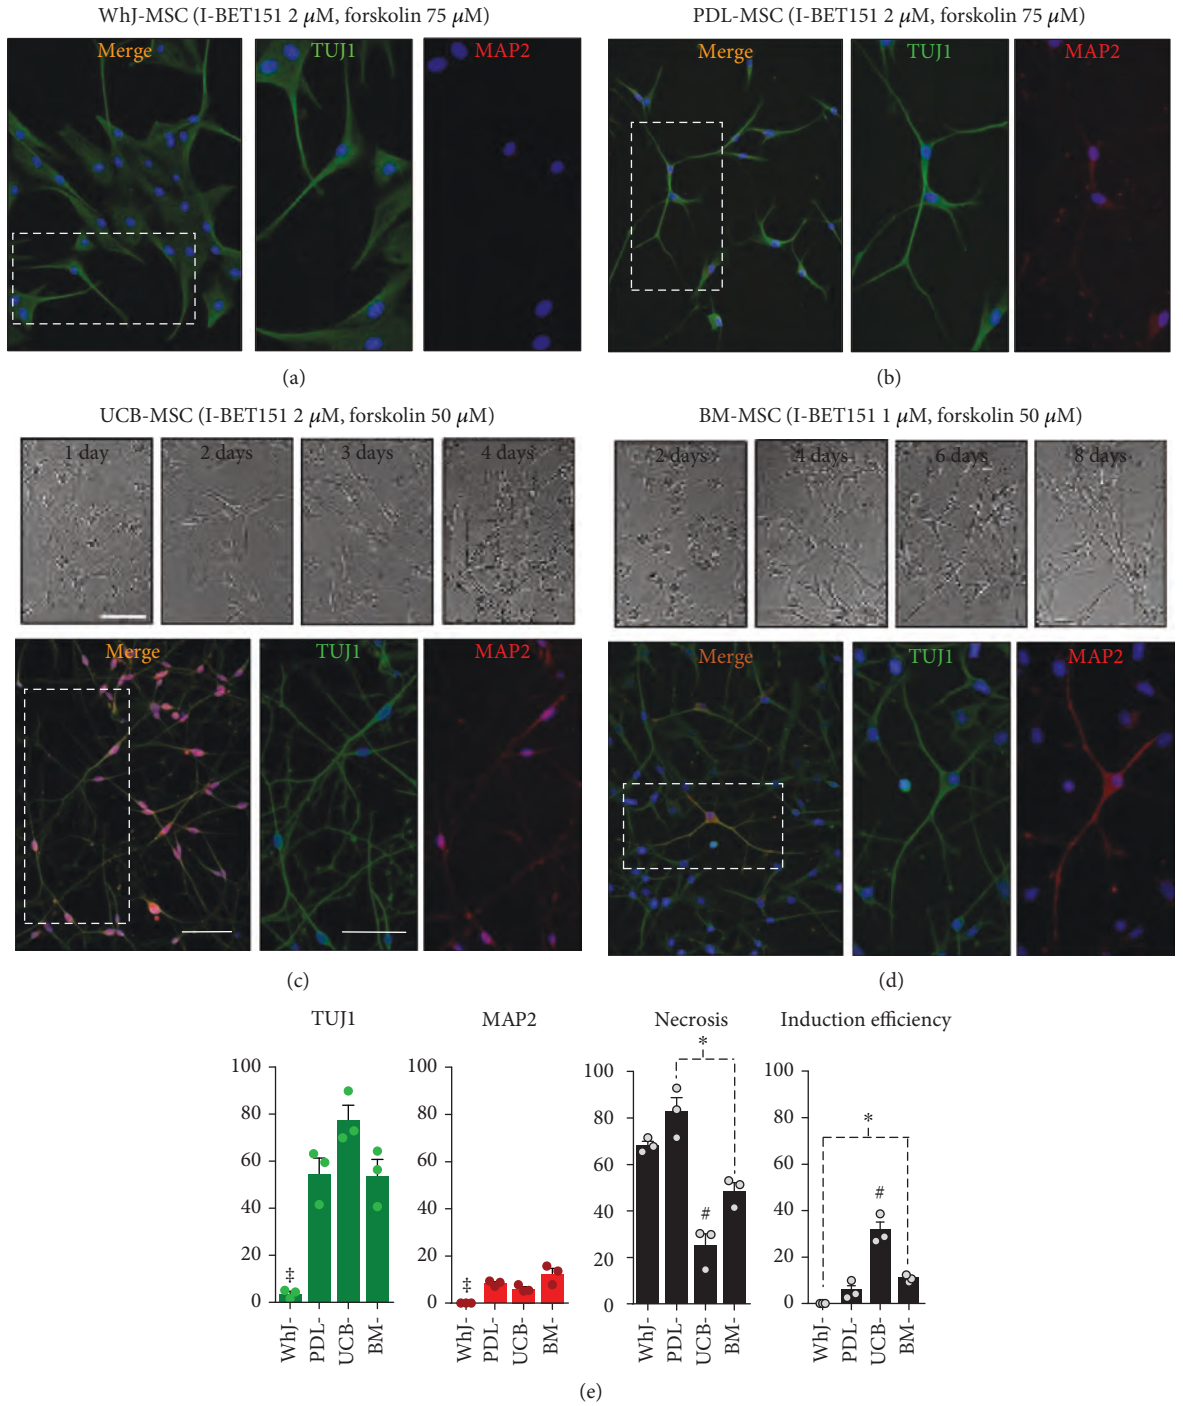

Figure 2: Effect of increasing I-BET151 and/or forskolin concentration on neuronal induction. Neuronal induction was conducted as in Figure 1, but the I-BET151 concentration was increased from 1 μM to 2 μM and/or forskolin concentration was increased from 50 μM to 75 μM. (a) Wharton's jelly cells did not show neuronal induction. (b) PDL-MSCs are shown as the representative source of an intermediate response (Supplementary Table 4), and (c, d) UCB and BM-MSCs show highly efficient neuronal induction. The morphological changes throughout culturing are shown in bright field pictures. UCB acquired neuron-like morphology after 2 days of induction, developing complex neuronal morphology at 4 days, while BM developed similar morphology after 8 days. Immunostaining shows that UCB- and BM-MSC developed complex TUJ1$^+$ and MAP2$^+$ neurite-like outgrowths. (e) Quantification of TUJ1$^+$ cells, MAP2$^+$ cells, and necrotic cells as in Figure 1. Induction efficiencies were calculated as the percentage of induced TUJ1$^+$ neuronal cells versus initial cell number at day 0. The data are presented as the mean ± SEM. Significant differences were determined using ANOVA and Tukey's test. $p < 0.05$: ‡WhJ-MSCs or $^#$UCB-MSCs vs. the other sources, and $^*p < 0.05$ between sources indicated with dotted lines. $n = 8$ from three independent biological replicates. Scale bars represent 100 μm.

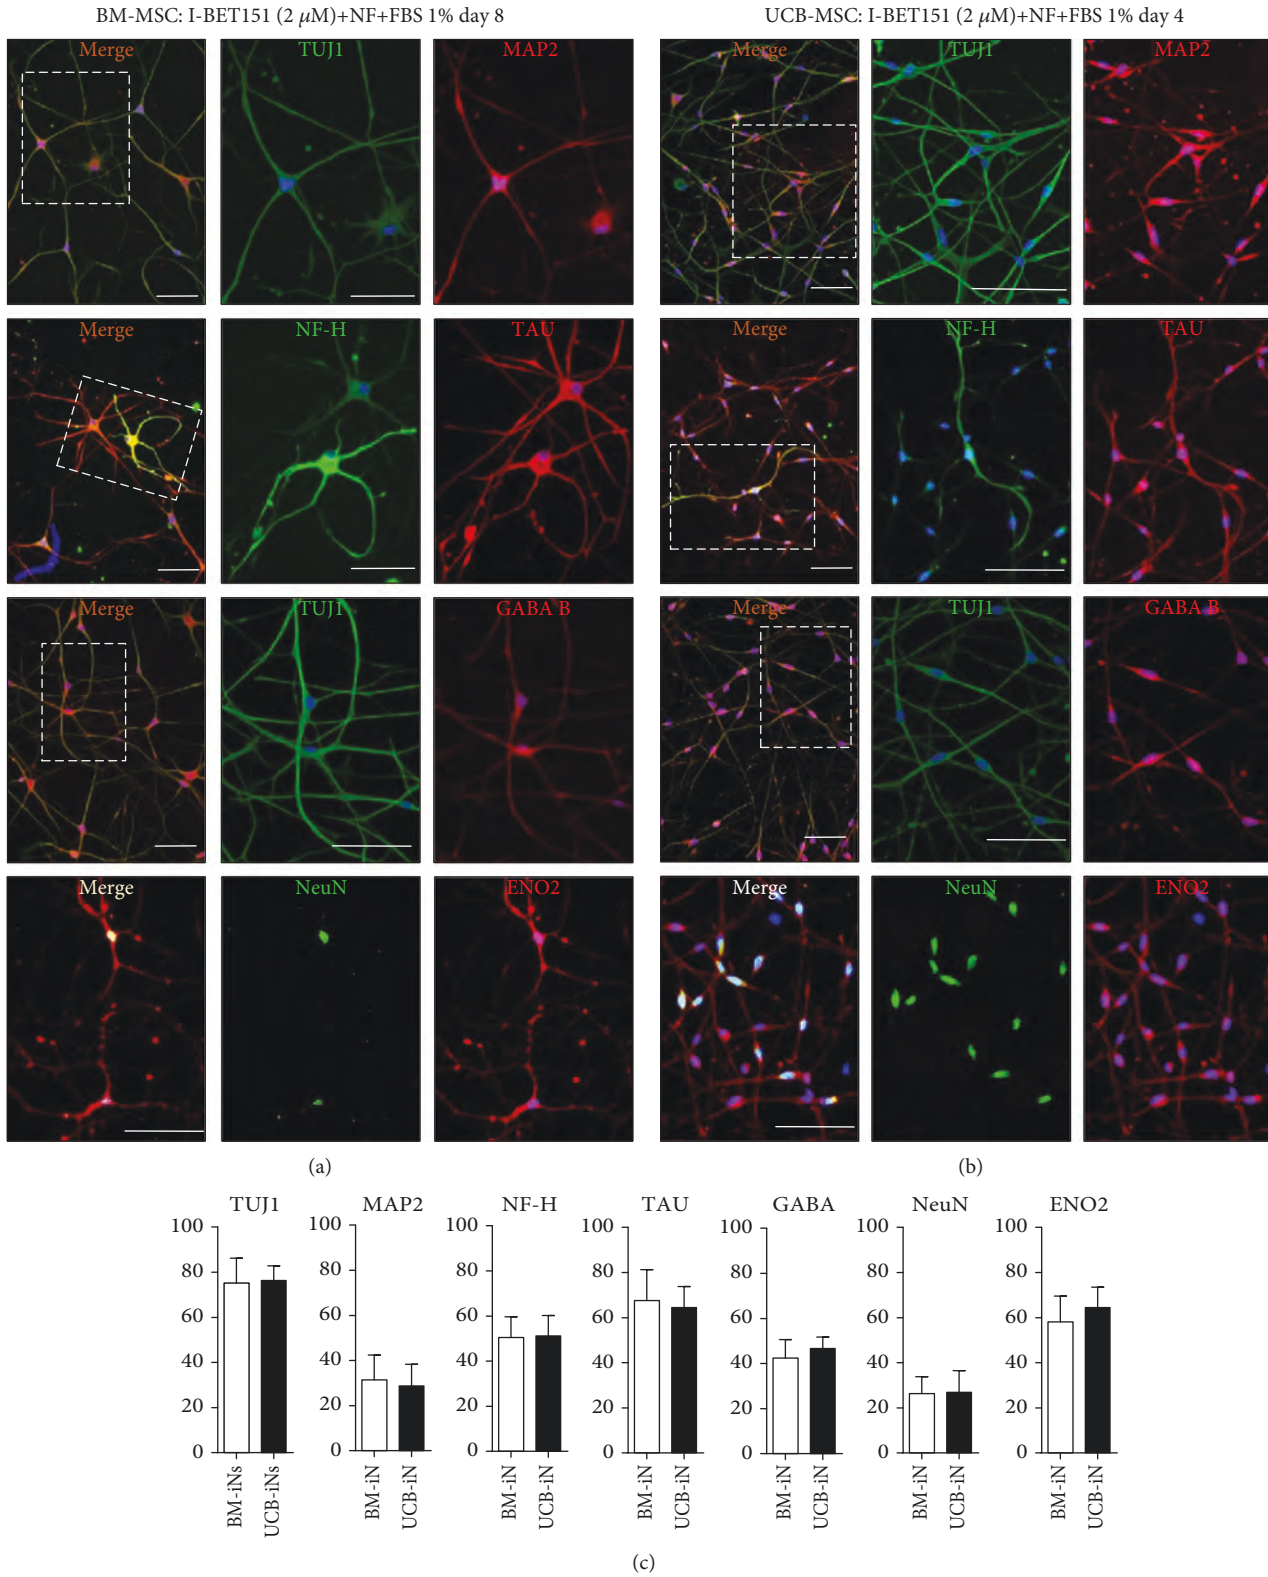

FIGURE 3: Presence of mature neuronal markers after induction with ICFRYA plus neurotrophic factors and FBS in UCB- and BM-MSCs. (a, b) Representative pictures of TUJ1, MAP2, TAU, NF-H, GABA B, ENO2, and NeuN positive cells after neuronal induction. The images on A show the merge, and the images on B and C show the individual signal for each antibody. (a) BM-MSCs after 8 days of induction and (b) UCB-MSCs after 4 days of induction. (c) Quantification of cells positive for the neuronal markers induced by the ICFRYA cocktail plus neurotrophic factors. The data are presented as the mean ± SEM ($^*p < 0.05$, Student's t-test) of $n = 8$ from three independent experiments. Scale bars represent 100 μm.

INFORME DE LABORES 2019

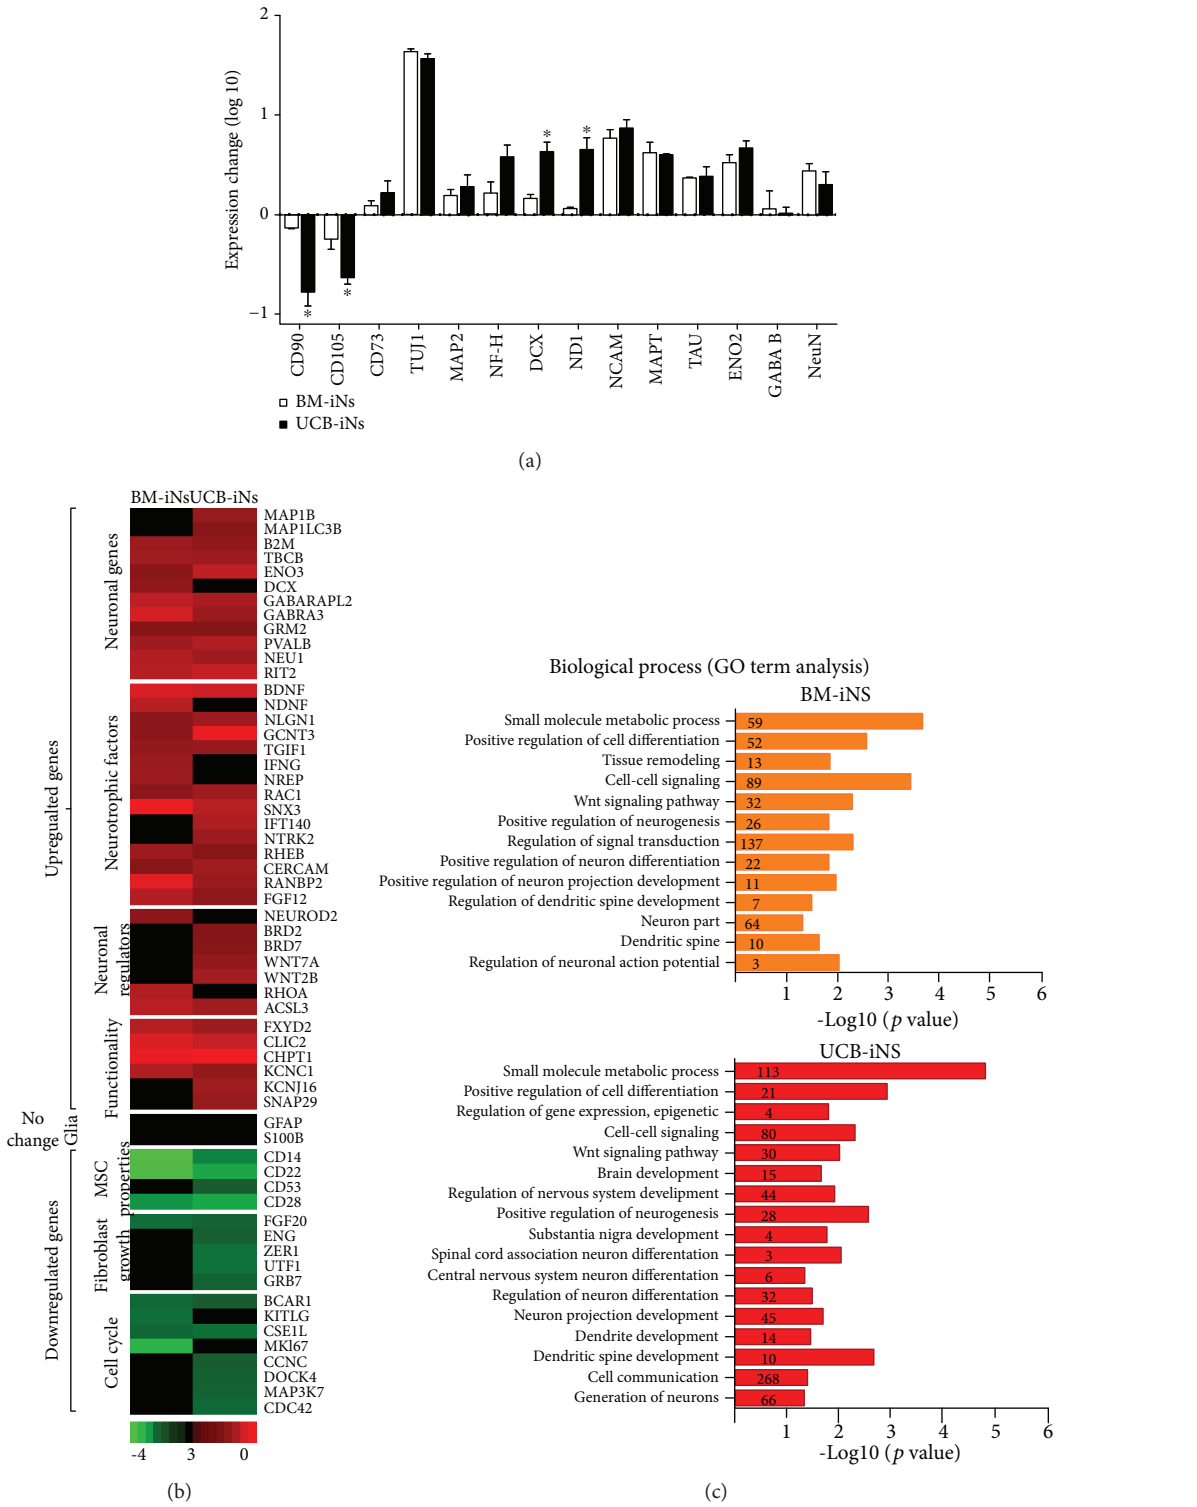

FIGURE 4: Gene expression analysis in neuron cells induced from UCB-MSCs (UCB-iNs) or BM-MSCs (BM-iNs). (a) Real-time qPCR evaluation of the expression of representative mesenchymal and neuronal genes. Data are shown as fold change versus noninduced MSCs (mean ± SEM, $n = 3$ independent experiments) ($^* p < 0.05$; Student's t-test). (b, c) Global gene expression analysis. (b) Heat map showing the change in expression of neuronal, glial, mesenchymal, and cell cycle genes from the microarray data after 8 and 4 days (BM-iNs and UCB-iNs, respectively) of induction by the ICFRYA cocktail plus neurotrophic factors. The fold change in expression was calculated by comparison with noninduced cells from the respective tissue source. Red color indicates increased gene expression while green indicates a decrease. (c) Gene Ontology (GO) analysis demonstrated that in BM-iNs and UCB-iNs, the genes with a ≥1.5-fold change in expression are implicated in the regulation of the neurogenic process. Highlighted in blue are the categories present in both BM- and UCB-INs. The number of genes implicated per category is indicated over the bars.

INFORME DE LABORES 2019

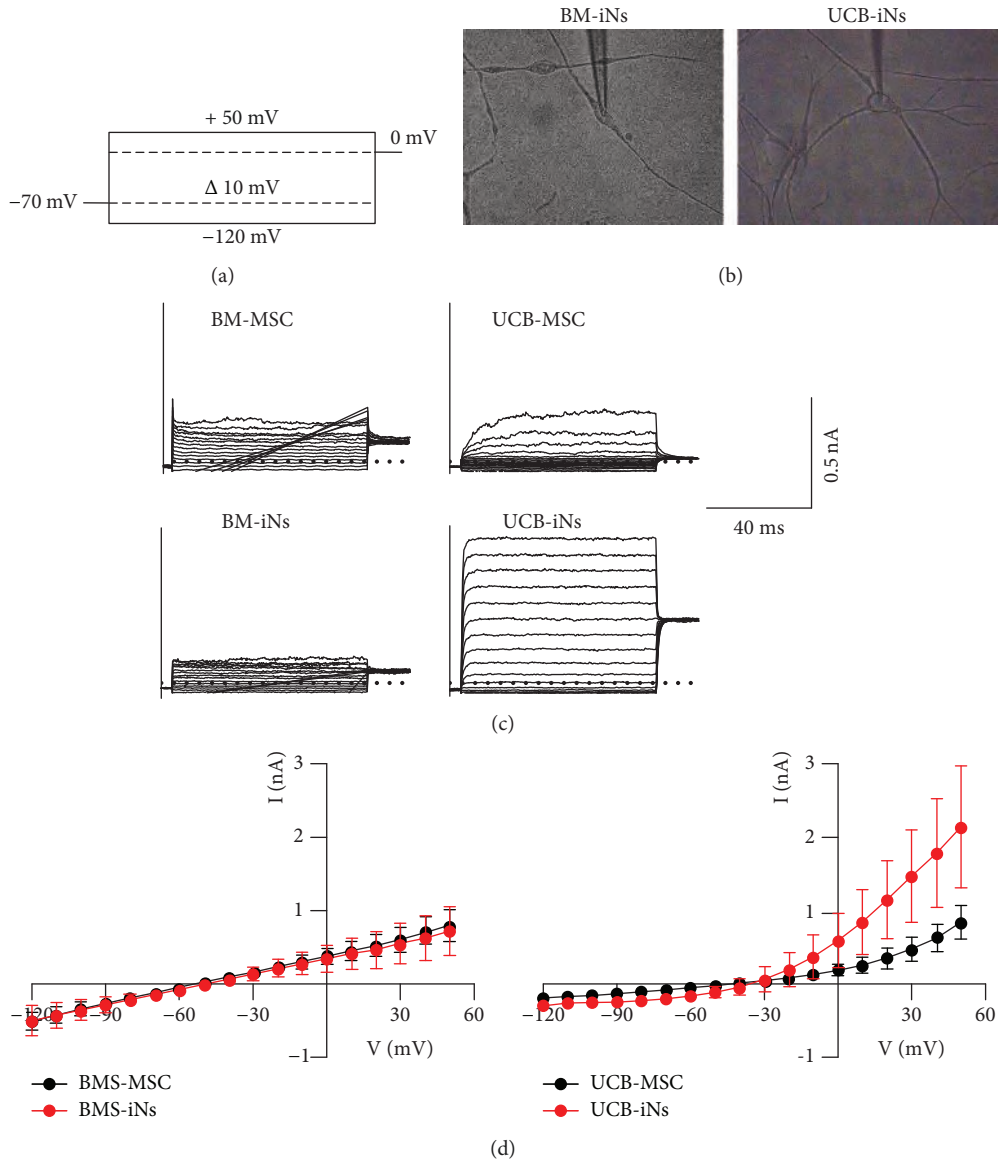

Figure 5: Ion currents in UCB-iNs and BM-iNs: (a) the voltage-clamp protocol used in all experiments (200 ms step pulses from -120 to +50 mV in 10 mV increments from a holding voltage of -70 mV); (b) iN-UCBs or iN-BMs with complex neuron-like morphology were selected for electrophysiological recordings; (c) representative traces of the currents recorded from the control or induced cells. UCB cells presented potassium-like currents, but Na^+-like currents were not detected. (d) Current-to-voltage relationships. The data are presented as the mean ± SEM.

magnitude were recorded in 6 of the 14 UCB-iNs, whereas in controls (UCB-MSCs), only small and irregular currents were recorded.

4. Discussion

Neuronal transdifferentiation without genetic manipulation from a suitable cell source is the most relevant cell replacement strategy in the brain. This strategy was approached in the present study by generating neuron-like cells from human MSCs with a small molecule cocktail.

The neuronal induction potential of neonatal and adult MSC sources was compared since some studies suggest that MSCs from neonatal sources may have greater plasticity and stemness than adult sources, possibly due to their lower degree of commitment [24, 32, 33]. This hypothesis was not confirmed in the protocol using the ICFRYA small molecule cocktail as the neuronal inductor because the best sources to generate cells with neuronal features were BM-MSCs and UCB-MSCs. In contrast, neuronal traits were not induced from WhJ-MSCs or were limited in the MSCs from dental tissues, SK-MSCs, and PLAC-MSCs.

In addition to the neuronal transdifferentiation potential, other studies have shown that MSCs from different tissues exhibit differences in other functional activities, such as cell proliferation, immune regulation properties, and trilineage differentiation potential [12, 26, 27]. The intrinsic properties of each MSC source or their tissue-specified functions may

explain the different responses; however, this has not been demonstrated. Each of the small molecules in the ICFRYA cocktail used to induce neuronal transdifferentiation regulates specific signaling pathways or epigenetic mechanisms [7, 9, 11, 34, 35]. By performing screening assays with small molecule combinations, it is possible to define whether the differences in the neuronal induction efficiency of each specific cocktail are related to the particular signaling pathway or epigenetic mechanism affected by the cocktail molecules in the different MSC sources.

Another relevant feature to be considered in the process of neuronal transdifferentiation is that cell death may function as a regulatory strategy *in vivo* to accomplish successful neurogenesis and neuronal connection in the neural network [36, 37]. During *in vitro* neuronal transdifferentiation, cell death could be a destabilization product of the process itself (activation/inhibition of metabolic pathways), resulting in the elimination of cells that could not adapt to changes. In other studies of neuronal transdifferentiation with small molecule cocktail protocols, cell viability was not examined or presented as a marker of induction efficiency [20, 21]. Here, we evaluated a possible correlation between necrosis and neuronal induction efficiency and found that the ICFRYA cocktail evoked high cell death without neuronal induction in WhJ-MSCs and high neuronal induction efficiency with low cell death in BM- and UCB-MSCs (Figure 2 and Supplement Table 4).

The relevant role of I-BET151 in the neuronal induction by small molecule cocktails has been reported for mouse fibroblasts [22], human astrocytes [20], and in our previous study on BM-MSCs [10]. This effect was extended for all the MSC sources studied here, since removing I-BET151 from the cocktail blocked the presence of neuronal properties regardless of the tissue source. I-BET151 is a regulator that disrupts the epigenetic memory of the original cell, thus favoring cell reprogramming [34, 38–40]. I-BET151 also arrests the cell cycle, a process that is associated with neuronal transdifferentiation [34, 41]; however, I-BET151 alone did not induce neuronal properties. The ICFRYA cocktail contains forskolin and dbcAMP, which increase the levels and synthesis of intracellular cAMP. CHIR99021 inhibits GSK3/beta catenin and promotes the expression of neuronal genes. RepSox is involved in the reprogramming processes that inhibit SMADS, and Y27632 inhibits ROCK to maintain cell viability [7, 35, 42]. Altogether, this suggests that the process of neuronal transdifferentiation requires the synergic regulation of pathways involved in neuronal transdifferentiation, neuronal specification, and survival.

During direct transdifferentiation, the original cells must first undergo partial dedifferentiation, allowing the repression of the lineage of origin and then differentiate into a new cell type [43, 44]; moreover, the cells have to arrest the cell cycle at the same time that the chromatin is modulated [41]. In BM-MSCs and UCB-MSCs, the ICFRYA cocktail enriched with neurotrophic factors (NT3, BDNF, and GDNF) favors the generation of cells with complex neuronal morphology, reactivity to mature neuronal markers, and upregulated neuronal genes and neuronal process. Moreover, mesenchymal markers were decreased, and genes related to mitosis, cell cycle, and mesenchymal lineage were downregulated. Considering all these criteria, the transdifferentiated cells were determined to be induced neurons generated from BM-MSCs (BM-iNs) and UCB-MSCs (UCB-iNs).

To be considered a functional iN, cells should exhibit electrophysiological activity, such as action potentials and synaptic transmission. To examine functional properties, the presence of voltage-gated potassium and sodium currents was evaluated in BM-iNs and UCB-iNs. Sodium currents were not detected, and potassium-like currents were present only in UCB-iNs. These results suggest that UCB-iNs may be in a transition phase towards functionally induced neurons. To obtain functional neurons, it is necessary to test other maturation strategies. Three-dimensional (3D) cultures have been shown to be an option to obtain functionally mature cells during the reprogramming or transdifferentiation processes of several cell types [45]. This option, together with the ICFRYA cocktail, may be a convenient strategy to generate functional iNs from MSCs.

It has been recognized that MSCs present advantages over other cell types and have a low tumorigenic risk in cell replacement therapies. Moreover, clinical studies in human and neurodegenerative animal models indicate that MSCs improve regeneration capacity and ameliorate brain injuries. Although BM-MSCs are commonly considered the "gold standard," other MSC sources are more accessible and raise fewer ethical issues. Therefore, identifying the most suitable cell type and cell source for neuronal conversion is an essential matter in cell therapy approaches for neurological disorders.

5. Conclusion

This study determines that human MSCs can be converted into transgene-free neuronal cells and establishes UCB-MSCs as the most suitable sources for undergoing neuronal transdifferentiation by a specific small molecule cocktail.

ABSTRACT

ISG15 (interferon-stimulated gene 15) exists as free ISG15 or conjugated ISG15 modifying its target proteins via ISGylation. Few proteins have been identified and studied as ISGylation targets, and their relevance is not completely clear. Here, we isolated ISG15 from MDA-MB-231 breast cancer cells using immunoprecipitation and identified non-muscle myosin IIA (NMIIA) using mass spectrometry as endogenously associated with ISG15. The identification of NMIIA as an ISG15-interacting protein was important, because levels of NMIIA mRNA were not deregulated in all breast cancers, and because our *in silico* analysis indicated that NMIIA was the target of different posttranslational modifications and had an interactome associated with cytoskeletal remodeling. Furthermore, our experimental assays of co-immunoprecipitation and immunofluorescence confirmed that ISG15 was covalently associated with NMIIA in the cytoplasm of breast cancer cells and that interferon γ (IFN-γ) increased this association without alterations in the NMIIA levels. Thus, NMIIA ISGylation is regulated by IFN-γ, and this modification may modulate its interactions with proteins that remodel the cytoskeleton, participating in the growth and progression of mammary tumors.

1. Introduction

Interferon-stimulated gene 15 (*ISG15*) encodes a small l5 kDa protein made up of two ubiquitin-like domains and the amino acid sequence LRLRGG in the C-terminal domain. This sequence has been shown to covalently bind target proteins, resulting in ISGylation, a modification that requires a system similar to ubiquitination formed by the UBE1L (E1-activating), UBCH8 (E2-conjugating), and E3 ligase enzymes such as HERC5, EFP, and HHARI. Additionally, this ISGylation system contains an enzyme to remove ISGylation, the USP18 de-ISGylase enzyme, also named UBP43 (Basters et al., 2014; Dastur et al., 2006; Feng et al., 2008; Okumura et al., 2007; Wong et al., 2006; Zou and Zhang, 2006; Kim et al., 2004; Zhao et al., 2004). Nonetheless, ISG15 can be detected when it is not covalently bound to its target proteins, designated as free ISG15. The free ISG15 form can be secreted from lymphocytes and monocytes and can be recognized by the lymphocyte function-associated antigen 1 (LFA-1) receptor to induce interferon γ (IFN-γ) release from natural killer cells (D'Cunha et al., 1996; Knight and Cordova, 1991; Swaim et al., 2017). So far, it has been proposed that protein ISGylation can interfere or collaborate with the ubiquitination pathway and/or can affect the interactions between proteins. Moreover, the majority of ISGylated proteins seem to be monoISGylated (Burks et al., 2014; Desai et al., 2006; Fan et al., 2015; Huang and Bulavin, 2014; Jeon et al., 2009; Liu et al., 2003).

With respect to the regulation of ISGylation, ISG15 is upregulated in several cancer types (Chen et al., 2016; Mao et al., 2016; Padovan et al., 2002; Satake et al., 2010; Wan et al., 2013). Moreover, type I interferons (IFN-α and IFN-β) have been shown to be inducers of *ISG15* in several cell types, and, recently, we demonstrated that IFN-γ increased free ISG15 and ISGylation levels in ERα+ and ERα− breast cancer cells (Malakhova et al., 2003; Recht et al., 1991; Tecalco Cruz and Mejia-Barreto, 2017; Tecalco-Cruz and Cruz-Ramos, 2018). IFN-γ is a unique member of type II interferons that can transduce its signal via a specific heterotetrameric receptor that activates the Janus protein tyrosine kinase (JAK)/signal transducer and activator of transcription 1 (STAT1) system to modulate the transcription of its target genes. IFN-γ has immunoregulatory functions and dual roles in some cancer types. In breast cancer, IFN-γ seems to induce cycle arrest and apoptosis, and gene signatures for interferons have been associated with the resistance to chemotherapy or endocrine therapy (Gooch et al., 2000; Legrier

INFORME DE LABORES 2019

et al., 2016; Ning et al., 2010; Niu et al., 2015).

Hence, the effects of IFN-γ on breast cancer cells are important as mammary tumors are highly heterogeneous, able to present or develop resistance to treatments, and progress to invade other tissues because of several deregulated molecular pathways, including nuclear receptors signaling (Tecalco-Cruz, 2018; Tecalco-Cruz and Ramirez-Jarquin, 2017). Furthermore, it has been suggested that free ISG15 has anti-tumor functions *in vivo*; however, downregulation of ISG15 decreases proliferation and migration of breast cancer cell lines (Burks et al., 2014, 2015; Desai et al., 2012). Nevertheless, ISGylation functions have yet to be elucidated, as only a limited number of proteins modified by ISG15 are known. Likewise, IFN-γ signaling and its relationship with specific protein modification by ISGylation in breast cancer have not been studied. Here, we identified non-muscle myosin IIA (NMIIA) as a cytoplasmic protein that is modified via ISGylation and modulated by IFN-γ in breast cancer cells.

2. Results

2.1. NMIIA is an endogenous ISG15-interacting protein in breast cancer cells

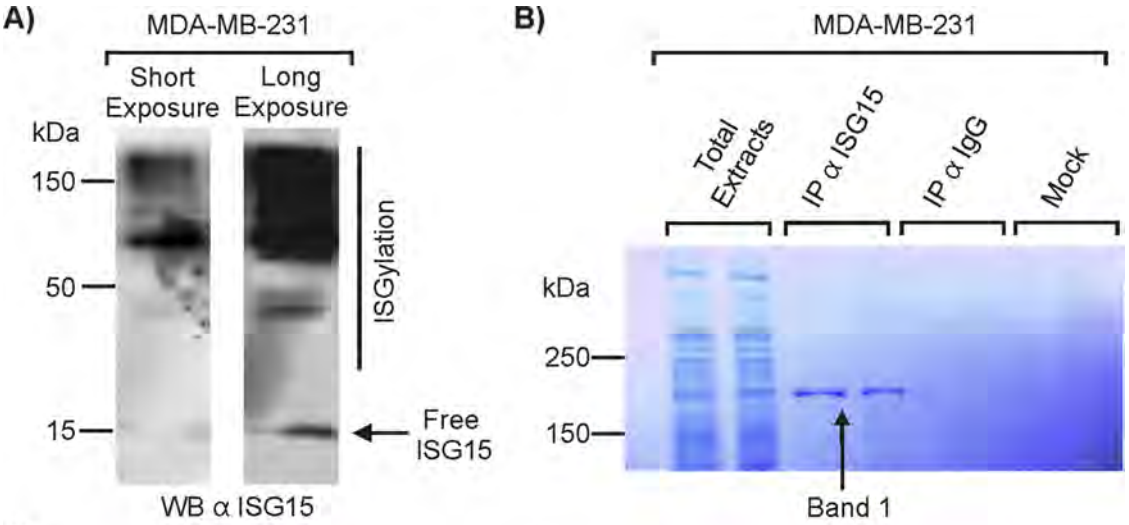
In order to identify endogenous ISGylation target proteins in breast cancer cells, we decided to use MDA-MB-231 cells as they had higher levels of conjugated ISG15 than free, as shown by western blotting (WB) against ISG15 using total extracts of these cells (Fig. 1A). These cells acted as an adequate model to identify proteins covalently conjugated to ISG15. Next, we used the total extracts from these cells to carry out an immunoprecipitation assay using a specific monoclonal antibody for ISG15. The endogenous ISG15 was immunoprecipitated and separated using sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) followed by Coomassie staining using IgG and a mock immunoprecipitation as negative controls. Among the detected bands, we selected one very dense band (approximately 250 kDa in size) to identify the ISG15-associated protein (Fig. 1B). Mass spectrometry (MS) revealed that this band corresponded to NMIIA (230 kDa in size) encoded by *MYH9*, a member of the non-muscle myosin family (NMII A, B, and C) (Fig. 1C and D). These proteins are comprised of a heavy chain encompassing a globular head domain that binds actin and adenosine triphosphate (ATP), a neck region that binds essential light chain (ELC), and a regulatory light chain (RLC) as well as a tail region that homodimerizes in a helical fashion. Light and heavy chains are conserved among NMII proteins; however, the end of the heavy chain tail is a sequence with considerable divergence between the NMII isoforms, as implicated in their regulation. NMII proteins associate with actin filaments, contracting them and forming the actomyosin complex that participates in cytoskeletal remodeling and regulation of shape, organization, polarity, and motility of the cell (Newell-Litwa et al., 2015; Ouderkirk and Krendel, 2014). Interestingly, our results indicate that only one of the NMII proteins described in humans, NMIIA, is endogenously associated with ISG15 in MDA-MB-231 breast cancer cells.

2.2. NMIIA mRNA is not deregulated in breast cancers, but NMIIA seems to be highly affected by posttranslational modifications and protein-protein interactions

Initially, we decided to explore the role of NMIIA expression in breast cancer and its regulation. We analyzed the expression of *MYH9* in normal mammary tissue and mammary tumors from patients. Using Oncomine, we selected the Curtis (2136 samples) database for this analysis and determined that *MYH9* expression was similar in breast cancers and normal conditions, as statistical analyses revealed that *MYH9* expression was not significantly different between breast cancer and normal mammary tissues (Fig. 2A). We also analyzed the reported and predicted posttranslational modifications for NMIIA using PhosphoSitePlus (PSP). Remarkably, NMIIA was a highly modified protein, mainly by phosphorylation but also through other modifications, including acetylation and ubiquitination (Fig. 2B). Using the Search Tool for the Retrieval of Interacting Genes (STRING) software, we also found proteins associated with cytoskeletal remodeling (RhoA, Ras, Cdc42, and ACTG1) in the interactome for NMIIA (Fig. 2C). Thus, *MYH9* expression was not deregulated in all mammary tumors from patients, suggesting that protein-protein interactions of NMIIA and its posttranslational modifications, including ISGylation, could be critical and interconnected in the regulation of the levels and functions of this protein.

2.3. Subcellular distribution of NMIIA and ISGylation mark in breast cancer cells

Because NMIIA has been reported as the central element of actomyosin, we first evaluated the subcellular distribution of this protein. We transfected the enhanced green fluorescent protein (EGFP)-NMIIA plasmid in AD293 cells (kidney cells with high transfection efficiency) and detected its localization in the cytoplasm using immunofluorescence (Fig. 3A). Next, we analyzed the localization of endogenous NMIIA protein in MDA-MB-231 and MCF-7 breast cancer cells using subcellular fractionation and immunofluorescence assays. NMIIA was detected mainly in the cytoplasmic fraction of these cells (Fig. 3B–D). Free ISG15 was localized in cytoplasm, and ISGylation was detected in both the nucleus and cytoplasm of these cells (Fig. 3B, C). We also performed immunofluorescence assays using anti-ISG15 and anti-NMIIA antibodies for the endogenous detection of these proteins in MDA-MB-231 and MCF-7 cells (Fig. 3D). Similarly, the results showed that NMIIA was mostly detected outside the nucleus, and ISG15 was detected in the cytoplasm and in the nucleus. Thus, NMIIA and ISG15 are principally co-localized in the cell cytoplasm as indicated by the merge of these images (Fig. 3D, E).



2.4. NMIIA is associated specifically with ISG15 in vivo

Based on our results, we evaluated whether ISG15 interacted specifically with NMIIA in *vivo*. We chose AD293 cells that had high levels of conjugated ISG15 and undetectable free ISG15 levels (Fig. 4A). Then, we used total extracts from AD293 cells transfected with EGFP-NMIIA and performed an immunoprecipitation assay to enrich endogenous conjugated ISG15 protein, followed by WB to detect EGFP-NMIIA. We determined that EGFP-NMIIA was contained in the immunoprecipitated ISG15 (Fig. 4B).

Similarly, AD293 cells were transfected with the EGFP-NMIIA plasmid. We performed an immunoprecipitation experiment for conjugated ISG15 and used anti-NMIIA antibody for the WB, resulting in detection of the exogenous (~260 kDa) and endogenous (~230 kDa) form of NMIIA in the transfected cells. Only endogenous NMIIA was observed in non-transfected cells, indicating a specific interaction between these proteins (Fig. 4C). Interestingly, ISG15-NMIIA interaction resulted in a shifted band compared to the band corresponding to NMIIA protein detected in total extracts by WB, suggesting that the association of these proteins occurred in a covalent manner.

2.5. NMIIA is an ISGylated protein in breast cancer cells

Based on the specific interaction between ISG15 and NMIIA, we verified this interaction in an endogenous context of breast cancer cells. We performed an immunoprecipitation assay using monoclonal antibody against ISG15 as well as IgG and/or mock immunoprecipitation as negative controls, followed by WB for NMIIA to demonstrate the specific endogenous binding between ISG15 and NMIIA in MDA-MB231 and MCF-7 cells (Fig. 5A). ISG15-NMIIA interaction (IP ISG15 WB NMIIA) resulted in a shifted band compared to the band of NMIIA protein detected by WB using total extracts (input) from breast cancer

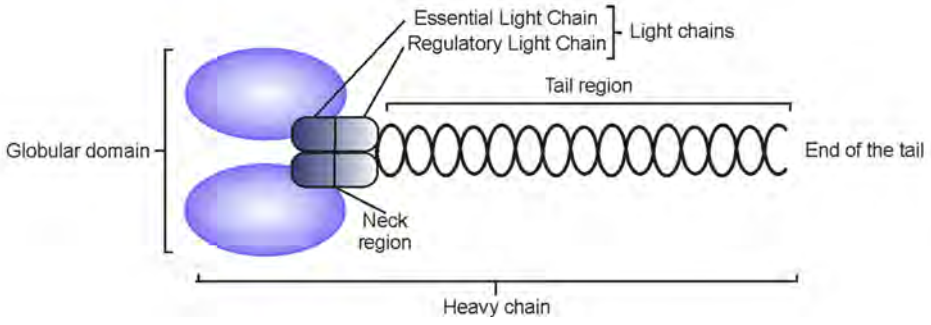

Fig. 1. Identification of non-muscle myosin IIA (NMIIA) as a putative interferon-stimulated gene 15 (ISG15)-associated protein.
A) Total extracts from MDA-MB-231 cells were analyzed by western blotting (WB) against interferon-stimulated gene 15 (ISG15). B) Coomassie staining of ISG15-immunoprecipitated complexes from MDA-MB-231 lysates. A band approximately 250 kDa in size was excised for analysis by mass spectrometry. Samples were analyzed in duplicate. C) ISG15-interacting protein identified by mass spectrometry is shown in the table. The identified peptides are indicated in green (bold) on non-muscle myosin IIA (NMIIA) protein sequence. NMIIA peptide coverage was 20%. D) Structural organization of NMIIA identified protein.

cells, indicating the covalent association between these proteins (Fig. 5A). The same assay was performed using cytoplasmic and nuclear extracts from these cells, and the interaction between ISG15 and NMIIA was strongly detected in the cytoplasm of these cells (Fig. 5B). Thus, we validated the endogenous interaction indicated by MS between ISG15 and NMIIA protein in breast cancer cells.

To discard the hypothesis of a non-covalent interaction between free ISG15 and NMIIA, we used MCF-7 cells, where both conjugated ISG15 and free ISG15 could be detected (Fig. 5C). We performed a reciprocal immunoprecipitation through the NMIIA protein immunoprecipitation, followed by a WB against ISG15 (Fig. 5D). Free ISG15 was detected in the total extracts (input); however, free ISG15 was not present in the immunoprecipitated NMIIA, suggesting that the interaction between ISG15 and NMIIA did not occur in a non-covalent manner but covalently via ISGylation. As control, the efficiency of NMIIA immunoprecipitation was tested, and the covalent interaction between ISG15 and NMIIA in these cells was confirmed (Fig. 5D bottom). These results indicate that ISG15 protein is covalently associated with NMIIA.

2.6. IFN-γ modulates NMIIA ISGylation in breast cancer cells

We previously showed that IFN-γ increased ISGylation levels in breast cancer cells; therefore, we sought to determine whether NMIIA ISGylation increased by treatment with IFN-γ. Using total extracts from MDA-MB-231 cells treated with IFN-γ or left untreated, we performed an ISG15 immunoprecipitation. The Coomassie staining showed that the band identified as NMIIA by MS was increased by IFN-γ treatment (Fig. 6A). Furthermore, we demonstrated that the specific interaction between ISG15 and NMIIA in MDA-MB-231 cells increased by IFN-γ treatment using WB with an anti-NMIIA antibody (Fig. 6B). This interaction was also enhanced by IFN-γ treatment in MCF-7 cells (Fig. 6C). Although IFN-γ enhanced the ISG15 and ISGylation levels after 24 h, no changes in the amount of NMIIA were detected in response to IFN-γ treatment in MDA-MB-231 and MCF-7 cells under these conditions (Fig. 6D and E)., suggesting that the availability of NMIIA was not affected by IFN-γ-induced ISGylation (Fig. 6F and G).

ISGylation has been reported to be associated with an increase or decrease in the protein stability and also in the protein-protein interactions. As NMIIA levels were not altered by IFN-γ-increased ISGylation, this modification could act affecting the interactions of NMIIA, many of them linked to cytoskeletal (Fig. 2C). For this reason, we performed an analysis using STRING software, evidencing an interconnection between the IFN-γ signaling pathway, ISGylation, and NMIIA, in which actin was the common protein that connected these pathways, similar to IQ motif containing GTPase activating protein 1 (IQGAP1), a cytoskeleton protein that has been reported to be a ISGylated target (Cerikan and Schiebel, 2017; Cerikan et al., 2016). Thus, our study demonstrated a new connection generated by the ISGylation of NMIIA modulated by IFN-γ. Moreover, our study suggests that IFN-γ may regulate the ISGylation of many other cytoskeleton proteins participating in the cytoskeletal dynamic in breast cancer cells (Fig. 7.

2.7. IFN-γ/ISG15-NMIIA-actin axis in cytoskeleton organization is important in modulation of the morphology of breast cancer cells

ISG15 conjugation to NMIIA had no effect on its stability (Fig. 6), but a functional interactome between NMIIA, cytoskeletal proteins and the IFN-γ/ISG15 route was suggested by our data (Fig. 7). Additionally, NMIIA interacts with F-actin to modulate cytoskeletal organization (Ouderkirk and Krendel, 2014). Based on these data, we considered that covalent interaction between ISG15 and NMIIA might have an effect on the cell morphology. Presently, immunofluorescence assays revealed greater elongation of MDA-MB-231 cells treated with IFN-γ, with an increasing co-localization of NMIIA with ISG15 in the cytoplasmic and perinuclear regions, in comparison with cells that were not treated with IFN-γ (Fig. 8A). Furthermore, co-localization of NMIIA and F-actin in the cytoplasm and at the edge of cells in response to IFN-γ was evident (Fig. 8B). Co-localization of NMIIA, ISG15, and F-actin occurred mainly in the cytoplasm of MDA-MB-231 cells treated with IFN-γ (Fig. 8C),

INFORME DE LABORES 2019

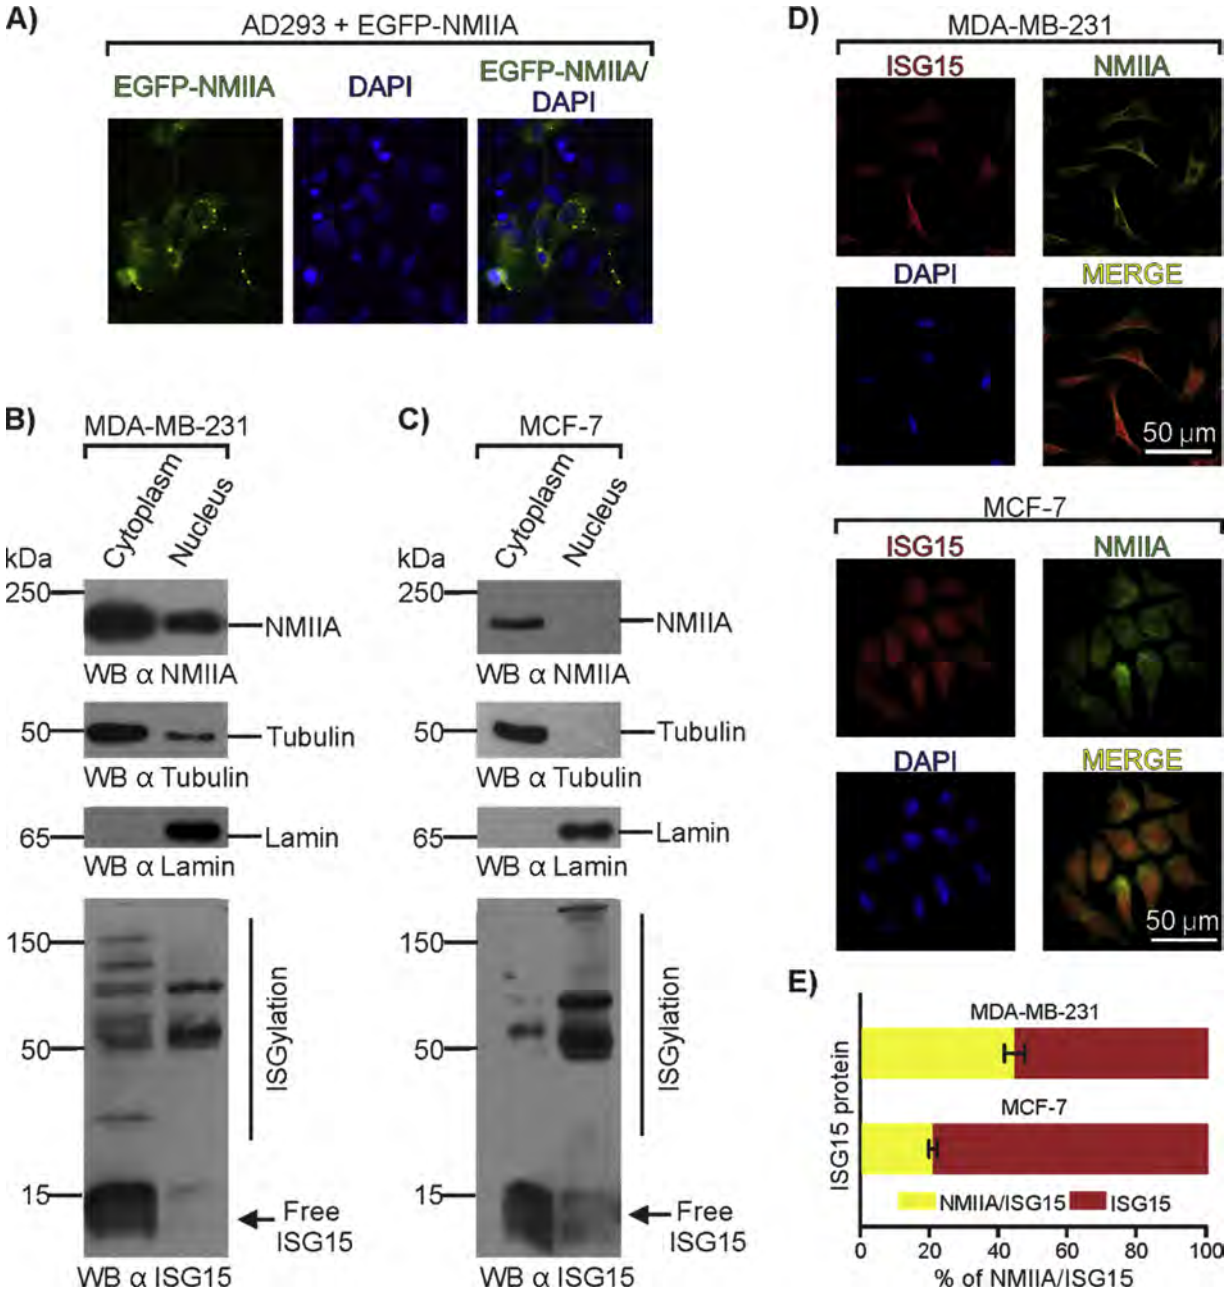

Fig. 3. Non-muscle myosin IIA (NMIIA) is a cytoplasmic protein associated with interferon-stimulated gene 15 (ISG15) in breast cancer cells.
A) Enhanced green fluorescent protein-non-muscle myosin IIA (EGFP-NMIIA) was detected in cytoplasm of AD293 cells. B) and C) Cytoplasmic and nuclear extracts from MDA-MB-231 and MCF-7 cells were analyzed by western blotting (WB) against NMIIA using tubulin and lamin as controls for cytoplasm and nucleus, respectively. D) Evaluation of subcellular distribution of interferon-stimulated gene 15 (ISG15) and NMIIA protein in MDA-MB-231 and MCF-7 using immunofluorescence assay. E) Analysis of co-localization for ISG15 and NMIIA in breast cancer cells.

suggesting that IFN-γ acting through ISG15 may be important to regulate the functional association of NMIIA and F-actin in the cytoplasm of breast cancer cells.

We decided to evaluate whether morphological changes induced by IFN-γ were associated with protein ISGylation (as ISGylated NMIIA), and whether this occurred in other breast cancer cell types. To this end, we examined MCF-7 cells, because they maintain an epithelial morphology, in contrast to MDA-MB-231 cells that present a mesenchymal-like morphology. Initially, we transfected these cells with EGFP-NMIIA or EGFP-NMIIA with ISG15, E1 (UBE1L), and E2 (UbcH8) ISGylation enzymes. ISGylation was increased when ISG15 and the ISGylation system was transfected (Fig. 8D). Under this condition, the immunoprecipitation of ISG15 and WB for NMIIA revealed the enhanced association of ISG15 with NMIIA, as well as EGFP-NMIIA (Fig. 8D bottom). Thus, ISG15-NMIIA interaction was increased when ISGylation enhanced, and MCF-7 cells displayed stress fibers with discrete morphological changes (Fig. 8E and 8F). Likewise, co-localization of NMIIA-ISG15 and NMIIA-F-actin was detected under the condition of ISGylation, in a manner similar to the co-localization of these proteins in MDA-MB-231 cells treated with IFN-γ (Fig. 8E and F). The results indicate that NMIIA ISGylation contributes to the changes in the morphology associated with F-actin organization in breast cancer cells.

2.8. NMIIA-ISG15 interaction occurs during spreading of breast cancer cells

Cell spreading is a critical event that involves actin polymerization

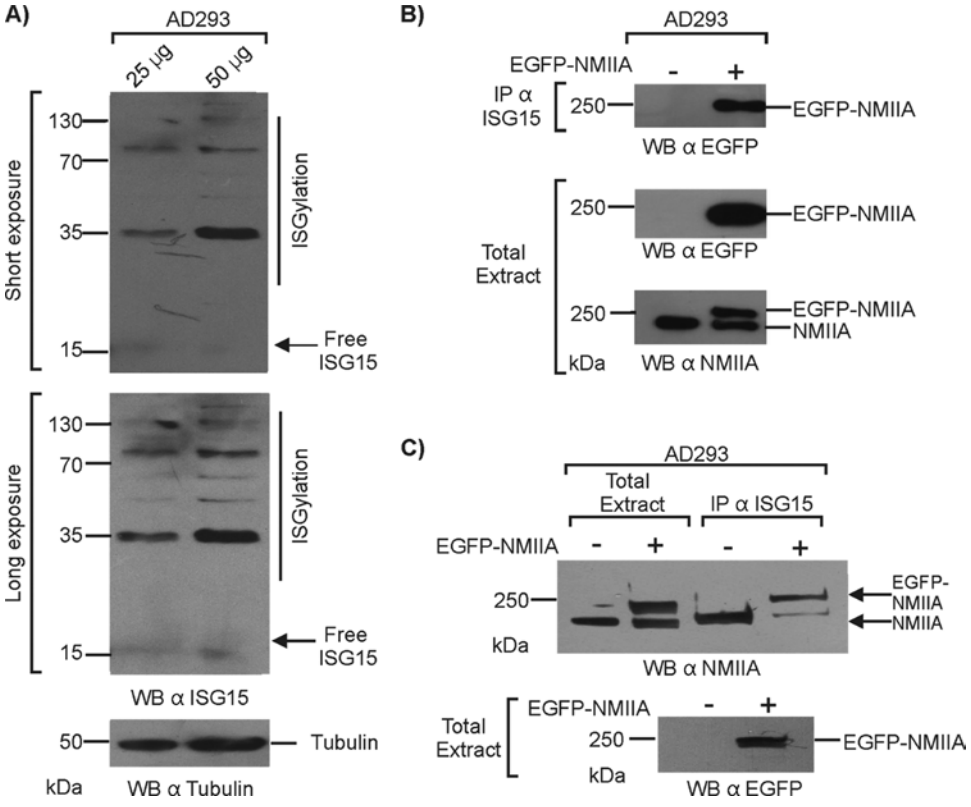

Fig. 4. Non-muscle myosin IIA (NMIIA) is specifically associated with interferon-stimulated gene 15 (ISG15).
A) Western blotting (WB) for interferon-stimulated gene 15 (ISG15) using 25 and 50 µg from AD293 cell total extracts. B) AD293 cells were transfected with or without enhanced green fluorescent protein-non-muscle myosin IIA (EGPF-NMIIA). After 48 h, the total extracts were used for ISG15 immunoprecipitation and WB for EGFP or C) WB for NMIIA.

to generate a cellular contact area with the extracellular matrix or substrate. NMII proteins participate differently in the generation of protrusive forces that regulate cell spreading for cell motility. NMIIA and NMIIB are recruited in the lamellar margin during the spreading of MDA-MB-231 breast cancer cells participating in the regulation of this process (Betapudi, 2010; Betapudi et al., 2006)

Since cell spreading is a fundamental NMII-regulated event, we examined whether NMIIA-ISG15 interaction can occur in the spreading

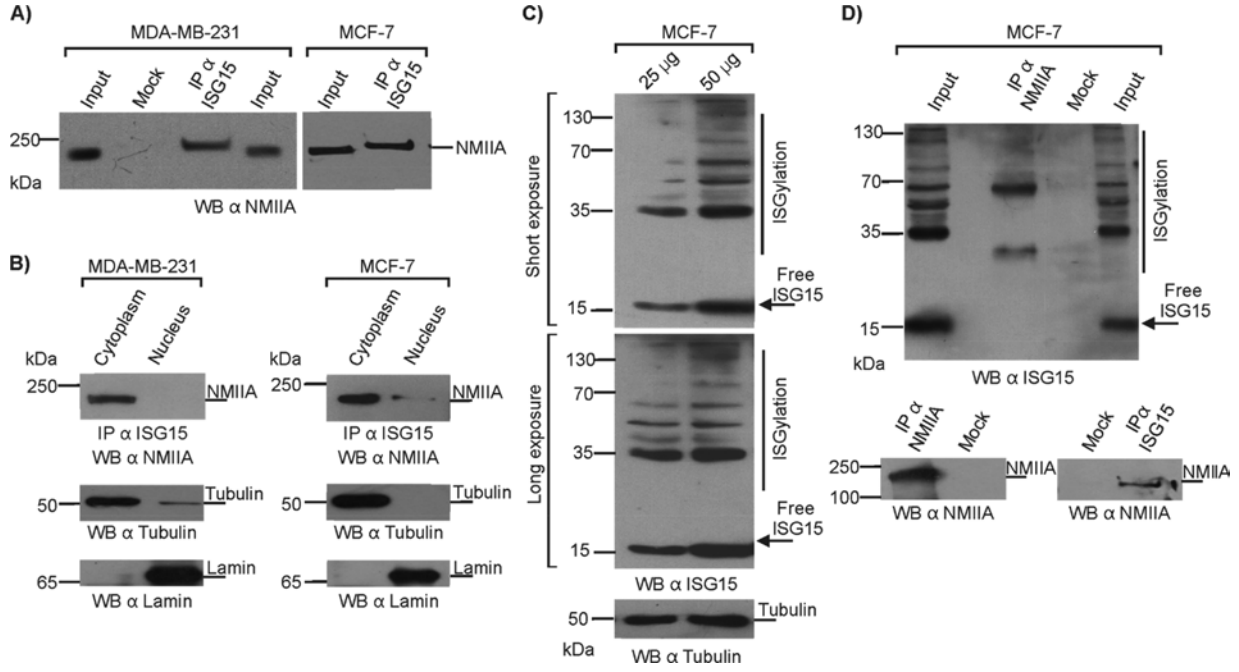

Fig. 5. Interferon-stimulated gene 15 (ISG15) is covalently associated with non-muscle myosin IIA (NMIIA) in breast cancer cells.
A) Interferon-stimulated gene 15 (ISG15) was immunoprecipitated from MDA-MB-231 and MCF-7 cell total extracts, and western blotting (WB) with anti-non-muscle myosin IIA (NMIIA) was performed. B) Cytoplasmic and nuclear fractions from MDA-MB-231 and MCF-7 cells were used for ISG15 immunoprecipitation followed by WB for NMIIA. Anti-tubulin and anti-lamin were used as controls for the cytoplasmic and nuclear extracts. C) WB for ISG15 using 25 and 50 µg from MCF-7 cell total extracts. D) Endogenous NMIIA immunoprecipitation from MCF-7 followed by WB for ISG15 was analyzed on 12% gels. Bottom: endogenous NMIIA and ISG15 immunoprecipitation followed by WB for NMIIA using total extract from MCF-7 cells.

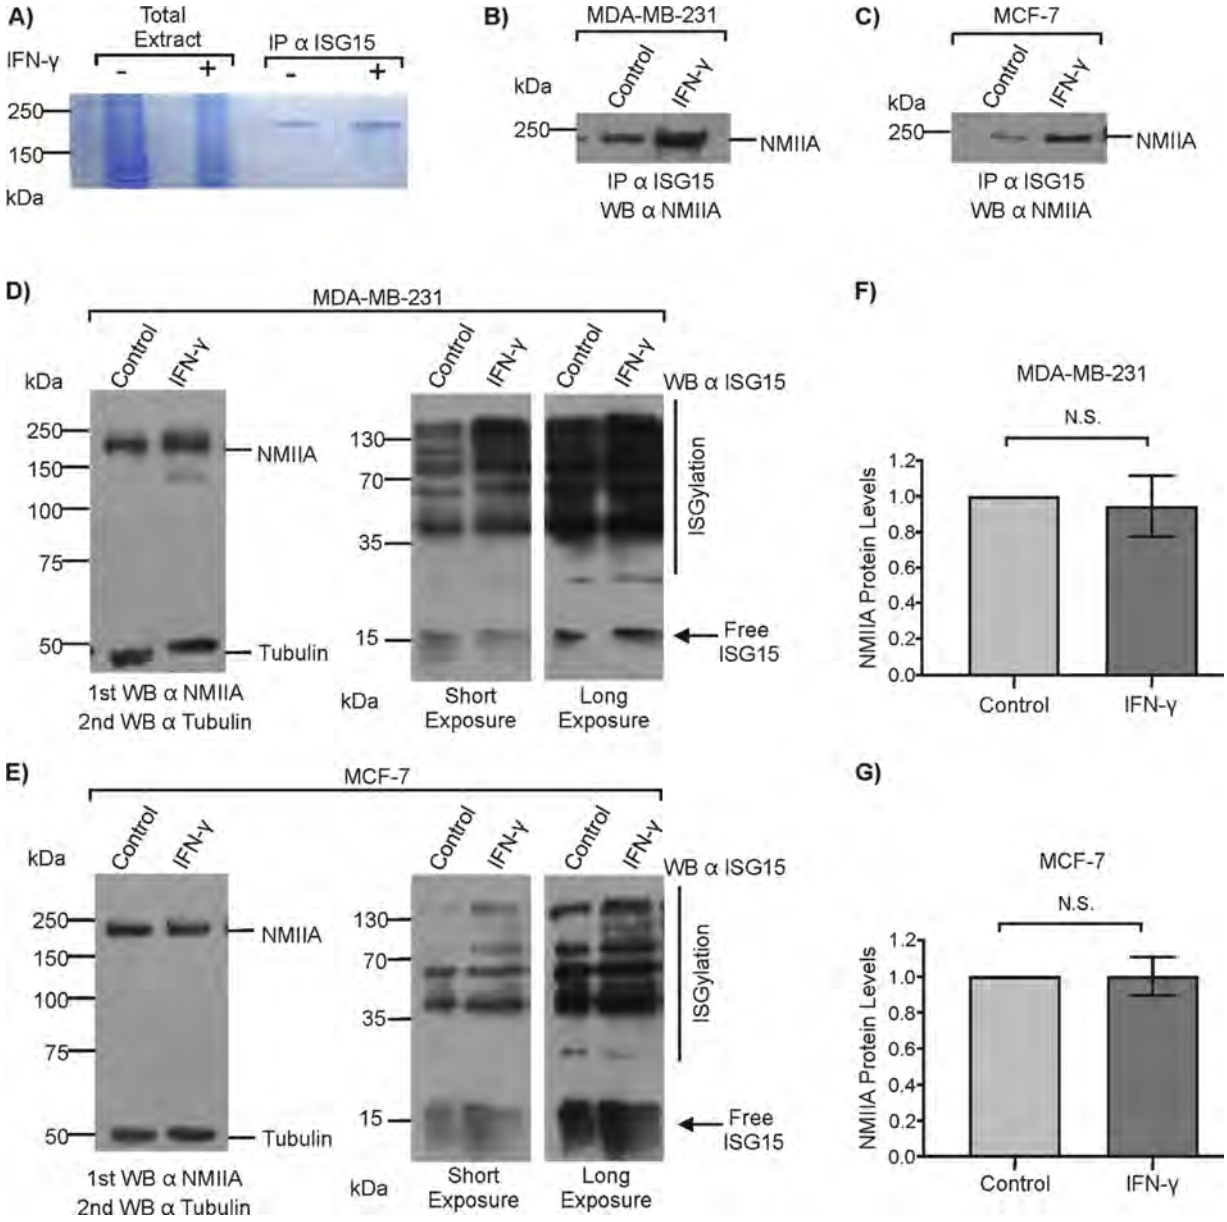

Fig. 6. Association between interferon-stimulated gene 15 (ISG15) and non-muscle myosin IIA (NMIIA) is increased by interferon γ (IFN-γ) treatment in breast cancer cells.

A) Coomassie staining of interferon-stimulated gene 15 (ISG15) immunoprecipitated complexes from MDA-MB-231 lysates treated or not treated with interferon γ (IFN-γ) (100 ng/mL) for 24 h. The band approximately 230 kDa in size that corresponds to NMIIA is enhanced in response to IFN-γ treatment. B) Endogenous ISG15 immunoprecipitation followed by western blotting (WB) for non-muscle myosin IIA (NMIIA), using total extract from MDA-MB-231 and C) MCF-7 cells treated or not treated with IFN-γ (100 ng/mL). D) and E) Total extract MDA-MB-231 and MCF-7 cells treated or not treated with IFN-γ (100 ng/mL) were analyzed by WB for NMIIA and ISG15, using tubulin as a loading control. F) and G) Densitometry of NMIIA protein levels in MDA-MB-231 and MCF-7 treated or not treated with IFN-γ. Not significant was indicated as N.S.

of MDA-MB-231 cells. We seeded cells in wells that were uncoated or coated with the fibronectin (FN) extracellular protein for 30 and 120 min. The early stage of spreading was detected at 30 min, whereas a well-defined spreading was observed at 120 min in the MDA-MB-231 cells seeded on FN in comparison with those seeded in uncoated wells (Fig. 9A and B). Since the later stages of cell spreading involve actin polymerization and myosin contraction, we analyzed the co-localization of NMIIA and ISG15, 120 min after seeding of MDA-MB-231 cells on glass treated with FN. ISG15 displayed mainly an extranuclear distribution that included its presence in lamellar margin, whereas NMIIA was detected completely as an extranuclear protein enriched in the lamellar margin. The collective results indicated that both proteins can co-localize during cell spreading, suggesting that ISG15-NMIIA association can occur in the marginal spreading lamellar region of MDA-MB-231 cells, as well as in more central regions in the cytoplasm of these cells during this event (Fig. 9C, arrowheads). Our results indicate that ISG15 and, NMIIA co-localize in the cytoplasm and lamellar region, and suggest that the association between these proteins may be critical in NMIIA-driven protrusive spreading events, in addition to the formation of focal adhesion complexes with the extracellular matrix.

3. Discussion

In contrast to other posttranslational modifications, ISGylation has not been extensively studied. This modification occurs when ISG15, an ubiquitin-like protein, is covalently bound to target proteins through an

INFORME DE LABORES 2019

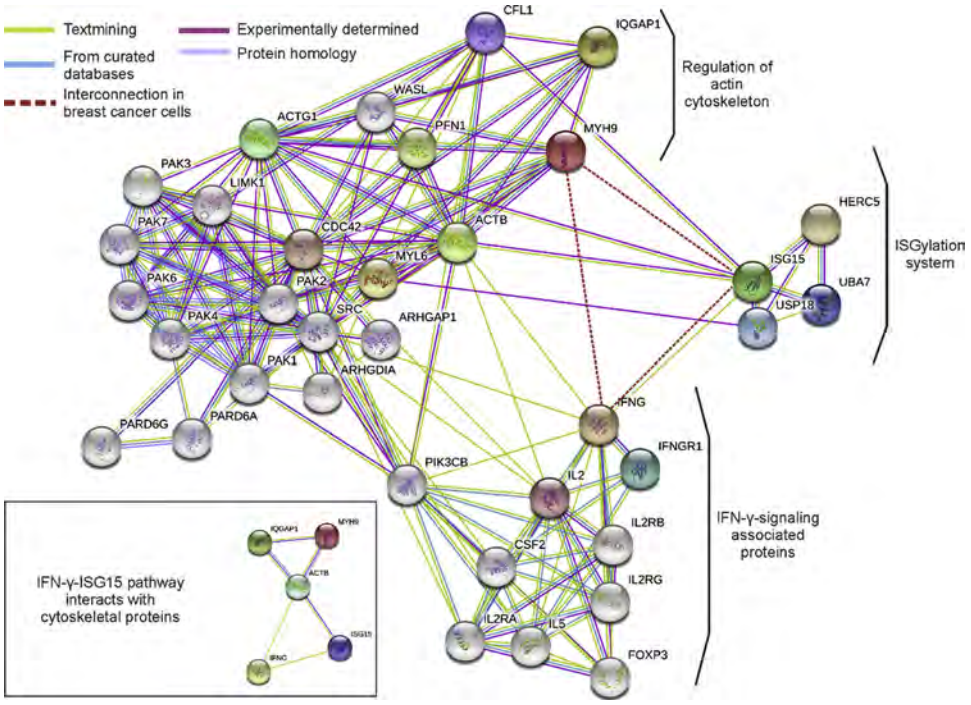

Fig. 7. Interconnection between interferon γ (IFN-γ) pathway, ISGylation system, and non-muscle myosin IIA (NMIIA).
Relationship between interferon γ (IFN-γ), interferon-stimulated gene 15 (ISG15), NMIIA. Analysis using STRING. Known interactions from curated databases, text mining, experimental determination, and protein homology are indicated in blue, green, purple, and dark blue lines, respectively. Connection of functional interactomes for IFN-γ, ISGylation system, NMIIA, and other proteins linked to cytoskeleton dynamic, is shown. Dashed red line indicates the interconnections suggested by our data.

enzymatic system similar to ubiquitination. A small number of candidate proteins have been proposed as ISGylation targets, and an even smaller number of ISGylated proteins have been studied mechanistically and functionally, including FILAMIN B, proliferating cell nuclear antigen (PCNA), IQGAP1, PARKIN, and C-terminus of Hsc70-interacting protein (CHIP). ISG15-dependent regulation of these proteins has important biological implications through modulating the stability and/or interactions of these proteins. Moreover, poly-ISGylation is not common as most proteins are mono or di-ISGylated (Jeon et al., 2009; Cerikan and Schiebel, 2017; Im et al., 2016; Park et al., 2014; Yoo et al., 2018).

ISG15 is upregulated in several cancer types, including breast cancer that has a characteristic profile of free ISG15 and ISGylation levels increased by IFN-γ (Tecalco Cruz and Mejia-Barreto, 2017; Tecalco-Cruz and Cruz-Ramos, 2018). However, proteins identified as ISGylation targets in this cancer are currently not studied. Here, we showed that NMIIA was endogenously associated with ISG15 in breast cancer cells using MS. This protein of high molecular weight (230 kDa) is important, as it is an element of actomyosin, participating in the cytoskeletal organization. Interestingly, our analysis indicated that *MHY9* expression was not altered in all mammary tumors compared to normal tissue, suggesting that posttranslational modifications might play a central role in regulating the NMIIA function. Bioinformatics analyses also showed many target sites in NMIIA for several different modifications that appeared to be critical in breast cancer. For example, NMIIA phosphorylation has been related to the contraction of actin filaments in the formation of protrusions and migration (Dulyaninova et al., 2007).

We identified NMIIA as an ISG15-interacting protein. This interaction occurred covalently in breast cancer cells. The results showed a migration for the band corresponding to ISG15-NMIIA interaction, revealing a band discretely higher than the detected band for NMIIA in total extracts. Our result was also validated by several co-immunoprecipitation assays using cell lines with high levels of conjugated ISG15. However, free ISG15 was not detectable, suggesting that proteins associated with ISG15 in these cells were ISGylated. In addition, our results are reinforced in part by a previous report that suggests that one of the several candidate proteins of ISGylation is NMIIA, confirming this covalent interaction in a non-endogenous system in 293T cells (Giannakopoulos et al., 2005). Thus, we showed an endogenous covalent association between ISG15 and NMIIA in breast cancer cells and demonstrated that this ISGylation of NMIIA was positively regulated by IFN-γ.

What is the function of ISGylation? It is a question not easily to understand so far, since this modification has been related to increased or decreased protein stability, and with stability-independent actions as the modulation of protein-protein interactions. Importantly, it has been reported that the NMIIA modification by monoubiquitination regulates its protein-protein interactions more than its stability or other functional aspects (Li et al., 2016). This is relevant because we show that the interaction between ISG15 ubiquitin-like protein and NMIIA in response to IFN-γ treatment has no effect on the abundance of this myosin but may affect its association with its protein partners. This observation is also supported by the fact that ISGylation alters some protein-protein interactions. For instance, FILAMIN B that binds actin and connects actin filaments to the cell membrane is also a scaffold for IFN-β signaling. Interestingly, IFN-β induces FILAMIN B ISGylation, and as a result, Ras-related C3 botulinum toxin substrate 1 (RAC1), MEKK1, and MKK4 are dissociated from FILAMIN B, thus blocking the activation of c-Jun N-terminal kinases (JNK) signaling. This occurs without any changes in FILAMIN B stability (Jeon et al., 2009). Moreover, ISGylation seems to be an important regulator of cytoskeleton dynamic as other proteins that participate in this process like IQGAP1 are modulated by this modification (Cerikan and Schiebel, 2017; Cerikan et al., 2016).

Hence, ISGylation is associated with stability and degradation of some proteins but also acts as a regulator of interactions between proteins. Therefore, NMIIA ISGylation may participate in modulating protein-protein interactions. The interactome analysis of NMIIA showed that many of its protein partners were related to cytoskeletal proteins and/or signaling and regulation of the actin cytoskeleton. Thus, NMIIA ISGylation induced by IFN-γ may affect the association between NMIIA and other cytoplasmic proteins involved in cytoskeletal remodeling. Furthermore, our data suggest that IFN-γ increases ISG15 levels and the ISGylation of its target proteins, including NMIIA. For this reason, the transfection of the ISGylation system also promoted an increase in the ISG15-NMIIA association. This association was apparent in the cytoplasm and perinuclear region of breast cancer cells. The increase of

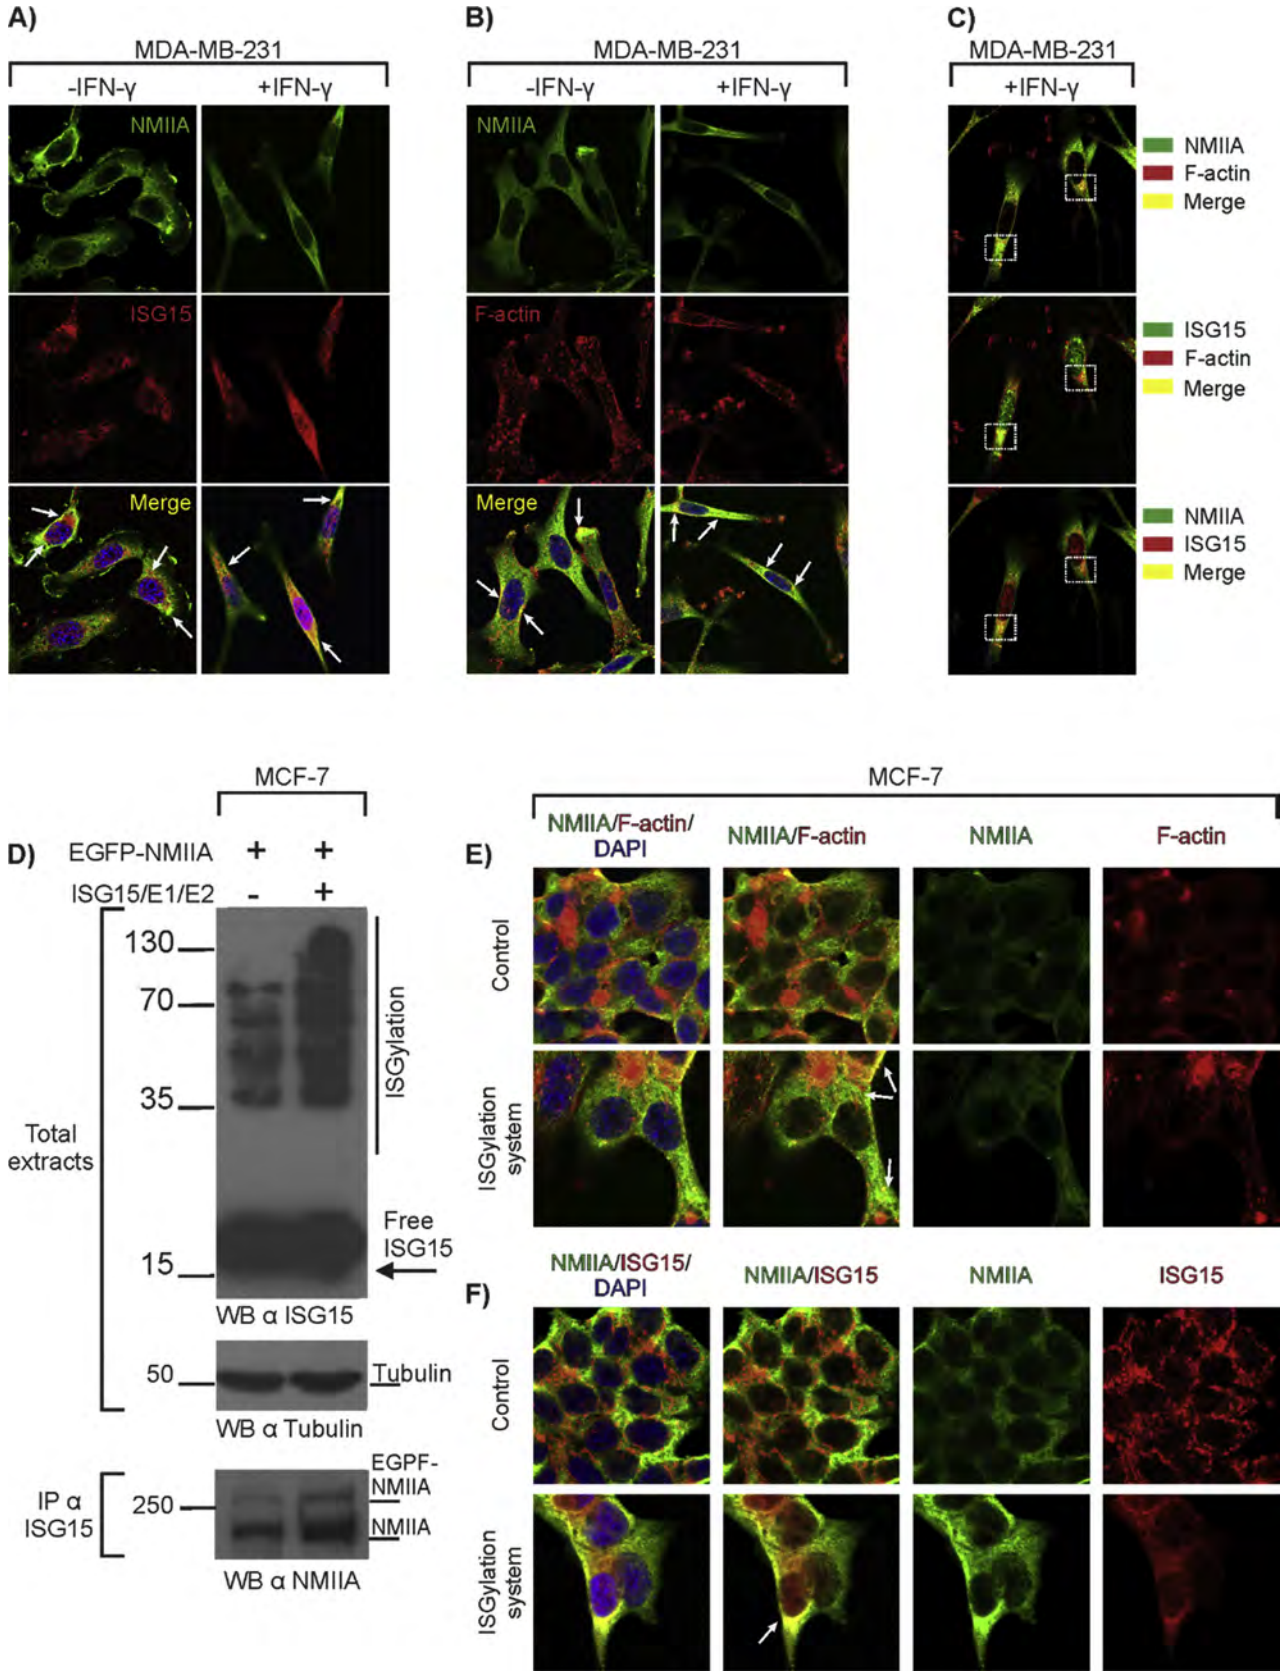

Fig. 8. Association induced by IFN-γ and the ISGylation system of non-muscle myosin IIA (NMIIA) and interferon-stimulated gene 15 (ISG15) is implicated in the morphology of breast cancer cells.

A-C) Evaluation of the subcellular distribution of NMIIA, and F-actin and/or interferon-stimulated gene 15 (ISG15) in MDA-MB-231 cells that were untreated or treated with IFN-γ using an immunofluorescence assay. D) Enhanced green fluorescent protein-non-muscle myosin IIA (EGFP-NMIIA) was expressed with or without ISG15 and E1 and E2 enzyme in MCF-7 cells. ISG15 and Tubulin were detected by western blotting (WB). Endogenous ISG15 immunoprecipitation was followed by WB for non-muscle myosin IIA (NMIIA), using total extract from MCF-7 cells. E and F) Immunofluorescence assay of the subcellular distribution of NMIIA and F-actin or interferon-stimulated gene 15 (ISG15) in control MCF-7 cells or cells expressing ISG15 and ISGylation system. Arrowheads, co-localization of NMIIA, ISG15 or F-

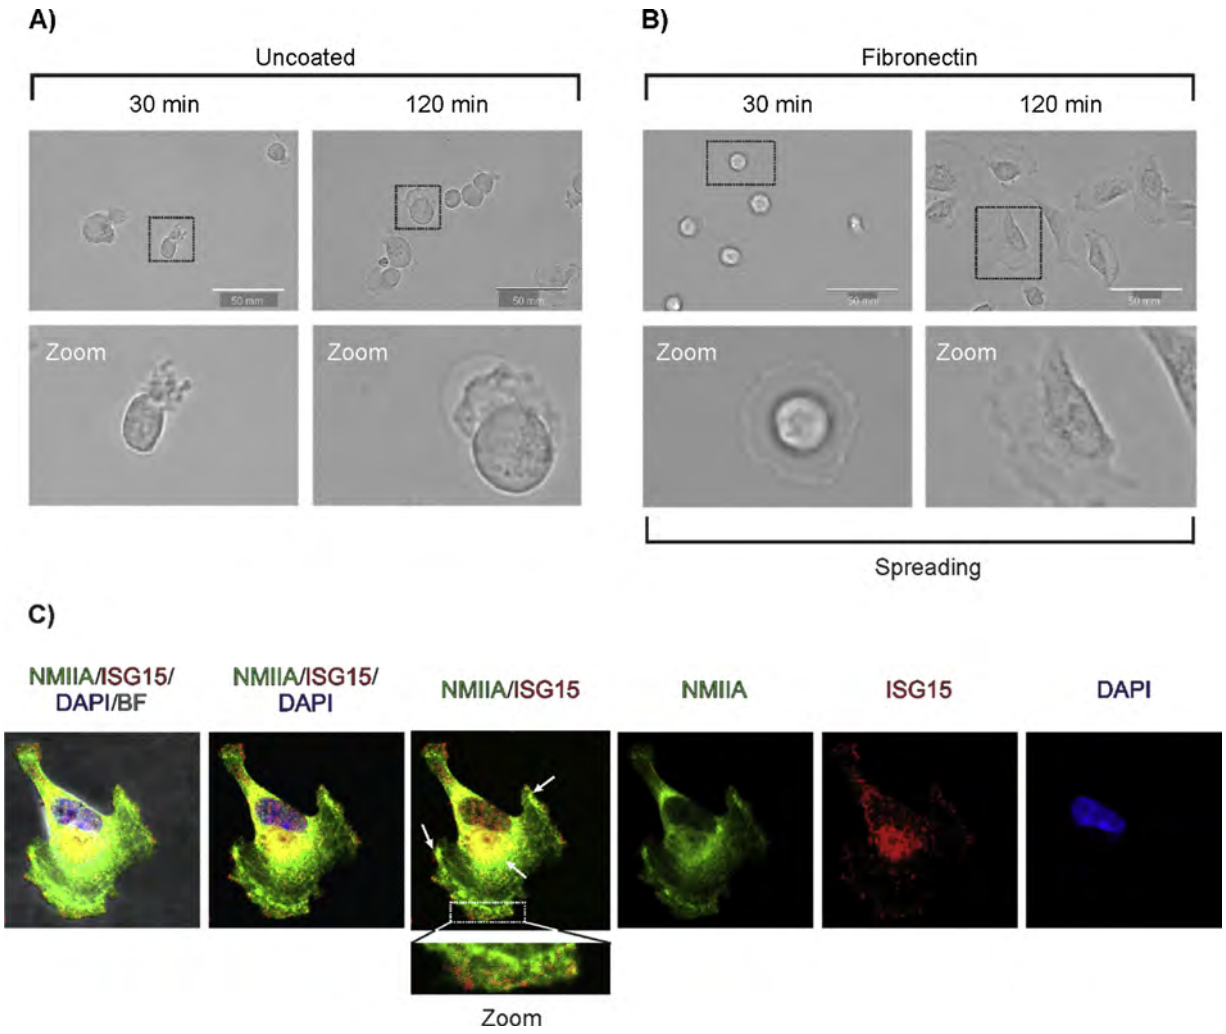

Fig. 9. Association of non-muscle myosin IIA (NMIIA) and interferon-stimulated gene 15 (ISG15) is implicated in the spreading of breast cancer cells induced by fibronectin (FN).

A and B) MDA-MB-231 cells were seeded in uncoated wells or wells coated with fibronectin (FN) and analyzed after 30 or 120 min. C) Immunofluorescence assay of the distribution and co-localization of NMIIA and ISG15 in MDA-MB-231 cells seeded in FN-coated wells after 120 min. Arrowheads and zoom image show co-localization regions.

ISG15-NMIIA association was accompanied by a more elongated morphology of the MDA-MB-231 cells (Fig. 8A–C), as well as with the formation of stress fibers of F-actin in MCF-7 cells (Fig. 8E). Thus, ISGylation of NMIIA may have implications in actin-cytoskeleton remodeling.

The dynamics of the cytoskeleton is also important in cell spreading, which is modulated by myosin proteins, and represents a critical step for the attachment and detachment of the cells with the substrate, a central event in cell migration. NMIIA and NMIIB are enriched in the lamellar margin. However, their functions are unclear. It has been suggested that they may have an opposite effect on spreading, with NMIIB promoting cell spreading (Betapudi, 2010; Betapudi et al., 2006; Cai et al., 2006). Interestingly, the ISG15-NMIIA association seems to occur in the spreading of breast cancer cells induced by FN, and this association is specific for NMIIA, but not for NMIIB. In addition, FN may induce *ISG15* expression and protein ISGylation via integrin-dependent signaling (Hermann et al., 2016).

Our findings are relevant since they open new avenues to understand ISG15 as a regulator of the NMIIA as a motor of the F-actin, and its effects in the spreading and migration of breast cancer cells, and its modulation by interferons and proteins of extracellular matrix as FN.

NMIIA has a high identity percentage with NMIIB and NMIIC isoforms (79% and 65%, respectively). Because NMIIA is a protein with high molecular weight, containing 10.56% lysine residues, there are many possible lysine residues for ISGylation. Our MS results identifying NMIIA suggest that lysines only in NMIIA but not in NMIIB and NMIIC may be involved in this covalent interaction. The generation of mutants of NMIIA to block its ISGylation may help to understand the function of this modification in NMIIA in breast cancer cells.

In conclusion, we have identified NMIIA as an endogenously and covalently ISG15-associated protein in the cytoplasm of breast cancer cells. NMIIA is modified by ISGylation, and this modification may regulate its protein-protein interactions, including its association with F-actin for cytoskeletal reorganization. IFN-γ treatment increases ISGylation of NMIIA and promotes changes in the morphology of breast cancer cells with the formation of stress fibers. The FN extracellular matrix protein may induce ISG15 expression and increases the ISGylation of NMIIA. This ISG15-NMIIA association seems also occur in the FN-induced and NMII-modulated spreading of MDA-MB-231 cells (Fig. 10). This new link between IFN-γ, ISGylation, and cytoskeletal proteins may be important in the progression of some cancers such as breast cancer.

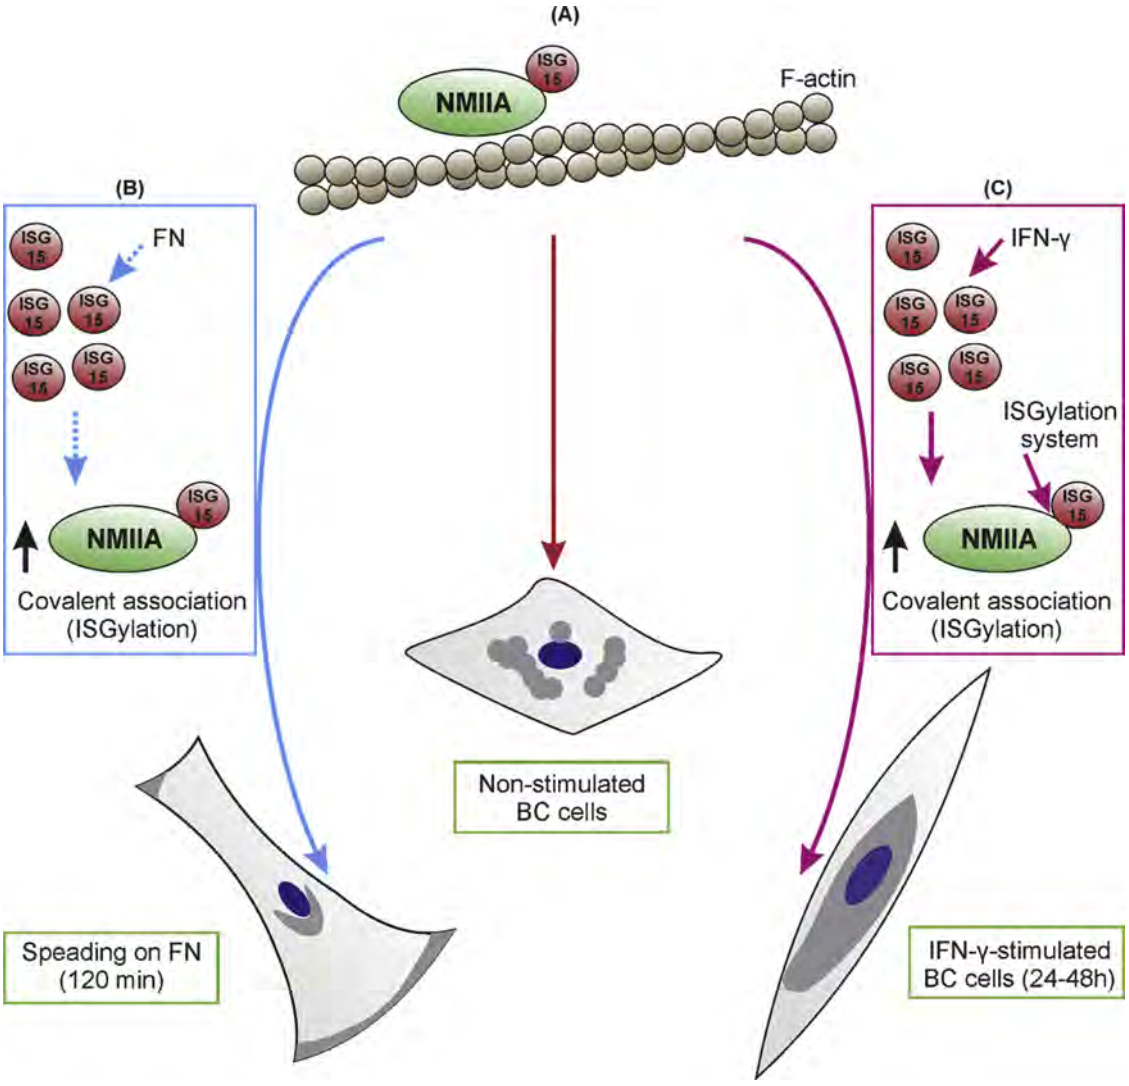

Fig. 10. Proposed model.
NMIIA is covalently associated with ISG15 in breast cancer cells. A) This modification of NMIIA by ISGylation may modulate the *actomyosin complex* (NMIIA-F-actin), which affects the reorganization of cytoskeleton and consequently the morphology of the cells. B) Extracellular matrix proteins like FN seem to induce *ISG15* expression, with subsequently increased NMIIA ISGylation. These events may be critical in FN-induced cell spreading, in which actomyosin activity is also required. C) In response to IFN-γ, *ISG15* expression and NMIIA ISGylation are increased, and changes in the cell morphology associated with F-actin organization are produced. These events are also generated by the overexpression of the ISGylation system. Thus, NMIIA ISGylation may have central implications in the proliferation and migration of mammary tumor cells. BC: breast cancer. In gray: ISG15, NMIIA and actin co-localization.

4. Materials and methods

4.1. Cell lines and reagents

The AD293 human embryonic kidney cell line and the MDA-MB-231 (ERα−, triple negative) and MCF-7 (ERα+) breast cancer cell lines were maintained in Dulbecco's modified Eagle's medium supplemented with 5% fetal bovine serum and penicillin/streptomycin. Recombinant human IFN-γ (285-IF-00) was obtained from R&D systems. Culture media were obtained from Invitrogen, and reagents were obtained from Sigma-Aldrich, AMRESCO-VWR, and Bio-Rad.

4.2. Plasmids and transfections

The pEGFPMIIAC3 plasmid was a gift from Dr. Anne R. Bresnick (Albert Einstein College of Medicine, USA) and plasmids pCAGGS-5HA-mISG15, pFlagCMV2-UbcH8, and pCAGGS-HA-hUBE1L were a gift from Dr. Dong-Er Zhang (Department of Pathology, Moores Cancer Center University of California, San Diego). AD293 or MCF-7 cells were seeded and grown to 80% confluence for transient transfection with plasmid DNA using the Lipofectamine 2000 system, according to the manufacturer's instructions (Invitrogen).

4.3. Total, cytoplasmic, and nuclear extract preparation

To obtain total extracts, cells were lysed with TNTE buffer (50 mM Tris−HCl, 150 mM NaCl, 5 mM ethylenediaminetetraacetic acid (EDTA), and 0.5% Triton-X-100) or radioimmunoprecipitation assay (RIPA) buffer (50 mM Tris−HCl pH 7.4, 150 mM NaCl, 1 mM EDTA, 0.5% deoxycholic acid, 1% NP-40, and 0.1% SDS) containing protease and phosphatase inhibitors. Subcellular fractionation was performed to obtain nuclear and cytoplasmic fractions, as described previously (Tecalco Cruz and Mejia-Barreto, 2017; Grewal et al., 2000). Briefly, cells were homogenized in homogenization buffer (250 mM sucrose, 3 mM imidazole, and protease and phosphatase inhibitors), passed through a 22−gauge needle 15 times for MDA-MB-231 cells and 12 times for MCF-7 cells, and then centrifuged at 700 × *g* for 10 min. The supernatant (cytoplasmic fraction) was separated from the pellet

INFORME DE LABORES 2019

(nuclear fraction). Both fractions were lysed with RIPA buffer at 4 °C for 1 h. Protein extracts were quantified using the Bradford method for the WB and immunoprecipitation assays.

4.4. Immunoprecipitation, Coomassie staining, and MS

Immunoprecipitation assays were performed with 0.6 or 1 µg of anti-ISG15 and anti-NMIIA antibodies, respectively. Immunoprecipitated complexes in Laemmli solution were separated by SDS-PAGE, followed by Coomassie Blue G staining for the selection of bands for MS analysis. The MS service from Instituto Nacional de Medicina Genómica (INMEGEN), Unidad de Proteómica, was utilized. The visible band was manually cut and reduced with dithiothreitol (DTT) 10 mM, alquilated with iodoacetamide 100 mM and destained with acetonitrile (ACN) (NH_4HCO_3 50 mM, 50:50 v/v). Protein digestion was carried out for 18 h at 37 °C with trypsin (Promega V528 A). The obtained peptides were extracted (ACN:H2O:formic acid, 50:45:5), the volume was reduced in a concentrator, and the sample was desalinated using a column C18 (ZipTipC18). The sample was loaded 6-fold using alpha-cyano as a matrix and analyzed using a MALDITOF/TOF 4800. A search was performed with the obtained MS/MS spectrums, using the Paragon algorithm from the software ProteinPilot.

4.5. Co-immunoprecipitation assays and WB

Cells were lysed using RIPA or TNTE lysis buffer as described previously (Tecalco-Cruz and Cruz-Ramos, 2018). Proteins were immunoprecipitated with specific anti–ISG15 (Santa Cruz Biotechnology), anti–NMIIA (Sigma-Aldrich), or anti–GFP (Clontech) antibodies. The immunoprecipitated proteins were separated by SDS-PAGE, followed by immunoblotting with specific primary antibodies (anti–GFP, anti-NMIIA, or anti-ISG15). The experiments were performed in triplicate, and representative images were shown. For analysis of total, cytoplasmic, and nuclear extracts, 25–100 µg of protein lysates were used. Protein lysates were separated by SDS-PAGE and then subjected to immunoblotting with anti-ISG15 (1:1000) (F-9, sc-166755), anti-α-tubulin (1:3000) (B7, sc-5286) obtained from Santa-Cruz Biotechnology, anti-lamin B1 (1:2000) obtained from Cell Signaling (D4Q4Z), anti-NMIIA (1:3000) (M8064), and anti-EGFP (1:3000) (632592) obtained from ClonTech. A secondary anti-rabbit IgG antibody was used (1:10,000 for anti-lamin and anti-GFP, 1:25,000 for anti-NMIIA) (sc-2004; Santa Cruz Biotechnology) as well as peroxidase AffiniPure goat anti-mouse (1:10,000 for anti-tubulin and anti-ISG15) (115-035-003, Jackson). Protein detection was performed using SuperSignal West Pico Chemiluminescent Substrates (Thermo Fisher Scientific) or Immobilon Western (Millipore). All experiments were performed in triplicate.

4.6. Immunofluorescence assay

Cells were seeded on glass coverslips coated with poly-L-lysine in 6-well plates. The cells were fixed in 4% paraformaldehyde for 10 min and then permeabilized with 0.1% Triton X-100 for 10 min. After blocking with 1% albumin for 1 h, cells were incubated overnight with anti-ISG15 (F-9, sc-166755; 1:100) and anti-NMIIA (M8064). After primary incubation, cells were washed and incubated with Alexa Fluor 647 anti-mouse IgG secondary antibody (ab150107, Abcam; 1:750) and Alexa Fluor 488 anti-rabbit IgG secondary antibody (ab150073, Abcam; 1:500) for 1 h in the dark. The slides were prepared with ProLong Diamond Antifade Mountant with 4′,6-diamidino-2-phenylindole (DAPI) (Invitrogen). For phalloidin assays (F-actin detection), after blocking, the cells were incubated for 1 h with phalloidin (1:40) and mounted with DAPI solution. An Olympus IX2 and FV10i confocal laser-scanning microscopes were used to visualize the cells, and ImageJ software was used for the imaging, processing, and analysis of results.

4.7. Spreading assays

MDA-MB-231 cells were seeded on wells or glass coverslips in 6-well plates treated with FN (25 mg/mL) for 1 h. After 30 or 120 min following seeding, cells were fixed and visualized, or were prepared for immunofluorescence assay. Cell morphology was evaluated using an Invitrogen EVOS FL Cell Imaging System. Co-localization was analyzed using an Olympus FV10i confocal laser scanning microscope.

4.8. Bioinformatics

The cancer microarray database Oncomine (www.oncomine.org) was consulted to analyze *MYH9* expression in patient-derived mammary tumors and normal mammary tissue. The analysis of post-translational modifications for NMIIA was performed with PhosphoSite (Hornbeck et al., 2015) (www.phosphosite.org), and analysis of protein-protein interactions for NMIIA was carried out using STRING 10.5 version (https://string-db.org/cgi/network.pl) (Szklarczyk et al., 2017).

4.9. Statistical analysis

Statistical analysis was performed with Student's *t*-test using GraphPad Prism 5 software (GraphPad). Densitometry for WB assays were performed using Fiji-ImageJ. Results were expressed as significant when $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***). Not significant is described as N.S.

Author contributions

E.C.-R. performed the experiments and prepared some figures. M.M.-S. participated in the data analysis. A. S-H performed a colocalization analysis and prepared the figures. A.C.T.-C. designed research, the bioinformatics analysis, some WB, and wrote the manuscript.

Funding

This work was supported by the DGAPA-UNAM (grant numbers PAPIIT-IA200916 to A.C.T.-C.).

Acknowledgements

We appreciate the kind gift from Dr. Anne R. Bresnick (Albert Einstein College of Medicine, USA) of the NMIIA plasmid, as well as, the kind gifts from Dr. Dong-Er Zhang (Department of Pathology, Moores Cancer Center University of California, San Diego) of the ISGylation system plasmids used in this work. We thank Dr. Josué O. Ramírez Jarquín for his technical support (Instituto de Fisiología Celular, UNAM). We thank Dr. Miguel Tapia Rodríguez (Instituto de Investigaciones Biomédicas, Unidad de Microscopia, UNAM) for his technical support in analyzing the immunofluorescence. We also thank Dr. Sergio Agustín Román González (INMEGEN, Unidad de Proteómica) for mass spectrometry service. We thank Dr. Claudia Rivera Cerecedo for her comments (Instituto de Fisiología Celular, UNAM).

Abstract

Non-alcoholic fatty liver disease (NAFLD) encompasses a broad spectrum of histopathological changes ranging from non-inflammatory intracellular fat deposition to non-alcoholic steatohepatitis (NASH), which may progress into hepatic fibrosis, cirrhosis, or hepatocellular carcinoma. Recent data suggest that impaired hepatic cholesterol homeostasis and its accumulation are relevant to the pathogenesis of NAFLD/NASH. Despite a vital physiological function of cholesterol, mitochondrial dysfunction is an important consequence of dietary-induced hypercholesterolemia and was, subsequently, linked to many pathophysiological conditions. The aim in the current study was to evaluate the morphological and molecular changes of cholesterol overload in mouse liver and particularly, in mitochondria, induced by a high-cholesterol (HC) diet for one month. Histopathological studies revealed microvesicular hepatic steatosis and significantly elevated levels of liver cholesterol and triglycerides leading to impaired liver synthesis. Further, high levels of oxidative stress could be determined in liver tissue as well as primary hepatocyte culture. Transcriptomic changes induced by the HC diet involved disruption in key pathways related to cell death and oxidative stress as well as upregulation of genes related to glutathione homeostasis. Impaired liver function could be associated with a decrease in mitochondrial membrane potential and ATP content and significant alterations in mitochondrial dynamics. We demonstrate that cholesterol overload in the liver leads to mitochondrial changes which may render damaged hepatocytes proliferative and resistant to cell death whereby perpetuating liver damage.

INFORME DE LABORES 2019

1 | INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is the most common form of chronic liver disease (Lonardo et al., 2017). Patients with NAFLD are at high risk of developing inflammatory steatohepatitis (NASH) which can progress into fibrosis, cirrhosis, and ultimately, hepatocellular carcinoma (HCC; Calvisi et al., 2011). Several lines of evidence indicate that structural and functional alterations of mitochondria significantly contribute to changes of the cellular lipid metabolism as well as oxidant stress response. Consistently, mitochondrial dysfunction is frequently associated with the development of NAFLD (Auger, Alhasawi, Contavadoo, & Appanna, 2015; Serviddio & Sastre, 2010). Oxidative stress is one of the key mediators of hepatic damage and a major contributor to the progression from steatosis to NASH, particularly when mitochondria are compromised (Bellanti et al., 2018). Oxidative stress can result in various deleterious processes that stem from an imbalance between the excessive formation of pro-oxidants and the counteracting antioxidant mechanisms (Gomez-Quiroz, Gutierrez Ruiz, Marquardt, Factor, & Thorgeirsson, 2017). It is well known that mitochondrial dysfunction can be induced by dietary-induced hypercholesterolemia, leading to organ insufficiency or failure, particularly in the liver (Marí et al., 2006). Although mitochondria, particularly the inner membrane, only have low levels of cholesterol in the cell, cholesterol content is essential for the proper functionality of mitochondria (Garcia-Ruiz et al., 2009). Alterations in mitochondrial cholesterol have been associated with a wide range of pathological conditions, including steatosis and cancer (Enríquez-Cortina et al., 2017). Recently, it has been published that a high cholesterol (HC) diet (1.25% cholesterol) in combination with a high fat diet (60% cocoa butter) synergistically enables development and progression of NAFLD to NASH by a mechanism driven by cholesterol derivatives (oxysterols) in presence of free fatty acids with impact in mitochondrial function and dynamics (Bellanti et al., 2018), but the effects displayed by dietary cholesterol alone remains partially characterized. In the present work, we were aimed to figure out the effects of cholesterol overload in the liver, particularly in hepatocytes, and the influence on the transcriptome and in the cholesterol-overloaded mitochondria dynamic.

2 | MATERIAL AND METHODS

All chemicals and reagents were of the highest analytical grade, and most of them were purchased from Sigma (St. Louis, MO). Reagents obtained from other suppliers are detailed in the text.

2.1 | Animal model

C57BL/6 male mice (8–10 weeks old) were purchased from Jackson Laboratory (Bar Harbor, ME) and were maintained in pathogen-free conditions with controlled temperature and humidity on a 12 hr light–dark cycle in the animal facility at the Universidad Autonoma Metropolitana. The experimental protocols used were approved and performed in accordance with the Animal Care Committee of the Universidad Autonoma Metropolitana and the NIH Guide for the Care and Use of Laboratory Animals.

2.2 | Experimental design

Twenty mice were randomly divided in two groups, 10 animals were fed with an HC diet (2% cholesterol and 0.5% sodium cholate; Gomez-Quiroz et al., 2016; Nuño-Lámbarri et al., 2016) for 30 days, the second group was fed with control standard Chow diet (LabDiet #5001) for the same period. After 30 days, animals were killed. Liver weight was monitored, and liver tissue, as well as serum, was collected for subsequent analyzes.

2.3 | Histological analysis

Liver sections from all groups were fixed in absolute ethanol and embedded in paraffin for routine hematoxylin and eosin (H&E) staining, and both, morphometric and NAFLD activity score (NAS; Kleiner et al., 2005) studies were performed. For morphometric study five H&E slides, five random- view fields were selected, and 100 cells were counted in each field. Data are reported as cell percentage considering normal, regenerative, and death phenotypes (Enriquez-Cortina et al., 2013). Tissue for Oil Red O staining were fixed in 4% paraformaldehyde/phosphate-buffered saline (PBS) for 30 min and was stained with freshly diluted 0.2% Oil red O solution for 4 hr after that we proceeded to microphotography.

2.4 | Primary mouse hepatocytes isolation and culture

Hepatocytes were isolated from HC and Chow mice by the two-step collagenase perfusion, as we previously reported (Gómez-Quiroz et al., 2008). The viability was assessed by trypan blue exclusion and generally exceeded >90%. Hepatocytes were seeded at 2.5×10^5 cells per cm^2 either in Lab-Tek chambered slides or in 10-cm dishes (Nalge, Nunc) in Ham's F-12/Dulbecco's modified Eagle's basal hepatocyte growth medium supplemented with 10% fetal bovine serum. After 24 hr, cells were used for reactive oxygen species (ROS) determination, Oil Red O staining, cholesterol, and mitochondrial potential determination.

2.5 | Biochemical determinations and analysis of liver function

Blood samples were obtained from the orbital venous plexus under Avertin (2-2-2 tribromoethanol) anesthesia before sacrifice. Serum activity of aspartate aminotransferase (AST), alanine transferase (ALT), and alkaline phosphatase (ALP) were determined by an automated method using Reflovet Plus (Roche, Mannheim, Germany).

2.6 | Cholesterol determination

For total cholesterol determination, 10 mg of liver or mitochondrial protein was saponified with alcoholic KOH in a 60°C heating block for 30 min. After the mixture had cooled, 3 ml of hexane and 600 μl of distilled water were added and shaken to ensure complete mixing. Appropriate aliquots of the hexane layer were evaporated under nitrogen with vacuum (Speed Vac, Savant, Cranbury, NJ) and used for cholesterol measurement with O-phthalaldehyde dissolved in acetic acid (0.5 mg/ml). After that sulfuric acid (1 ml) was added and then read at 550 in a spectrophotometer (Rudel & Morris, 1973).

2.7 | Triglycerides determination

Triglycerides (TG) content was determined using the triglyceride determination kit (Sigma-Aldrich, St Louis, MO) following manufacturer's instructions.

2.8 | Oil red O staining

To detect intracellular neutral lipids accumulation, the cells were seeded into 24-well chambers. After treatments, cells were washed with ice-cold PBS and then fixed with 2.5% paraformaldehyde for 1 hr. The cells were stained with freshly diluted 0.2% Oil red O solution for 4 hr; after that, we proceeded to microphotography.

2.9 | In situ ROS determination

Animals were euthanized in parallel exclusively for in situ ROS determination. Fresh tissue was rapidly sectioned, frozen in liquid nitrogen, and embedded in optimum cutting temperature reagent (Sakura Finetec, Torrance, CA). Subsequently, 8-μm frozen sections were obtained in a cryostat (Leica CM-3050S) at −20°C and the slides were immediately incubated for 15 min, in the dark, at room temperature with either 2′,7′–dichlorofluorescin diacetate (DCFDA, 5 μM), a cell-permeable non-fluorescent probe that is intracellularly de-esterified and converted to the highly fluorescent 2′,7′-dichlorofluorescein (DCFH) upon oxidation by ROS, particularly peroxides, or with dihydroethidium (DHE, 1 μM) for determination of superoxide anion radical detecting ethidium fluorescence. Samples were covered and observed using a confocal microscope at excitation and emission wavelengths of 480 and 520 nm, respectively, for DCFDA; and excitation and emission wavelengths of 485 and 570 nm, respectively, for DHE-derived ethidium fluorescence, as we previously reported (Nuño-Lámbarri et al., 2016).

2.10 | Western blot

The whole liver homogenate was prepared in ice-cold PBS using dounce homogenizer. The cellular pellet was suspended in 200 μl of M-PER (Pierce Chemical, Rockford, IL); lysis buffer was supplemented with proteases and phosphatases inhibitors (Roche). Lysis was performed on ice for 15 min, and cell debris was removed by centrifugation at 13,000*g* at 4°C for 10 min and the supernatant was recovered (Hernández et al., 2015). Total protein concentration was determined using a bicinchoninic acid kit (Pierce Thermo Scientific, Rockford, IL), according to the manufacturer's instructions. Proteins were separated by electrophoresis using 10% gradient Duramide precast gels (Cambrex, Rockland, ME) and transferred to a polyvinylidene difluoride membranes (Invitrogen, Carlsbad, CA; Clavijo-Cornejo et al., 2013). Immunodetection was performed using antibodies listed in Supporting Information Table 1.

2.11 | Mitochondria isolation

Mitochondria were obtained by homogenization and differential centrifugation. Briefly, cells were suspended 50% w/v in mitochondrial buffer 0.22 M mannitol, 0.7 M sucrose, 2 mM HEPES, pH 7.4) plus 0.1% BSA and were homogenized. The homogenate was centrifuged in an F21- 8 × 50 y Sorvall rotor at 1017*g* for 5 min. Then the supernatant was recovered and centrifuged at 10,700*g* for 10 min. The pellet was suspended in mitochondrial buffer containing BSA and centrifuged at 3,600*g* for 5 min. The supernatant was recovered and centrifuged at 17,000*g* for 10 min. The resulting pellet was suspended in a small volume of mitochondrial buffer (without BSA), and protein was determined by Biuret (Rosas-Lemus, Uribe-Alvarez, Chiquete-Félix, & Uribe-Carvajal, 2014).

2.12 | Mitochondrial transmembrane potential ($\Delta\Psi$)

The $\Delta\psi$ was determined using 10 μM safranine-O, following the absorbance changes at 511–533 nm in a DW2000 Aminco spectrophotometer in dual mode (Åkerman & Wikström, 1976). At the end of each trace, $\Delta\psi$ was collapsed by adding 5 μM of the protonophoro m-chlorophenylhydrazone (CCCP). Additionally, changes in mitochondria membrane potential were addressed by using the rhodamine-based dye Mito Red, which upon mitochondria localization emits fluorescence in a membrane potential-dependent manner.

2.13 | ATP determination

Hepatic ATP concentration was determined colorimetrically in liver homogenates of Chow and HC mice using the Abcam ATP-assay kit (Abcam, MA) according to the manufacturer's instructions. Briefly, 30 mg of liver was lysed in the ATP assay buffer and centrifuged at 13,000*g* for 2 min to pellet-insoluble materials. Samples were deproteinized and neutralized with PCA-KOH. The supernatant was added to a 96-well plate and followed by the addition of 50 μl of the Reaction Mix to each well and was incubated at the room temperature in the dark for 30 min. Absorbance was read at 570 nm using a multimode detector DTX 880 (Beckman Coulter). The ATP content was calculated based on a standard curve generated at the same time.

INFORME DE LABORES 2019

2.14 | Electron microscopy

Tissues were fixed with 2% glutaraldehyde in 0.1 M phosphate buffer (pH 7.4) followed by 1% OsO_4. After dehydration, thin sections were stained with uranyl acetate and lead citrate for observation under an EOL JEM 12000 EII transmission electron microscope (TEM).

2.15 | Global transcriptomic analysis by microarray

Microarray analysis was performed as we previously described (Gomez-Quiroz et al., 2016). As input, 200 ng total RNA from liver tissue were used for the in vitro transcription reactions, which were incubated for 16 hr at 37°C. Hybridization, washing, detection (Cy3-streptavidin, Amersham Biosciences, GE Healthcare), and scanning were performed on an Illumina iScan system (Illumina) using reagents and protocols supplied by the manufacturer. The biotinylated cRNA (750 ng per sample) was hybridized on Sentrix whole genome beadchips mouse Ref-8v2 for 18 hr at 58°C while rocking (5 rpm). The beadchip covers ~24,000 RefSeq transcripts. Image analysis and data extraction were performed automatically using Illumina GenomeScan Software. Gene expression values were adjusted by subtracting background noises in each spot by GenomeStudio (Illumina) and normalized by quantile normalization method across all samples. A signal intensity with a detection *p*-value greater than 0.05 was treated as a missing value, and only genes with sufficient representation across the samples were included in further data analysis (presence in ≥2 replicates/group). Differentially expressed genes were identified by Bootstrap *t*-test with 10,000 repetitions (Neuhauser & Jockel, 2006). Genes with a Bootstrap *p*-value ≤ 0.01 were considered significantly different. Only genes with more than two fold differences and *p*-value ≤ 0.01 were included in further analyzes. Ingenuity Pathway Analysis tool (IPA, Ingenuity Systems Inc.) was used to explore the functional relationships among the differentially expressed genes. The significance of each network, function, and pathway was determined by the scoring system provided by IPA tool. The microarray datasets have been deposited to the Gene Expression Omnibus database (http://www.ncbi.nlm.nih.gov/geo, accession number GSE30651).

2.16 | Caspase 3 activity

Tissue was lysed in reaction buffer and incubated for 30 min on ice. For each reaction, caspase 3 synthetic tetrapeptide fluorogenic substrate (Ac-DEVD-AMC) was added (BD Pharmigen) and then the tissue lysate; after that, the samples were incubated for 1 hr. The amount of AMC released was measured by fluorometry at an excitation wavelength of 380 nm and an emission wavelength of 420 nm.

2.17 | Statistical analysis

The data are presented as mean ± standard error (*SE*). for at least three independent experiments. Comparisons between groups were made using Student's *T*-test follow post ad hoc by U Mann–Whitney using GraphPad Prism 6 for Mac OSX, a $p \leq 0.05$ was considered significant.

3 | RESULTS

3.1 | An HC diet consumption resulted in hepatic steatosis and liver damage

Livers of C57BL/6 mice fed with HC diet for 30 days showed hepatomegaly, the characteristic pale color of the fatty liver and increased liver to body weight ratio (Figure 1b,c). An increase in lipid content in the tissue was confirmed by Oil Red staining (Figure 1e). Further, total liver cholesterol increased 6.5-fold and triglycerides 5.2-fold compared with Chow diet fed mice (Figure 1f,g). Consistently, a steatotic phenotype and alterations of the liver architecture was present (Figure 1i), dispersed inflammation (white arrow) and hepatocyte ballooning (yellow arrow) were consistent with NASH according to the NAS (or Kleiner Scoring System, Supporting Information Table 2; Kleiner et al., 2005).

In addition, cellular hypertrophy with numerous hyperchromatic hepatocytes unveiling nuclear condensation were observed (Figure 1i, asterisks). The morphometric analysis confirmed significantly higher percentages of both, dead and proliferating cells, as well as a decrease in normal cells in liver from HC fed animals (Figure 1j). Mice fed with HC showed increased signs of liver injury, judged by an increased activity in ALT, AST, and ALP (Figure 1k).

In confirmation of the steatotic phenotype observed and the increment of neutral lipids in the liver of HC mice, oil red O staining, and filipin fluorescence further demonstrated that cultured primary hepatocytes isolated from HC mice maintained high levels neutral lipids (Supporting Information Figure 1b), and free cholesterol content (Supporting Information Figure 1d).

3.2 | Global transcriptomic analysis

Next, transcriptomic profiling of HC diet livers was performed. In comparison to Chow, a total of 938 differentially expressed genes (439 upregulated and 499 downregulated (Supporting Information Table 3) could be detected. These genes were highly efficient in separating the two different diets using unsupervised clustering analysis (Figure 2a). We found that a significant number of differentially expressed genes related to hepatic cell death and oxidative stress (Ccnd1, Cers2, E2F1, Sod2, Scd, Pon3, Hmox 1, Sod1, Plin5, App, Usp10, Adar, Casp7, Nr1i3, Gstz1, Gnmt, Irf5; Figure 2b–d). Interestingly, most of the genes related to glutathione homeostasis were upregulated (Gsta1, Gsta2, Gstm4, Gpx4, Gss), and many nuclear genes encoding mitochondrial proteins were downregulated (Abcb8, Abcb6, Mtif3, Shmt2, Slc25a23, Slc25a10, Hmgcs2, Gls2, Hsd17b10Bcat2) clearly indicating a compromise of mitochondrial functions.

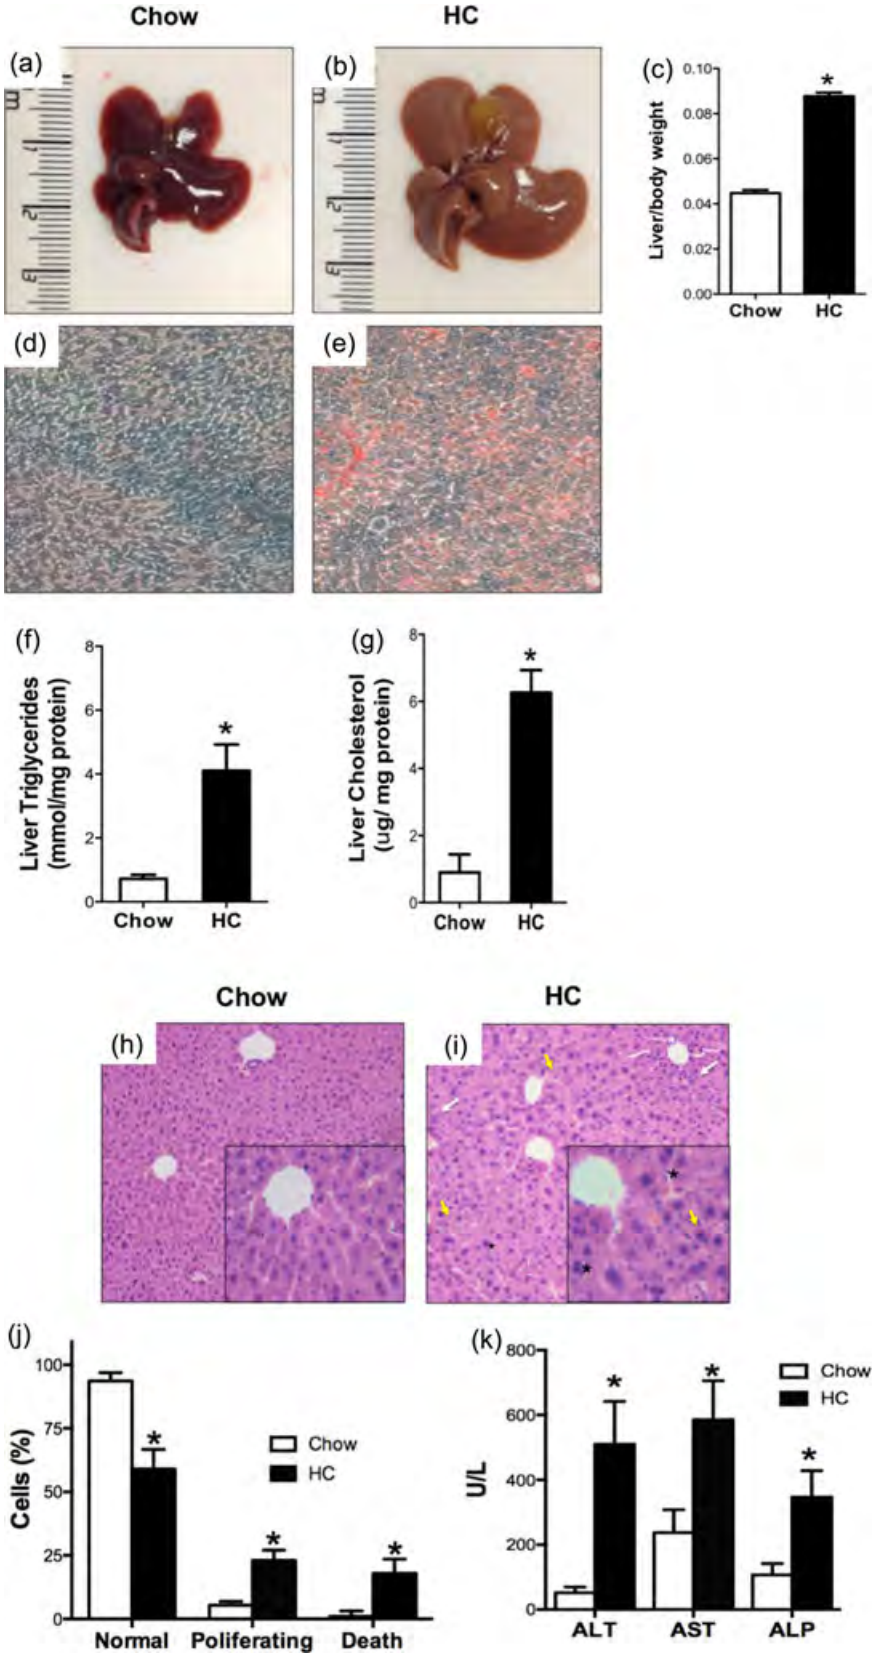

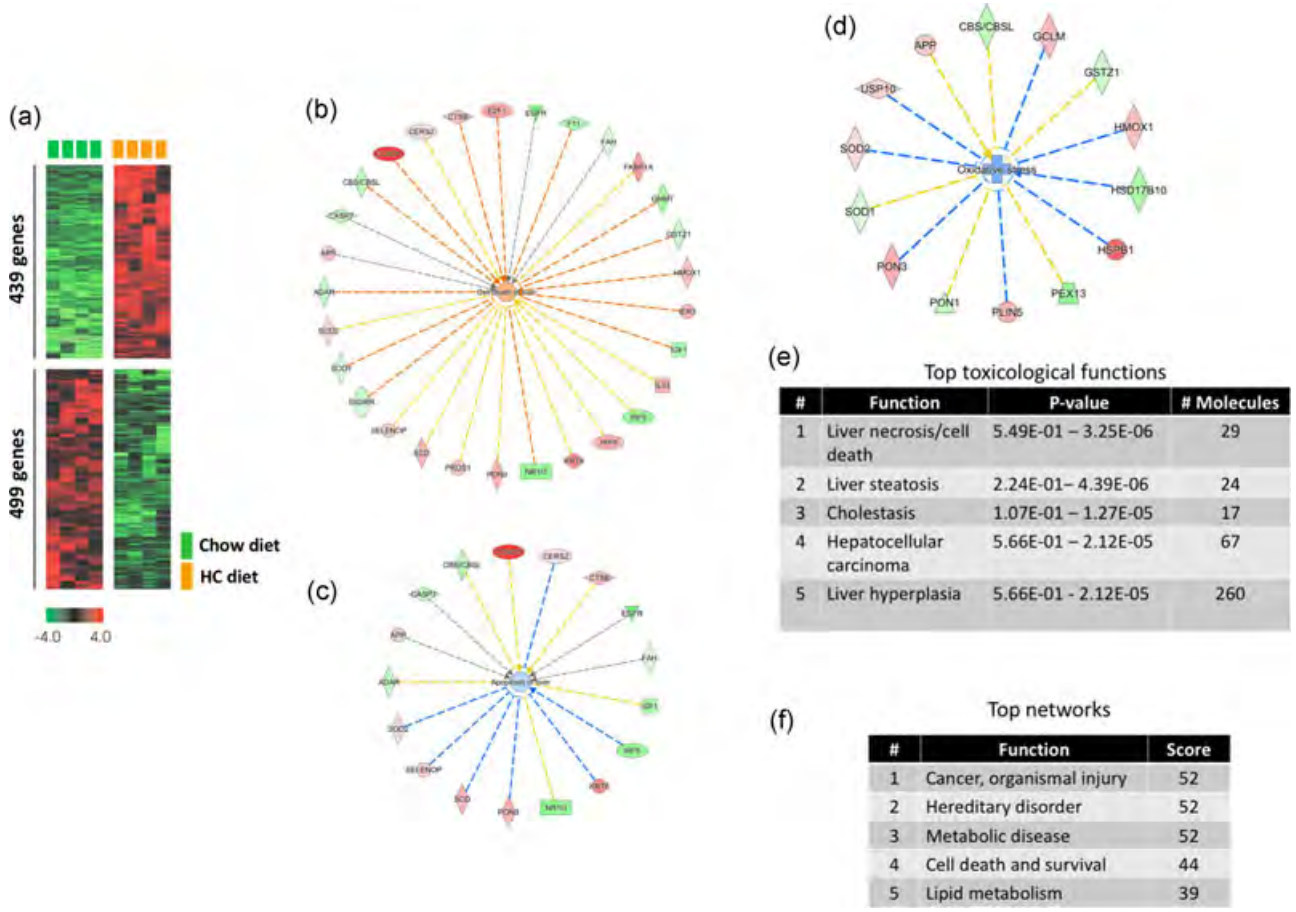

FIGURE 1 A high cholesterol diet consumption resulted in hepatic steatosis and liver damage. Gross inspection of the liver from mice fed with (a) chow control diet, (b) HC diet, (c) Liver to body weight ratio. Neutral lipid content determined by oil red O staining in liver tissue from animals fed with (d) chow control diet (e), HC diet. Biochemical determination of (f) triglycerides and, (g) cholesterol content in liver tissue. Histology analysis by H&E staining of liver tissue from mice fed with (i) HC diet or, (h) chow control diet. Original magnification 100 ×, (inset 200 ×), yellow arrow, hepatocyte ballooning; asterisk, nuclei condensation; white arrow inflammation. (h) Morphometric analysis of the H&E staining. (k) Liver function test. Each column represents the mean ± standard error of the mean (*SEM*) in at least four different mice. $^{*}p \leq 0.05$ versus Chow control mice. Images are representative of at least three independent experiments. ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase; HC: high cholesterol; H&E: hematoxylin and eosin

Consistently, affected toxicological functions were involved in liver cell death, steatosis, cholestasis, and HCC (Figure 2e), while top networks affected were cancer, organismal injury, metabolic diseases and lipid metabolism, among others (Figure 2f). Data clearly show an extensive impact in gene expression, indicating a profound adaptation of the cholesterol-overloaded liver.

FIGURE 2 Global transcriptomic analyzes by microarray. (a) Unsupervised hierarchical cluster analyses of liver tissue from mice fed with an HC diet or normal Chow diet for 30 days. A total of 938 differentially expressed genes were identified using bootstrap *t*-test with 10,000 repetitions (*p*-value 0.01). Gene regulatory networks associated with (b) cell death, (c) apoptosis and (d) oxidative stress in the liver overloaded with cholesterol, determined by IPA analysis. (e) Top toxicological functions and (f) top networks involved in cholesterol overload in the liver, determined by IPA analysis. HC: high cholesterol; IPA: ingenuity pathway analysis

3.3 | An HC diet induces increment of reactive oxygen species and oxidative stress

To evaluate the effect of cholesterol overload in the production of ROS, peroxides and superoxide were determined using specific probes for the superoxide anion (DHE) and peroxides (DCFH). Data show that lipid overload remarkably increased DHE fluorescence, showing that superoxide increased in both, liver tissue (Figure 3b,e) cultured primary hepatocytes (Supporting Information Figure 2b). Also, peroxides were considerably elevated, as shown by increased DCFH fluorescence (Figure 3d,e Supporting Information Figure 2d).

Next, we determined the content of the main enzymes responsible for peroxide and superoxide detoxification, as well as the levels of Nrf2, a key transcription factor involved in antioxidant response (Figure 3f). As expected, Nrf2 expression decreased dramatically in livers of animals fed with HC diet, whereas catalase content did not change. Further, while SOD1, a cytoplasmic enzyme responsible for converting superoxide radical to molecular oxygen and hydrogen peroxide, decreased in HC livers, SOD2, a mitochondrial manganese-dependent SOD increased dramatically. GST, an enzyme that conjugates xenobiotics, among them hydroperoxides to glutathione (GSH) and thereby detoxify cellular environments, markedly raised in lipid-overloaded tissue.

We also assessed the content of two intracellular GSH-dependent selenoperoxidases known to catalyze organoperoxides detoxification, GPx-1 and GPx-4. Consistent with our results from the gene expression profiling GPx-1 levels were significantly lower in HC livers, while GPx-4 significantly increased (Figure 3f). All Western blot results corroborate the data obtained by microarrays. Densitometric analysis of Western blots could be found in Supporting Information Figure 3.

3.4 | The development of hepatic steatosis and altered mitochondrial homeostasis in HC livers

Consistent with the hypercholesterolemic phenotype, cholesterol content in isolated mitochondria of HC livers revealed a two-fold increment compared to Chow (Figure 4a). To further characterize the influence of cholesterol overload in mitochondria functionality, we determined mitochondrial membrane potential using Mito Red. A significantly reduced fluorescence was observed in HC hepatocytes

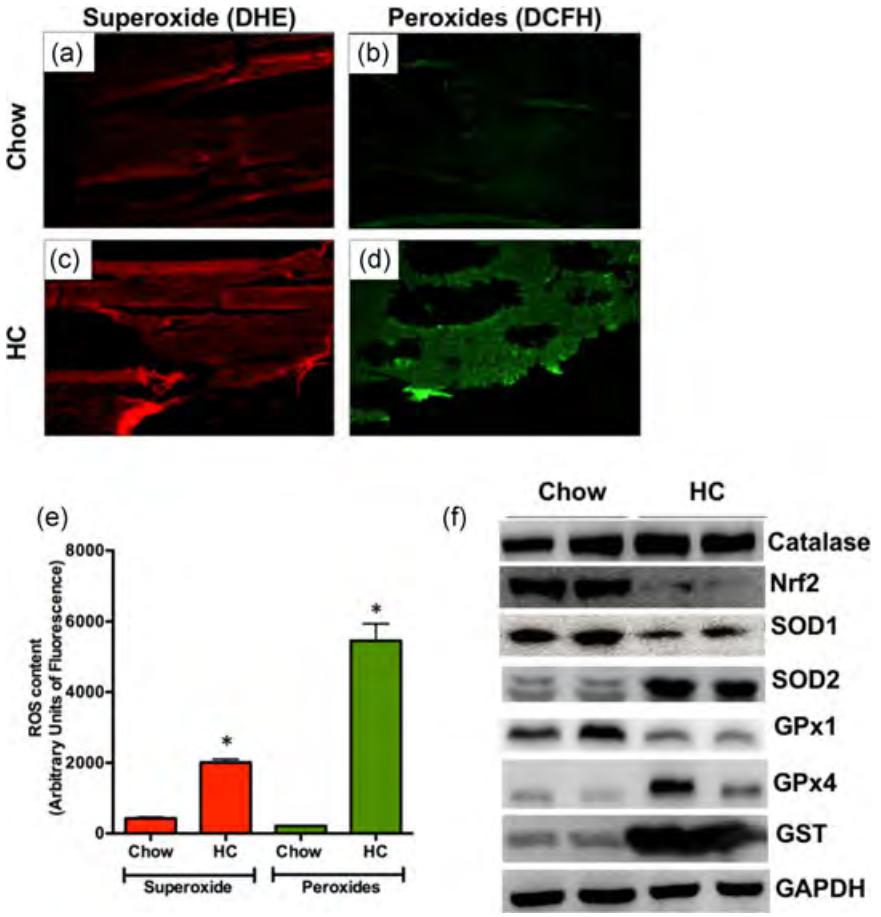

FIGURE 3 A high cholesterol diet induces increment of reactive oxygen species and oxidative stress. Reactive oxygen species content in liver tissue were determined by both, DHE (1 μM, in red) and DCFH (5 μM in green) fluorescence, in liver tissue from mice fed with Chow diet (a,c), and high cholesterol diet (b,d), representative images obtained by confocal microscopy. Original magnification ×100. (e) Fluorescence quantification. Each column represents the mean ± standard error of the mean (*SEM*) in at least four different mice. $^{*}p \leq 0.05$ versus Chow control mice. (f) Western blot analysis of the main antioxidant proteins using antibodies depicted in Supporting Information Figure 1. GAPDH was used as loading control. Images are representative of at least three independent experiments. DCFH: 2′,7′-dichlorofluorescein; DHE: dihydroethidium; GAPDH: glyceraldehyde-3-phosphate dehydrogenase

(Figure 4c), indicating that the membrane potential of mitochondria was decreased when compared cwith hepatocytes from Chow fed mice (Figure 4b). This result was corroborated in isolated mitochondria from mice under both diets. A significantly diminished membrane potential of liver mitochondria from HC fed mice determined by spectrophotometry using safranine was present (Figure 4d). HC mitochondria exhibited 50% of loss in membrane potential compared with those from Chow livers. In line with this, a 60% decrease in ATP content could be revealed for HC livers (Figure 4e), clearly suggesting impairment of mitochondrial functionality.

3.5 | HC diet causes imbalance of mitochondrial dynamics and fission

To estimate the structural impairment of mitochondria induced by HC diet, we performed TEM. HC diet led to abnormal mitochondria, with loss of cristae, rarefied matrix, and lipid droplet accumulation (Figure 5b). These signs of mitochondrial damage were not seen in cells from Chow fed mice (Figure 5a). Congruently, while the number of mitochondria was significantly increased the corresponding size in HC livers was reduced (Figure 5c). To evaluate the impact of HC diet on mitochondrial dysfunction, we studied the content of the main proteins involved in mitochondrial dynamic: PGC-1α, a central regulator of mitochondrial biogenesis through interactions with multiple transcription factors; Drp1, a main regulator in mitochondrial fission; OPA1, a mitochondrial dynamin like GTPase located at the inner membrane that regulates mitochondrial fusion and cristae remodeling alongside with mitofusin (Mfn) 1 and 2. Figure 5d, Supporting Information Figure 4, show an increase in the activation of Drp1 (Ser-616), and in the expression of PGC-1α, whereas OPA1, Mfn1, and Mtn2 all decreased significantly in the hepatocytes from HC mice. These results suggest that components regulating mitochondrial fission and biogenesis were increased by HC diet, contributing to the imbalance in mitochondrial dynamics.

3.6 | HC diet promotes cell survival

Compromised mitochondria homeostasis might affect cellular survival. Therefore, we evaluated the expression levels of the main mitochondrial survival-related proteins (Figure 6a, Supporting Information Figure 5). Interestingly, pro-apoptotic Bax protein was significantly increased and Bcl-2 was downregulated, but feasible compensatory antiapoptotic response was displayed by the increment of Bcl-X_L and, remarkably by Mcl-1.

The outstanding elevation in Mcl-1 was also associated with a strong activation of Stat3 in HC samples, its main transcription factor. As expected, apoptosis was unaffected, judged by caspase 3 activity, (Figure 6b), suggesting that cholesterol overload in mitochondrial

INFORME DE LABORES 2019

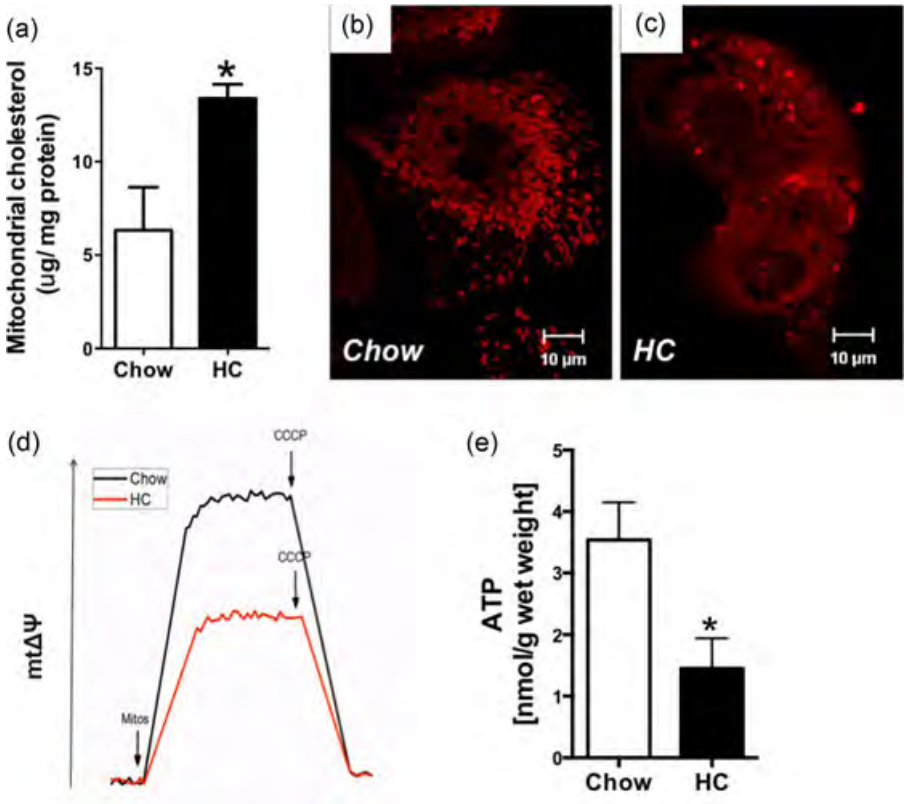

FIGURE 4 The high cholesterol diet induces mitochondria overload in mitochondria altering mitochondrial morphology and functionality. (a) Mitochondrial cholesterol content. Confocal Microscopy inspection of the mitochondrial transmembrane potential assayed by Mito Red fluorescence in cultured primary hepatocytes isolated from (b) HC diet fed mice and (c) Chow diet fed mice. (d) Mitochondrial transmembrane potential ($\Delta\Psi$) determined by using 10 μM safranine-O, following the absorbance changes at 511–533 nm. $\Delta\psi$ was collapsed by adding 5 μM of the protonophoro m-chlorophenylhydrazone (CCCP). Images are representative of at least three independent experiments. (e) ATP determination in liver homogenates from both HC and Chow diet fed mice. Each column represents the mean ± standard error of the mean (*SEM*), at least four independent experiments. $^{*}p \leq 0.05$ versus Chow

might yield to apoptosis resistance, despite ROS overproduction by a mechanism that could be mediated, particularly, by Mcl-1.

4 | DISCUSSION

We and others have reported that cholesterol overload in the liver promotes oxidative stress, liver damage and sensitizes to a more severe damage (Domínguez-Pérez et al., 2016; López-Islas et al., 2016; López-Reyes et al., 2015; Mari et al., 2006) in the context of relevant cytotoxic stimuli ultimately leading to advanced liver disease as well as cancer (Enríquez-Cortina et al., 2017). Moreover, mitochondrial dysfunction has been implicated in the progression of steatosis to NASH (Kim et al., 2017). Although mitochondria dysfunction has been frequently associated to chronic liver diseases and hepatocarcinogenesis, detailed molecular and functional characteristics remain partially characterized, in addition to the unknown effect in global gene expression signature.

In the current study, we aimed to dissect the effects of cholesterol overload in the mouse liver with emphasis on the mitochondria homeostasis and the relevance in the transcriptome.

An increased liver content of TG and cholesterol were observed, although HC mice maintained the same body weight as control, due to both experimental diets being isocaloric. Histopathological examination of the liver revealed microvesicular steatosis after 30 days of HC diet feeding (Figures 1i, and 5b), phenotype in agreement with that observed in rats under same diet (Marí et al., 2006). Liver function tests were elevated, and an increase in ROS content was found in tissue and in hepatocytes primary culture. Previous data from our group showed the ratio of reduced GSH to oxidized GSH (GSSG) was significantly decreased by the HC diet as compared to the corresponding Chow fed mice. HC mice also displayed a greater increase in lipid oxidation as measure by the rate of production of thiobarbituric acid-reactive substances (Gomez-Quiroz et al., 2016).

One of our main interest was to address the gene expression profile induced by cholesterol liver overload, HC diet induced dysregulation 938 genes, 493 were upregulated, and 499 downregulated, indicating a prominent impact in gene expression tending to an adaptive response, that could be related, among other physiological processes, to apoptosis resistance in a mechanism involving mitochondria homeostasis and function, narrowed linked to changes in mitochondria redox state, judged by the overexpression of SOD2 (Figures 2b and 3f) key regulator

of the mitochondria redox status, and the selenoprotein (Selenop) another antioxidant protein particularly expressed in the liver. Figure 2e,f show that this gene expression signature favoring particularly hepathopaties such as cholestasis, HCC, and hyperplasia, consistent with our previous findings in a mice model of HCC (Enríquez-Cortina et al., 2017), previous work we have reported that under HC diet, and in the presence of a carcinogenic stimulus, mice develop an aggressive phenotype of HCC (Enríquez-Cortina et al., 2017), correlating with the present transcriptomic data; interestingly, we found the overexpression of Hspb1, a gene encoding the HSP 27, which has been reported to be associated with poor clinical outcome (Choi et al., 2017), in fact, we reported the finding of metastasis in lungs, and resistance to

INFORME DE LABORES 2019

cell death, but in the present work we are observing that this issue is related to cholesterol overload rather than N-diethylnitrosamine carcinogenic effect.

HC diet induced liver damage and dysfunction, associated with a decrease in mitochondrial membrane potential and ATP content. It has been reported that increased mitochondrial cholesterol content can lead to mitochondrial dysfunction (Balboa et al., 2017), including reduced fluidity of mitochondrial membranes (Garcia-Ruiz et al., 2009), reduced ATP generation (Yu et al., 2005), and decreased mitochondrial GSH import (Marí et al., 2006). Our data show decreased mitochondrial membrane potential, ATP production, and increased cholesterol levels in the organelle.

From the perspective of HC diet, we found that it induced several patterns of mitochondrial alteration: (a) increment in cholesterol content, which plays an important role in the change of membrane fluidity (Marí et al., 2006), (b) it induced sensitization to oxidative stress, leading to mitochondrial insufficiency and metabolic abnormality, (c) it impaired mitochondrial bioenergetics, and (d) it promoted steatohepatitis, leading to the retardation of mitochondrial function, as it has been recently reported (Bellanti et al., 2018). Mitochondria obtained from HC liver presented twice cholesterol content compared to control, and biogenesis and mitochondrial fission were observed. Mitochondrial cholesterol content is relevant for the transport of mitochondrial-reduced GSH. In fact, it has been found that cholesterol incorporation in isolated mitochondria decreases mGSH stores (Fernandez-Checa & Kaplowitz, 2005). Furthermore, we found alterations in mitochondrial dynamics in HC cells. Our study provides evidence of an increase in the activation of Drp1 related with increased fission (increased mitochondrial number), but not fusion, as suggested by the downregulation of Mfn1, Mfn2 and OPA-1 in addition, the increment of PGC-1α, strongly suggest mitochondrial biogenesis Both fission and fusion are critical mechanisms for the growth, redistribution, and maintenance of healthy mitochondria or disease-related processes, especially apoptosis and mitophagy. In the current study, HC diet induced the imbalance of fission and fusion proteins as shown by a high activation of Drp-1 and a low expression of OPA-1 and mitofusins.

An increased content of antiapoptotic proteins, particularly Mcl-1, in HC livers explains the result of caspase 3 activity which shows no changes despite Bax increment and Bcl-2 decrement.

Lucken-Ardjomande and coworkers (Lucken-Ardjomande, Montessuit, & Martinou, 2008) using the cationic sterol U18666A as a tool to increase mitochondrial cholesterol levels, reported that cholesterol prevents apoptosis impeding Bax activation after its insertion into the mitochondrial outer membrane. Mitochondria could sense stress to allow for cellular adaptation to the environment, with the flexibility to adapt. Our results show that mitochondria adapt to high levels of cholesterol content increasing fission. Also, a decrease in apoptosis was observed conferring cell survival in HC adverse condition. Thus, an increase in cholesterol could favor that damaged hepatocytes do not enter apoptosis and proliferate, perpetuating liver damage.

STAT3, a cell proliferation related transcription factor that modulates many genes related to apoptosis, cell cycle and epithelial to mesenchymal transition, was activated in HC hepatocytes.

All findings in this study, and the increase in p-STAT3 (Ser727) content and DNA oxidation (data not shown) in liver after one month HC diet could suggest that damaged hepatocytes could proliferate and perpetuate liver damage. NAFLD is an increasing cause HCC.

Recently, we have reported that an HC diet increases oxidative DNA damage and a rapid carcinogenic process, this was associated to an impairment in the activation of DNA repair enzymes, resulting in liver tumors with an aggressive phenotype in comparison with animals under Chow diet (Enríquez-Cortina et al., 2017), demonstrating that certainly, cholesterol could display tumor promoter properties. Even more, recently it was published that free fatty acids and cholesterol derivatives by autoxidation, synergically facilitates development and progression of NAFLD to NASH by impairing mitochondria function, supporting our findings particularly on cholesterol effects (Bellanti et al., 2018), although This study remarkably shows the relevance of cholesterol participation in NAFLD to NASH progression, our work focuses on the impact of cholesterol alone, providing evidence that mitochondria impairment is independent of free fatty acids overload.

In summary, cholesterol overload in the liver, and particularly in mitochondria, induces remarkably transcriptomic changes, mainly associated to mitochondria function and dynamic which favors oxidative stress, apoptosis resistance that could promote transformation, as we recently probed.

Whole-Genome Duplication and Yeast's Fruitful Way of Life

Ximena Escalera-Fanjul,[1] Héctor Quezada,[2] Lina Riego-Ruiz,[3] and Alicia González[1,*]

Studies on the fate of *Saccharomyces cerevisiae* paralogous gene pairs that arose through a whole-genome duplication event have shown diversification of retained duplicated genes. Paralogous functional specialization often results in improved function and/or novel function that could contribute to the adaptation of the organism to a new lifestyle. Here, we analyze and discuss particular case studies of paralogous functional diversification that could have played a role in the acquisition of yeast fermentative metabolism.

Highlights

S. cerevisiae genomic duplication resulting from an allopolyploidization event gave rise to a hybrid allotetraploid.

Retention and diversification of WGD paralogous genes allowed the establishment of fermentative metabolism.

Global analysis and case-specific studies are beginning to uncover the molecular mechanisms by which WGD paralogous diversification enabled the development and establishment of a 'new way of life'.

Origin and Significance of Yeast's Whole-Genome Duplication

Saccharomyces cerevisiae was the first eukaryote whose genome was fully sequenced. Genome analysis revealed the presence of duplicated gene blocks, indicating that this yeast lineage arose from a **whole-genome duplication** (**WGD**) (see Glossary) [1–3]. WGDs are a recurring phenomenon in evolution. Some fungi, most species of flowering plants, and vertebrates descend from ancestors that doubled their genomes. WGDs have been associated with the acquisition of novel traits as well as increased species richness [4].

It has been proposed that the selective conservation of duplicated genes in *S. cerevisiae* has been essential for the acquisition of a predominantly fermentative lifestyle, also termed the 'make-accumulate-consume' strategy (i.e., upon sugar availability, ethanol is produced, accumulated, and finally consumed). This strategy largely relies on the Crabtree effect (Box 1) that allows yeast to out-compete other microorganisms [5]. The retention of 551 WGD gene pairs involved in different cellular processes and the complexity of the Crabtree effect make it difficult to demonstrate whether the selective retention of WGD paralogous genes led to 'a new way of life'. *S. cerevisiae* is presently the best suited model to study this phenomenon due to the vast amount of technical resources and information available for this organism [6]. In addition, the advancement of whole-genome sequencing and phenotyping of 1011 *S. cerevisiae* isolates from diverse geographical locations has provided valuable information into the ecological and evolutive niche of this yeast [7]. This review examines evidence provided by different experimental approaches addressing the role of WGD in the acquisition of fermentative metabolism in *S. cerevisiae*.

Mapping the Beginning of the Fermentative Lifestyle

After the publication of the complete *S. cerevisiae* genome sequence in 1996, several studies focused on understanding its origins and evolution. While some groups supported the idea that the duplicated regions observed in this yeast's genome were the signatures of an ancient WGD [3,5], others proposed that these duplicated regions arose independently by local duplication events [8]. This controversy was not solved until 2004, when the genomic sequences of other yeast species were published and used for comparative genomic analyses. Independent studies revealed that the genome of *S. cerevisiae* mapped in 2:1 manner to non-WGD yeast genomes, supporting the WGD model [9–11]. Further scrutiny and the development of the

Box 1. *Saccharomyces cerevisiae* Fermentative Metabolism

The majority of cells only use fermentation when respiration is impaired, for example, when oxygen concentration is low (Pasteur effect). However, in the presence of high glucose concentrations and regardless of oxygen availability, *Saccharomyces cerevisiae* prefers to ferment glucose to ethanol. This physiological phenomenon is named the Crabtree effect [64]. In this metabolic state, the cytoplasmic pyruvate produced by glycolysis is transformed to acetaldehyde and then to ethanol, which diffuses to the extracellular medium [21].

During fermentation, the energy for growth is mainly provided by glycolysis and not by the oxidative respiration pathway. However, the amount of energy produced from a glucose molecule by fermentation is lower than that produced by its complete oxidation. Consequently, during fermentation *S. cerevisiae* displays a high glycolytic flux to match its growth requirements. The increased glycolytic rate under the fermentative regime helps yeasts grow much faster than when they grow in non-fermentable carbon sources, such as ethanol, where the oxidative respiration pathway is used to produce energy [65].

During fermentation, glucose repression reduces the mass and energy flux through the tricarboxylic acid (TCA) cycle, the respiratory chain, and the oxidative phosphorylation. However, the TCA cycle displays enough activity to provide the necessary precursors to produce the macromolecular components to sustain rapid growth rate [65,66]. Under these conditions, the TCA cycle does not work as a cycle, but rather in a branched manner, mainly because the succinate dehydrogenase complex does not operate under these conditions [67]. When glucose becomes limiting, cells undergo a so-called diauxic shift, a transient phase in which they switch to a fully respiratory metabolism, catabolizing the released ethanol via the TCA cycle [65].

S. cerevisiae response to sugar availability is dependent on different time scales and biological levels, from the reprogramming of gene expression to enzyme allosteric regulation, including post-transcriptional and post-translational regulatory mechanisms. It also involves a variety of cellular processes as different signal transduction pathways, energy and fatty acid metabolism, carbohydrate storage, and amino acid biosynthesis [68].

Yeast Gene Order Browser, an online tool for visualizing gene order context (synteny) of any gene from several yeast genomes [9,10,12], showed that the whole *S. cerevisiae* genome is duplicated [1–3,12]. Furthermore, it has now been confirmed that as well as *S. cerevisiae*, several other yeasts such as *Candida glabrata* arose from WGDs [13]. When WGD was initially proposed [3], it was not possible to tell whether it was the result of an **autopolyploidization** or an **allopolyploidization** event [14,15]. However, autopolyploidization constituted the most parsimonious hypothesis. Later, evidence was presented in favor of allopolyploidization, indicating that the *S. cerevisiae* lineage arose from an interspecies hybridization between a strain related to the *Kluyveromyces*, *Lachancea*, and *Eremothecium* (KLE) clade and another related to *Zygosaccharomyces rouxii* and *Torulaspora delbrueckii* (ZT) clade [9,16]. This proposal was extensively analyzed and accepted [2]. Therefore, the pair of **paralogous genes** that are observed today could have both originated from one of the parental species (ohnologous pairs), or each one of the parental species involved in the allopoliplodization event could have independently generated one member of the pair (homeologous genes) [16].

Even before the WGD controversy was settled (1996–2004), the fact that the WGD could have allowed *S. cerevisiae* to develop an oxygen-independent metabolism, through the retention and further specialization of duplicated genes/products, was considered for the first time [3,5] (Box 2). This proposition was based on the observation that the majority of yeasts were unable to grow in absence of oxygen [17].

The progress in comparative genomics in the 2000s allowed a better understanding of the evolution of the *S. cerevisiae* genome and a proper classification of the phylogenetic relationships among yeasts [13,18]. The new phylogenetic trees provided a framework to locate some major evolutionary events that could have contributed to the improved fermentation ability of

Glossary

Adaptive radiation: evolution of organisms into a wide variety of types adapted to specialized modes of life.
Allopolyploidization: a mechanism that generates an individual or strain with two complete sets of chromosomes, each one from a different species.
Autopolyploidization: in contrast to allopolyploidization, the two different sets of chromosomes are from the same species.
Biased fractionation: a phenomenon observed after WGDs where the ohnologues of a subgenome are preferentially lost.
Feedback inhibition: the phenomenon where the output of a process is used as an input to control the behavior of the process itself.
Genome dominance: a phenomenon observed after WGD where, in general, the ohnologues from one subgenome display higher transcriptional levels than their onhologous pair derived from the other subgenome.
Hetero-oligomers: a complex made of different protein subunits is called a hetero-oligomer; when only one type of protein subunit is used in the complex, it is called a homo-oligomer.
Moonlighting functions: protein moonlighting function is a phenomenon by which a protein can perform more than one biological role.
Orthologous: genes in different species that evolved from a common ancestral gene by speciation; orthologs retain the same function in the course of evolution.
Paralogous or ohnologous genes: duplicated genes in the same organism that were evolved from either a gene duplication, an autopolyploidization event, or an allopolyploidization event.
Robustness: the ability of a system to maintain its function despite a perturbation.
Small-scale duplication (SSD): doubling of a small-scale genomic regions involving one to a few genes.
Subgenome: set of genomic regions of a WGD species inherited from one of the parental species.

Box 2. Fate of Duplicated Genes

Gene duplicates, also called paralogs, are found in all three domains of life, suggesting that an important amount of genes were generated by gene duplication [69]. Although the immediate consequence of gene duplication is the doubling of the ancestral function (functional redundancy), after duplication genes can experience divergence that may result in the generation of new or specialized functions and thus shape evolution. This box summarizes the possible scenarios determining the fate of duplicated genes.

Loss of function: Loss of function occurs when functional redundancy is not advantageous and therefore one of the paralogous genes gradually becomes a pseudogene, through the accumulation of loss-of-function mutations [70]. Interestingly, soon after WGDs polyploids experience a rapid loss of genetic redundancy. The current hypothesis is that when WGDs result from an autopolyploidization, the loss of duplicated genes is randomly distributed between the two parental **subgenomes** (non-biased fractionation). By contrast, when the WGD derives from an allopoliploidization, loss of duplicated genes is biased towards a certain parental subgenome (**biased fractionation**), frequently towards the one displaying lower gene expression, a phenomenon called **genome dominance** [71,72].

Gene-dosage amplification: Gene-dosage amplification holds that after gene duplication, both gene copies are conserved since either incrementing the ancestral function represents a selective advantage or both copies are necessary to maintain the appropriate stoichiometry of higher complexes (e.g., protein complexes) [16,71,73,74]. However, it must be considered that increased gene copy number does not necessarily lead to an equivalent function increment, since function/product dosage can be negatively regulated [75–77]. Thus, the gene-dosage amplification requires that the increment in copy number produce an increase in the codified function.

Subfunctionalization: Subfunctionalization occurs when the ancestral function(s) is distributed between the two copies or is differentially specialized in each one, as a result of either the accumulation of degenerative mutations (duplication-degeneration-complementation model) or by positive selection (escape from adaptive conflict model). In both cases, both paralogs are necessary to perform the function that, in the ancestor, was carried out by a single gene [78–81].

Neofunctionalization: Neofunctionalization is the mechanism explaining the origin of novel functions through gene duplication. It considers that while one of the copies conserves the ancestral function, the other is free to acquire a new adaptative function through the accumulation of neutral mutations [82].

Whole-genome duplication (WGD): mechanism by which an organism doubles its chromosome number.

yeasts, such as the loss of the respiratory complex I, the horizontal transfer of the bacterial *URA1*, and the rewiring of rapid growth elements [19].

Starting in 2007, the role of the WGD in the acquisition of yeast fermentative metabolism began to be recognized, mainly through the characterization of the phenotypic responses of various representative species of the Saccharomycetaceae [19–21]. It was found that the Crabtree effect was present in several species of the above-mentioned family. However, yeasts closer to *Saccharomyces* in the phylogenetic tree displayed a more pronounced Crabtree effect, and with the exception of the *Tetrapisispora* group, were able to generate non-respiring mutants, while most of the non-WGD species could not [19,21]. As for the ability to grow under anaerobiosis, the post-WGD species were able to generate sufficient energy to grow under strictly anaerobic conditions, while non-WGD species showed a reduced Crabtree effect and ability to grow in the absence of oxygen [20]. These contributions support the proposition that yeasts' transition to a fermentative lifestyle began before the WGD in non-WGD yeasts in a rather multistep process. However, for Saccharomycetae, this metabolic trait was established after the WGD event [19]. This comparative physiological evidence, and the dating of both the WGD (from 150 to 100 Mya) and the **adaptive radiation** of flowering plants (from 101 to 66 Mya) in the Late Cretaceous [3,22,23], led to the hypothesis that the WGD allowed yeasts to compete for the increased amount of sugars present in fruits [19]. It could thus be expected that retained WGD genes could be enriched in cellular processes related to the make-accumulate-consume strategy.

WGD and Small-Scale Duplications Contribution to Fermentative Metabolism

The contribution of WGD to *S. cerevisiae* fermentative lifestyle could be assessed comparing WGD and **small-scale duplication** (SSD) gene sets in terms of genetic interactions and divergence in expression and functions. One of the first studies on this matter proposed that WGD, but not SSD, must have provided the raw material for conservation of dosage-sensitive genes and groups of genes expressed at a precise stoichiometric ratio, such as those encoding ribosomal proteins [24]. It has been proposed that such dosage and stoichiometric effects could have been involved in the conservation of glycolytic genes [25]. Consistent with this it was found that gene duplicates (combined WGD and SSD) were overrepresented in central carbon metabolism and hexose transport [26]. However, the separate analysis of the gene sets revealed that enrichment in genes involved in carbohydrate metabolism was higher for WGD than for SSD [27]. Divergence in the expression patterns between members of a pair has also been reported to be higher for the WGD than for the SSD set of paralogs [27]. It may be possible that divergent regulation between members of some duplicated pairs could have contributed to the specialization of one paralog for glycolysis-ethanol production and the other for gluconeogenesis-ethanol consumption phases. The impact of such differential regulation on the acquisition of fermentative metabolism could be estimated by comparing the rates of negative expression correlations between members of a pair during growth on glucose or ethanol as carbon sources. To explore this possibility, data from a quantitative proteomic study were used where the relative abundances of 3609 proteins were determined [28]. Comparison of the abundance of both paralogs during fermentation, diauxic shift, and glucose exhaustion phases indicated that 29% of WGD and 19% of SSD duplicates showed differential regulation during fermentative and respiratory metabolism. The same trend was observed using data from a transcriptomic study that determined the fold change in transcript levels for 5800 genes from cells cultured on rich media with glucose or ethanol as carbon sources [29]; the estimated percentage of divergent expression was 26% for the WGD and 14% for the SSD duplicates (for analysis details of proteomic and transcriptomic data, see the legend of Figure S1 in the supplemental information online). Interestingly, the enzyme-coding subset of genes with differential expression during fermentative and respiratory metabolism among WGD genes clustered around carbohydrate metabolism (Figure 1A; Figure S1A). By contrast, enzymes encoded by SSD paralogs seem to be randomly dispersed around various metabolic pathways (Figure 1B; Figure S1B) [28,29].

Comparison of gene ontology (GO) categories' fold enrichment between divergent and complete sets of genes (Figure 2) shows that for the WGD group, glucose metabolism GO terms are overrepresented (Figure 2A). Furthermore, the WGD divergent set displays a higher fold enrichment in glucose metabolism GO terms than that exhibited by the WGD complete set (Figure 1A; Figure S1A). Moreover, glucose metabolism is not represented in the SSD group (Figure 2B), which for divergent and complete categories is enriched in biosynthetic processes, suggesting a different evolutionary trend. Overall, these results indicate that the WGD set of genes display a more relevant contribution than those of SSD set to the acquisition of a fermentative lifestyle in the *S. cerevisiae* lineage.

Duplicated Genes Case Studies Uncover Molecular Mechanisms behind Subfunctionalization

Detailed analysis of subfunctionalization of particular paralogous pairs is necessary to identify the molecular mechanisms involved in functional diversification and the roles of specific duplicate genes in the acquisition of fermentative metabolism. We first analyze four examples

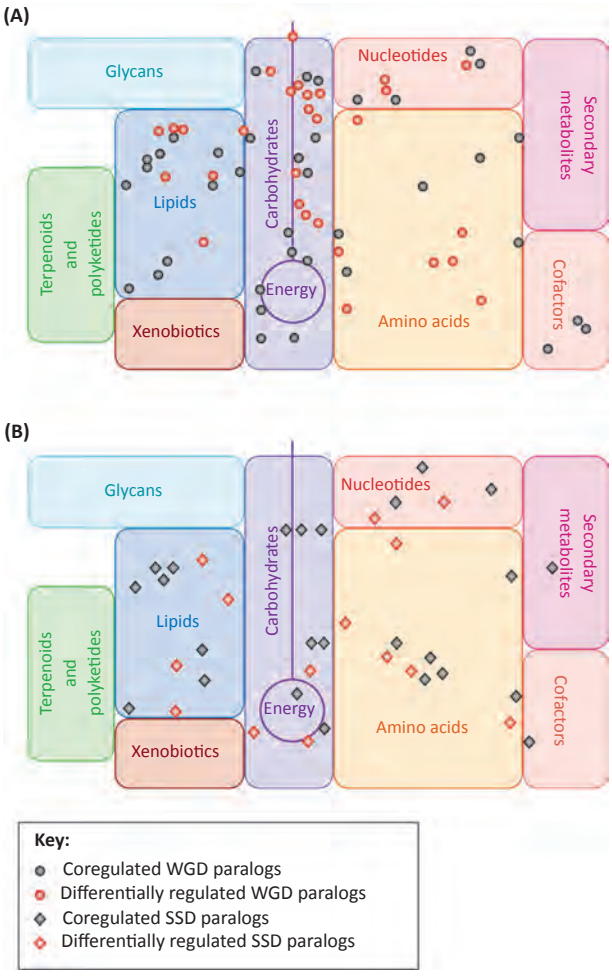

Figure 1. Duplicated Gene Pairs Originated from WGD Are Enriched for Genes Encoding Enzymes Involved in Carbohydrate Metabolism. Enzymes encoded by whole-genome duplication (WGD) (A) or small-scale duplication (SSD) (B) paralogs were mapped on the Kyoto Encyclopedia of Genes and Genomes refer pathway map (http://www.genome.jp/kegg/pathway/map/map01100.html) [84]. Coregulated or differentially regulated paralogs were selected according to their regulation pattern during fermentative or respiratory conditions from global studies [28,29]. For pathway details, gene identity, and analysis, please see Figure S1 in the supplemental information online.

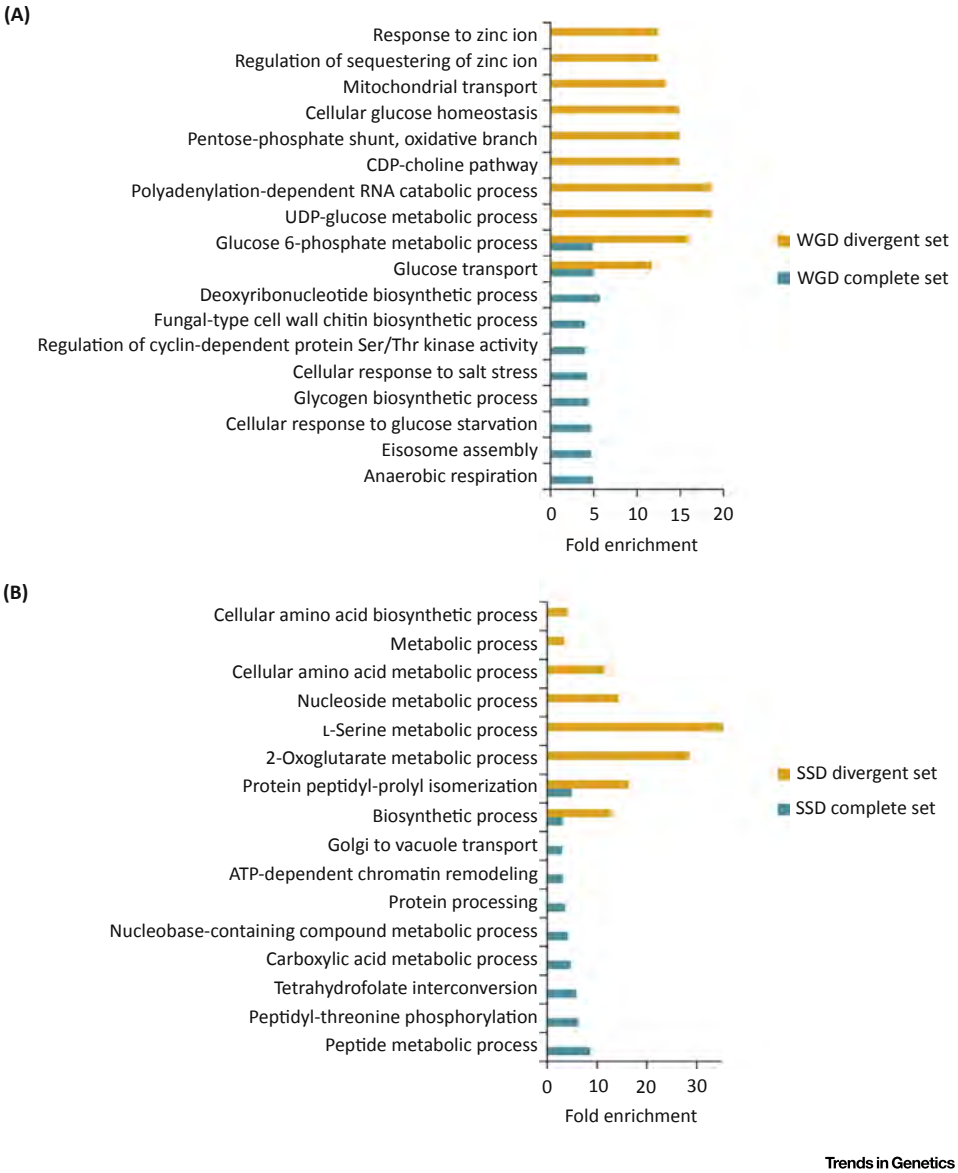
of gene pairs that, according to the phylogeny-based prediction of PhylomeDB v4, could be proposed as ohnologous WGD pairs [30].

ENO1- and *ENO2*-encoded phosphopyruvate hydratases catalyze the reversible conversion of 2-phosphoglycerate to phosphoenolpyruvate. Under fermentative conditions, Eno2 constitutes the predominant form, while under respiratory conditions both polypeptides are present and contribute to gluconeogenesis [31]. Random assortment of Eno1/Eno2 monomers allows the formation of homo- and hetero-dimers: Eno1-Eno1, Eno2-Eno2, and Eno1-Eno2, whose peculiar organization could influence the opposed role these enzymes play in the glycolysis and gluconeogenesis [32] (Figure 3).



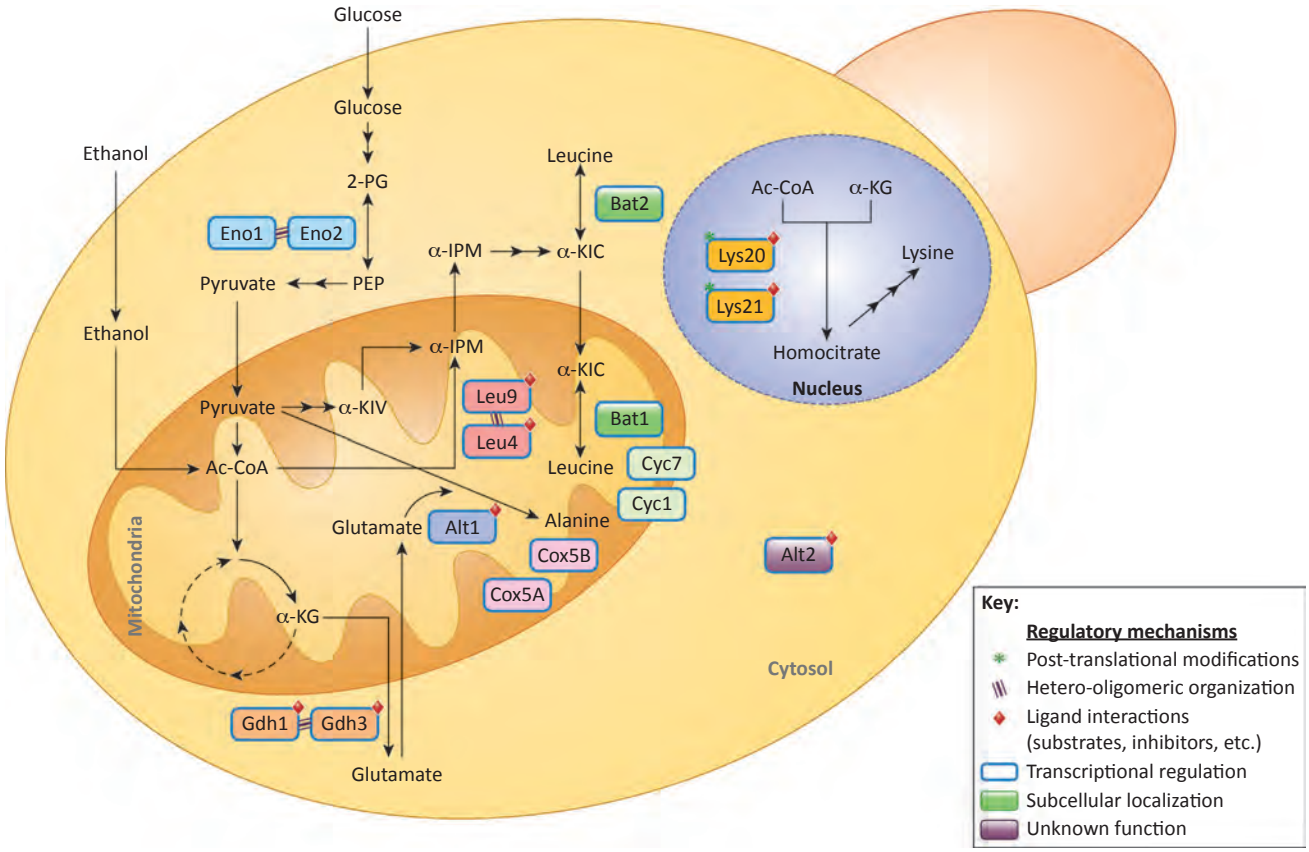


Figure 2. WGD and SSD Gene Sets Contribute to Different Cellular Processes during Fermentative and Respiratory Metabolism. Top ten GOTERM_BP_DIRECT categories with higher enrichment fold values among whole-genome duplication (WGD) (A) or small-scale duplication (SSD) (B) gene sets are shown ($P < 0.01$). The complete gene sets include 1094 and 674 genes for WGD and SSD, respectively. The sets with divergent expression patterns include 328 and 106 genes for WGD and SSD, respectively. Paralogs with divergent regulation between members of a pair were obtained from global studies [28,29] analyzed as described in Figure S1 in the supplemental information online. For the set of SSD paralogs with divergent regulation, only eight terms result with $P < 0.01$. Gene annotation enrichment analysis was made using the DAVID 6.7 website (https://david.ncifcrf.gov/) with default values. CDP, cytidine diphosphate; UDP, uridine diphosphate.

Formation of heteromeric isozymes plays a role in functional diversification of the two ohnologous WGD-pair [33] encoding cytosolic NADP-GDHs (*GDH1* and *GDH3*), catalyzing glutamate biosynthesis from ammonia and α-ketoglutarate (α-KG). While the homo-hexameric Gdh1 is the sole isoform present under fermentative conditions, the homo-hexameric Gdh3

Trends in Genetics

Figure 3. Molecular Mechanisms of Paralog Subfunctionalization. Enzyme-coding whole-genome duplication paralogs can diverge and become specialized in different metabolic conditions. Illustrative examples and the corresponding mechanisms of subfunctionalization are shown. Ac-CoA, acetyl coenzyme A; α-IPM, alpha isopropylmalate α-KG, alpha ketoglutarate; α-KIC, alpha ketoisocaproate; KIV, alpha ketoisovalerate; PEP, phosphoenolpyruvate; 2-PG, 2-phosphoglycerate.

is only present in a *gdh1*Δ mutant grown on ethanol as sole carbon source and the Gdh1-Gdh3 hetero-hexameric isoform(s) prevail under respiratory conditions [34]. Accordingly, *GDH1* expression is maintained through the different growth phases, while that of *GDH3* is null during fermentation and due to chromatin remodeling increases 70-fold when cells enter diauxic shift and respiratory growth [35].

The affinity of the three isoforms towards α-KG (Gdh1-Gdh1 > Gdh1-Gdh3 > Gdh3-Gdh3) agrees with the idea that under fermentative growth, energy is provided by glycolysis; thus, the high rate activity of Gdh1 does not compromise energy yield. Under respiratory conditions when the tricarboxylic acid (TCA) cycle contributes to energy production, *GDH1* and *GDH3* are simultaneously expressed and a variety of isozymes can be built up depending on the Gdh1:Gdh3 ratio. Therefore, the modulable heteromeric isoforms constitute a pacemaker mechanism determining glutamate biosynthesis and balanced α-KG utilization [34,36] (Figure 3).

The kinetic properties of the NADP-*Lk*Gdh1 present in the non-WGD yeast *Lachancea kluyveri* are closer to those of Gdh1, while kinetics of the *Kluyveromyces lactis* NADP-*Kl*Gdh1 resemble those of Gdh3, suggesting there is a correlation between the NADP-GDHs kinetic properties

and the level of adaptation to the fermentative or respiratory lifestyle [33]. The above-mentioned results indicate that both *GDH1* and *GDH3* originated from the KLE lineage, supporting predictions obtained through PhylomeDB v4 [30].

Paralogous mitochondrial homo- and heteromeric isozymes were formed by the *LEU4*/*LEU9* ohnologous WGD-pair [30], encoding α-isopropylmalate synthases that synthesize α-isopropylmalate (α-IPM) from acetyl-coenzyme A (CoA) and α-ketoisovalerate, an intermediate of leucine biosynthesis and co-activator of the Leu3 transcriptional regulator [37]. Leu4-Leu4 and Leu9-Leu9 homodimers are leucine sensitive or resistant isoforms, respectively, while the heterodimeric isoform Leu4-Leu9 shows intermediate leucine sensitivity. On ethanol as carbon source, *LEU4* expression is 3-fold increased compared to that found in glucose, while that of *LEU9* is low on both carbon sources. Leu4-Leu9 and Leu4-Leu4 formation prevents leucine and α-IPM over-synthesis, mediating a more balanced distribution of pyruvate and acetyl-CoA to intermediary biosynthesis and energy yielding metabolism particularly under respiratory conditions. Exclusive expression of Leu9, in a *leu4Δ* genetic background, results in slow growth on either glucose or ethanol as carbon sources and leucine accumulation, indicating that Leu9-Leu9 resistance to leucine **feedback inhibition** impairs flux control through the biosynthetic pathway [37] (Figure 3).

Lys20 and Lys21 nuclear homocitrate synthases participate in lysine biosynthesis by catalyzing homocitrate production, condensing acetyl-CoA with α-KG [36]. Lysine is a strong inhibitor for Lys21, inducing positive cooperativity for α-KG binding. Under fermentative conditions, Lys20 and Lys21 play redundant roles, and even when *LYS20* and *LYS21* ohnologous WGD-pair are overexpressed, and lysine pools increase 4- to 10-fold, growth rate is not reduced, confirming the conclusion that α-KG drainage is not deleterious under fermentative conditions [36]. Lys21 activity is crucial for growth under respiratory conditions and can sustain wild-type growth by itself. Subfunctionalization includes differential *LYS20* and *LYS21* expression and a post-transcriptional mechanism that determines the abundance of each enzyme. Differential lysine inhibition, α-KG modulation, and the control of the intracellular amount of the two enzymes result in a regulatory mechanism determining the rate at which α-KG is diverted to either lysine biosynthesis or to other metabolic pathways (Figure 3) [38].

The above-mentioned presented cases show that the combined action of the formation of paralogous homo- and hetero-oligomeric isozymes with peculiar kinetic properties and contrasting gene expression results in functional diversification, providing a means to differentially control metabolic fluxes under fermentative or respiratory conditions.

The four next examples correspond to WGD-pairs that could be tentatively proposed as homeologous, according to PhylomeDB v4 prediction [30]. Bat1 and Bat2 branched chain aminotransferases are located in mitochondria and cytosol, respectively; thus, formation of **hetero-oligomers** is impeded. Diversification of the *BAT1* and *BAT2* relies on the acquisition of opposed expression profiles [39]. Bat1 has a biosynthetic character, since *BAT1* expression is privileged in the absence of branched chain amino acids, while Bat2 displays a catabolic role. *BAT2* expression is maximal in the presence of branched chain amino acids [39,40]. Acquisition of environmentally regulated expression profiles could allow operation of differential or redundant roles depending on the peculiar environments found in *S. cerevisiae* natural habitats [7,41,42].

In regard to the contribution of Bat1 and Bat2 adaptation to fermentative metabolism, *BAT1* decreased expression under respiratory conditions and resulted in diminished metabolic flow to

amino acid biosynthesis, favoring energy-yielding pathways (Figure 3) [40]. The *KlBAT1* **orthologous gene**, present in *K. lactis* non-WGD yeast, encodes an enzyme displaying the dual biosynthetic-catabolic character that was later specialized among the *S. cerevisiae BAT1/BAT2* paralogous pair [39].

Functional characterization of the *ALT1/ALT2* WGD-pair gene/products established that only Alt1 possessed the presumed role of alanine transaminase activity [43]. The analysis of the only orthologous gene/product present in *L. kluyveri* and *K. lactis* non-WGD type yeasts suggested that Alt2 functional diversification resulted in the loss of its alanine transaminase activity [44]. Probably, as the result of a structural change modifying the interaction with its cofactor pyridoxal 5-phosphate (PLP), allowing the formation of only one of the two tautomeric PLP isomers necessary for the transamination reaction. The fact that Alt2 forms a catalytically active Schiff base with PLP and is found in a phylogenetic branch with several *Saccharomyces* genera, which do not harbor Alt1, suggests this enzyme has a yet undiscovered function (Figure 3) [45].

Cytochrome *c* oxidase (COXC) is a complex composed of several proteins that transfer electrons from cytochrome *c* to molecular oxygen [46]. Cox5 is essential for complex assembly and has two paralogous isoforms: Cox5A and Cox5B. *CYC1* and *CYC7* encode paralogous isoforms of the electron carrier protein cytochrome *c*, promoting the final transfer of electrons to oxygen by COXC. Under aerobic conditions, *COX5A* and *CYC1* are expressed, whereas *COX5B* and *CYC7* are Rox repressed and are only expressed under hypoxia. Differential expression of these genes had been previously considered to be important in yeast evolutionary adaptation to anaerobic growth [3]. As for *BAT1* and *BAT2*, functional diversification is achieved through the acquisition of opposed transcriptional patterns [40].

For some cases, orthologous *K. lactis* and/or *L. kluyveri* counterparts have been analyzed; however, it would be important to study both a KLE and a ZT representative for each case. This is mandatory to clarify whether sub- or neofunctionalization has occurred.

WGD Paralogous Genes Impart Robustness and Phenotypic Plasticity

As mentioned above, duplicated genes allow *S. cerevisiae* to adjust its phenotype to properly respond to a changing environment. The role of paralogous homo- and hetero-oligomers as key players regulating metabolic fluxes leading to new phenotypes has also been highlighted. In this section, we discuss this evidence in terms of **robustness** and phenotypic plasticity (Box 3). Gene duplicates have been associated to genetic robustness [47–49]; however, a recent study found opposing evidence suggesting that in some cases gene duplication can impart fragility [50]. By analyzing the protein–protein interaction network of 56 pairs of duplicated genes (WGD or SSD), it was found that in one-third of the cases, upon deletion of a paralogous copy, the remaining copy conserved its capacity to interact with its native binding partners and increased its association with those of the deleted copy, thus compensating paralogous pair loss [50]. In a similar amount of cases, after deletion of its cognate pair, the remaining copy decreased interactions even with its own binding partners, demonstrating dependency on its paralogous copy. In these cases, the lower expressed copy of the homologous pair was the only one displaying the dependency phenotype, indicating asymmetry and showing a stronger decrease in fitness (fragility) than that displayed by the independent copies. Furthermore, in the absence of its pair, the protein concentration of the dependent copy decreased, although its mRNA showed wild-type levels, suggesting protein destabilization [50,51].

Considering that, in general, dependent pairs form paralogous hetero-oligomers, it was proposed that the different paralogous isoforms could be degraded at different rates

Box 3. Duplicated Genes Contribute to Genetic Robustness

Robustness is defined as the ability of a system to maintain its function upon a perturbation. In living systems, perturbations can either be environmental or genetic. Multiple mechanisms that confer robustness to biological systems have been described. (i) Distributed robustness. Upon a perturbation, specific biological functions can be accomplished by alternative pathways, as in signaling and metabolic routes [49,83]. (ii) Redundancy. Multiple functional copies of a given component of the biological system can compensate the failure of another highly similar component, for example, paralogous genes [49,83]. (iii) Feedback control. By sensing the output of a function, it is possible to modulate the input to either narrow the output function (negative feedback) or to amplify and maintain signals against noise (positive feedback). This type of control contributes to preservation of cellular function (homeostasis) [47–49]. (iv) Modularity. The confinement of functions minimize the effects of disturbances by containing perturbations and damage locally [47–49].

It is considered that duplicated genes contribute to genetic robustness since the paralogous copies maintain a certain degree of functional redundancy. Thus, when one of the gene duplicates is deleted, the remaining copy can provide enough function to compensate the deletion of its paralogous pair. In several cases, the wild-type function of the retained copy is enough to compensate the deleted pair (passive paralogous compensation). In many other cases, the remaining paralog needs to modify its performance, to avoid the phenotypic or fitness defects produced by the deletion of its pair (active paralogous compensation). Different molecular mechanisms of active paralogous compensation have been identified: (i) Transcriptional reprograming. Some paralogous genes are upregulated upon the genetic perturbation, functionally compensating the deleted copy. (ii) Protein relocalization. Even though there are limited examples, the remaining copy could experience relocalization to the subcellular compartment were the deleted copy used to reside. (iii) Protein interaction rewiring. Some paralogous genes can increase the association with the binding partners of the missing copy [51].

Another important attribute of biological systems is phenotypic plasticity. This plasticity is recognized as the ability of a single genotype to produce different phenotypes, allowing a best performance within changing environments. Often phenotypic plasticity is considered to be the opposite of robustness [54]. However, paralogous genes have also been associated with phenotypic plasticity [62].

(independent homo-oligomers < hetero-oligomers < dependent homo-oligomers < monomers) [52,53]. However, the above-mentioned analysis did not account for self-interactions [50]. Interestingly, for the paralogs proteins Leu4 and Leu9 the formation of the Leu4-Leu9 heterodimer is preferred over that of the homodimers, possibly as the result of a higher affinity between different monomers than between self-monomers. However, both paralogous copies can form homodimers; nevertheless, it cannot be ruled out that when the concentration of the independent form is too low, oligomer:monomer equilibrium may be displaced towards the monomeric forms, resulting in higher degradation [52]. Besides Leu4-Leu9 heterodimers, other paralogous genes are capable of forming hetero-oligomeric complexes such as Gdh1-Gdh3 and Eno1-Eno2. For Leu4/Leu9 and Gdh1/Gdh3, in all cases the three different isoforms show specific kinetic parameters [32,34,37]. The coexistence of more than one isoform allows coping with a wider range of metabolite concentrations (substrates, inhibitors, etc.) than when there is only one isoform, providing a buffering effect and thus contributing to robustness (feedback control).

Another important attribute of biological systems is the phenotypic plasticity. This plasticity is recognized as the ability of a single genotype to produce different phenotypes, allowing a best performance within changing environments. Often phenotypic plasticity is considered to be the opposite of robustness [54]. However, since different isozymes are used in distinct metabolic context [34,37], regulating carbon flux to biomass production. It is possible that the ability to form hetero-oligomers contribute to the acquisition of the Crabtree effect and thus to phenotypic plasticity. If this is the case, heteromeric forming paralogous proteins could be considered as major regulators of both robustness and phenotypic plasticity, providing optimal fitness within changing environments [55].

Concluding Remarks and Future Directions

Recent advances in entire genome sequencing have generated an increasing interest in understanding the role of polyploidy on ecological shifts. In particular, different approaches have been used to elucidate the relationship between WGD and the acquisition of fermentative metabolism in *S. cerevisiae*. By comparing some physiological traits among the Saccharomycetaceae, it was possible to determine the central role of the WGD in the establishment of a new way of life for *S. cerevisiae*. The localization of the origin of fermentative metabolism before the WGD [19] suggests the prior existence of a selection pressure towards an oxygen-independent metabolism. The evolutionary trends followed by paralogous genes originated from WGD, which were identified through global analyses, have unveiled the general strategies that favored the establishment of a new lifestyle [26,29]. Moreover, the detailed analysis of particular duplicated pairs has shown some of the mechanisms behind the functional diversification of paralogous genes. Although detailed studies are scarce, some general rules on how particular changes in paralogous pairs have contributed to the acquisition of fermentative metabolism are starting to emerge (Figure 3).

Particularly interesting has been the finding that formation of hetero-oligomeric complexes contributes to robustness and phenotypic plasticity by enhancing the role of paralogous enzymes influencing the intracellular concentration of key metabolites such as α-IPM controlling the Leu3 transcriptional network [40]; leucine influencing cell growth control [56,57]; lysine determining response to oxidative stress [58]; and α-KG playing a functional role in aging [59].

Although the neolocalization of a paralogous copy is frequently observed [60], the evolutionary and physiological role of diversification of subcellular localization remains to be fully addressed (see Outstanding Questions) and certainly constitutes an open pathway to understand functional diversification of paralogs. In this respect, the analysis of **moonlighting functions** could govern the diversification of subcellular localization.

Future studies of paralogous pairs diversification must imperatively include specific analyses to understand whether a particular pattern is the outcome of sub- or neofunctionalization. To this end, pertinent paralogous functional characterization will also have to be addressed in non-WGD yeasts.

The rapidly increasing amount of *S. cerevisiae* isolates and the availability of their entire genome sequences will promote the systematical study of WGD genes from yeast strains collected from natural habitats [7,41,42,61–63] that could lead to the understanding of the involvement of duplicated genes in other processes besides the fermentative metabolism observed in controlled environments.

Outstanding Questions

What is the role of subcellular localization in paralogues functional diversification? Although it has been '*a priori*' considered that subcellular localization could have an important influence in the physiological role of a protein, no experiments have been performed that result in re-localization or co-localization of paralogous enzymes.

Are moonligthing properties inherited from the ancestor or did they arise after WGD? Do moonlighting properties diversify between paralogs? There are several examples of paralogous genes generated through WGD in which one of the members of the paralogous pair has an identified additional function (moonlight). However detailed analysis of its counterpart is compelling to definitively establish whether the moonlighting property has been conserved in both paralogs. Differential localization of enzymes such as Bat1 and Bat2 placed in mitochondria and cytosol, respectively, could be considered as a mechanism preventing formation hetero-oligomers. However, since Bat1 has a moonlighting function forming a complex with aconitase, its mitochondrial localization could have an important role in TCA regulation and not in its aminotransferase function.

Mathematical models have proven useful in understanding complex system behavior. Models may help answer the following questions at a systemic level: How does gene duplication alter metabolic fluxes and transcriptional regulation? What are the underlying regulatory mechanisms that allowed yeasts to acquire a fermentative lifestyle? How do WGD homologous genes orchestrate energy metabolism and biomass production to sustain the rapid growth rate observed during the Crabtree effect?

What are the most appropriate culture conditions to address the role of duplicated genes?

What is the relative contribution of post-translational modifications to divergence in regulation of proteins encoded by duplicated genes?

Small-molecule fluorescent probes having optimized optical properties, such as high photostability and brightness, local microenvironment sensitivity and specific subcellular localizations, are increasingly available. Although the basis for designing efficient fluorophores for bioimaging applications is well established, implementing an improvement in a given photophysical characteristic always tends to compromise another optical property. This problem has enormous consequences for *in vivo* imaging, where ensuring a specific localization and precise control of the probe response is challenging. Herein we discuss a fluorescent probe, **CC334**, as a case study of the chromenylium-cyanine family that commonly exhibits highly complex photophysical schemes and highly interfered bioanalytical responses. By an exhaustive and concise analysis of the **CC334** optical responses including detailed spectroscopic calibrations, steady-state microenvironment effects, ultrafast photophysics analysis and computational studies, we elucidate a new strategy to apply the probe in the singlet oxygen reactive oxygen species ($^1O_2$-ROS) monitoring using *in vitro* and *in vivo* models. The probe provides a new avenue for designing fluorescent probes to understand the dynamic behavior of subcellular environments.

Introduction

Chromenylium-cyanine (**CC**) probes are a well-studied family of fluorophores combining good photostability,[1] low cytotoxicity,[2] privileged structural diversity,[1–3] and low to moderate fluorescence quantum yields (QY_f),[4] expanding their applications from materials chemistry to fluorescence bioimaging.[1–5] Such properties, in part, are a consequence of their coumarin- and/or rhodamine-like identity, an intrinsic feature retained in their structure, exhibiting similar properties but lower QY_f. This brings the possibility to use these molecules as *fluorogens*, molecules able to activate their fluorescence in response to a given stimulus.[6] In fact, sacrificing QY_f to some extent enables different activation/deactivation pathways of the probe to be exploited in different stimuli-responsive scenarios. **CC** probes then comprise one of the most important examples of how existing fluorophores can be structurally modified to activate different response channels. However, the optical properties and the corresponding analytical responses of such 'recycled probes' are far from trivial. Activating a more versatile photophysical process in a fluorescent probe has several advantages, as mentioned, but the decrease in the QY_f and the signal-to-noise ratio are not the only disadvantages; in imaging microscopy more acquisition times are needed and unavoidable interference problems with the subcellular environment and misinterpretation of the output responses arise. For example, previously described **CC** probes are sensitive to acid–base,[7] oxidative,[8] local polarity,[9] ionic species,[10] temperature,[11] and reductant[12] stimuli, all of them however, present the same response scheme being extremely difficult to calibrate single-channel fluorescence profiles without no interference or cross-talk problems. Here we address the above-mentioned limitations using a **CC** probe having similar fluorescence responses upon exposure to different stimuli. Then, we describe a new strategy to analyse the multi-stimuli scenario of **CC** probes. The probe is derived from a chromenylium ion and coumarin 334, termed **CC334**. Finally, *in vivo* studies were implemented using Zebrafish models to draw a more robust conclusion.

Results and discussion

The chemical structures of **CC334** as well as some previously reported **CC** probes are presented in Fig. 1. To analyse their multistimuli-responsive profile, it is worth noticing that the

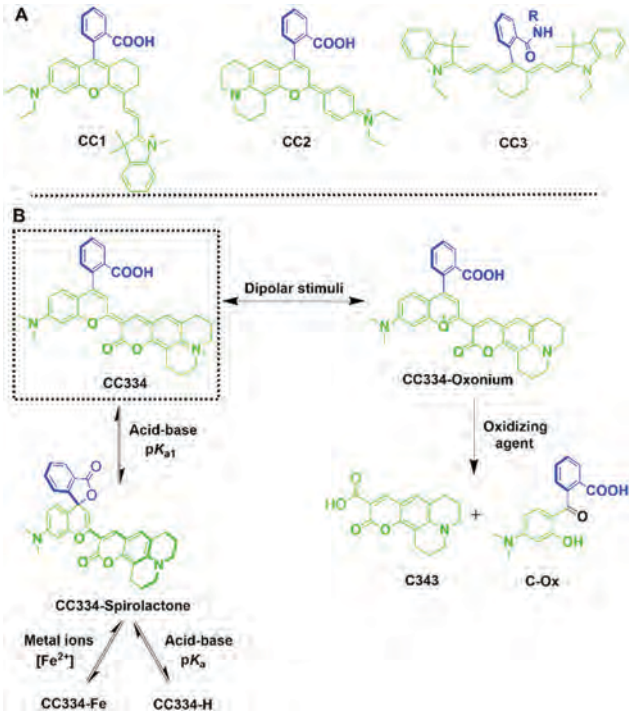

Fig. 1 Chemical structure of (A) three **CC** probes previously described[1–5] and (B) probe **CC334** upon exposure to different stimuli, *i.e.* dipolar: equilibrating the quinoline *vs.* oxonium cations, acid–base: promoting the closed spirolactone form *vs.* open acid form, oxidative: to release coumarin **C343** and a C-oxidation by-product. Further acid (**CC334-H**) or metal ion (Fe^{2+} ion, **CC334-Fe**) stimuli are also possible (see below).

probes exist in an equilibrium between the open-acid and closed-spirolactone forms. Previously reported **CC** structures suggest the spectroscopic features to be a consequence of this acid–base equilibrium. Such a general conception comes from the fact that the electronic conjugation between these forms is substantially different, favoring the open form to exhibit a near infrared (NIR) emission and the closed form to exhibit a visible (Vis) fluorescence. While the Vis-NIR emission pattern of **CC** probes can be modulated with acid–base stimuli, this dual-emission behaviour can also be tuned with redox, polarity (in terms of dielectric constant) variations and some environmental cues, Fig. 1.[13] The spectroscopic characterization of **CC334** is shown in Fig. 2. As can be seen, it is possible to calibrate the probe response to several stimuli which comprises an analytical problem of **CC** probes not described before. In panel A, although showing low fluorescence intensities, a clear dual-band pattern (λ_{em1} = 488 nm; λ_{em2} = 725 nm) is observed in methanol with a fluorescence quantum yield of 0.06 in this solvent. Panel B shows a quantitative interaction scheme for polarity using a continuous variation of dioxane:water volume fractions ($\phi_{dioxane}$), which is a suitable system to separate polarity from other solvent parameters.[14] As solvent polarity increased, both fluorescence intensities (I_{fl}) increased as well and the corresponding maximum wavelengths for the red-shifted emission at 720 nm and the blue one at 520 nm exhibited a remarkable hypsochromic shift to 655 nm and 485 nm, respectively. Notably, the blue-component showed a stronger intensity increment while the red-component showed a stronger wavelength shift. The position of I_{fl} and solvent polarity were used to construct calibration curves (Fig. 2B, inset) showing that altering the polarity of the surroundings is the major contributor to the observed changes in the blue- and red-components.

Then, the acid–base properties of **CC334** were studied in detail to know which species exist at a determined pH for imaging experiments, Fig. 2C. Proton dissociation constants were estimated by potentiometry. The obtained pK_a values were used to calculate the pH distribution of molar fractions for individual open forms (diprotic–dicationic and monoprotic–monocationic) and closed form (neutral) of **CC334**, Fig. S1 (ESI†). The first protonation at the dimethyl(amino) group has a pK_a = 2.21 ± 0.08, and the spirolactone cyclization reaches a pK_a = 10.74 ± 0.09. The pK_a assignment is corroborated by spectro-photometry. Thus, the acid form activates the NIR band where **CC334** is totally conjugated and planar in geometry, while the closed spirolactone form (non-planar with the electron conjugation dominating over the coumarin moiety) contributes more to the VIS band at 500 nm. Importantly for imaging experiments, the potentiometric data indicated a 100% molar fraction of the individual open-acid form at pH 5.5 to 8.5.

Once the pH properties were analysed and the possible species existing in a mitochondrial environment (pH ∼ 8.0) was determined, the oxidation interactions were studied since chromenylium ions are known to exhibit important reactivity for these analytes,[1,8] Fig. 2D–F. A strong binding interaction at pH 7.4 with the Fe^{2+} metal ion was only observed. However, the same result observed for Fe^{2+} was found for Fe^{3+} ions, which can be attributed to the fast oxidation of Fe^{2+} to Fe^{3+} ions upon ligand binding.[15,16] Then, the stability constant for Fe^{2+} ions determined at pH 7.4 showed a complex trend (Fig. 2D) probably because of simultaneous Fe^{2+}/Fe^{3+} oxidation and **CC334** ligand oxidation after one equivalent addition could be involved in this titration. The fitting of the titration results using the HypSpec program revealed the formation of a 1 : 1 complex with a logarithm of the observed stability constant K_{obs} of 5.01. This result highlights the ability of **CC** probes to interact with metal ions through oxygen functional groups.

Similarly, as shown in Fig. 2E and F, **CC334** also exhibits a strong fluorescence increment upon interaction with singlet oxygen ($^1O_2$), while competition experiments with common oxidizing agents revealed no significant interaction, Fig. S2 (ESI†). These results indicate that **CC334** is a specific $^1O_2$-ROS reporter providing the classical molecular probe scenario, *i.e.* oxidation of **CC334** to coumarin 343 (C343), a stronger green-fluorophore as confirmed by chemical characterization using high-resolution mass spectrometry and ^{1}H-NMR spectroscopy (see Fig. S3, ESI†). Note that such oxidation interactions make the fluorescence profiles of the red-shifted band disappear as **CC334** is fragmented to form coumarin 343. Fig. 2F shows the corresponding λ-ratiometric calibration plot for the **CC334**–$^1O_2$ interaction. A good linear fit was obtained at a wavelength ratio r (490/720) nm, such a fluorescence intensity variation is a consequence of the strong blue emission band increment with a simultaneous red emission deactivation.

On the other hand, *in vitro* experiments were carried out to study the subcellular permeability and localization of the probe. Fig. 3 shows a highly specific mitochondrial localization in a human cell line. The mitochondrial localization is a consequence of the lipophilic and positive charge balance of **CC334**. In fact, octanol partitioning was measured, giving a log$P$ value of –0.51, reaching the lipophilic threshold for mitochondrial distribution.[17] This was corroborated by colocalization with the commercial dye MitoTracker Deep Red®, Fig. 3B. As discussed, **CC334** is an oxidizing-sensitive probe. Thus, mitochondrially generated ROS

The image was manually focused, and excitation light was fully shielded between recordings to prevent artefacts and photobleaching. Scale bars represent 20 μm.

species can in principle be monitored using the fluorescence profile of **CC334**. Stimulating ROS formation in our *in vitro* studies by using low-dose singlet oxygen $^1O_2$ photodynamically generated under laser irradiation from 0.1 to 0.3 J cm^{-2} using 5-amino-levulinic acid (ALA), which is a common photosensitizer of intramitochondrial $^1O_2$ production,[18,19] resulted in a detectable fluorescence signal redistribution from mitochondria to cytosol and then into the nucleoli when recording with the confocal-green channel (λ_{exc} = 503 nm, λ_{em} = 512 nm), Fig. 4. This type of coumarin distribution in the nuclei has been described to occur because of DNA groove interactions.[20–22] Then, $^1O_2$–**CC334** interaction was analysed in more detail by UV-Vis and fluorescence spectrophotometry. However, to demonstrate that no signal interference or false positives are observed during such re-localization dynamics from mitochondria to nucleoli, the typical co-localization controls by staining those organelles with commercial co-localizers (in this case MitoTrackers® for the mitochondrion and DAPI or Hoechst® for the nuclei) and then probing that **CC334** moves from one organelle to the other are not enough and more precise structural information is required. Then, the confocal microscopies that are spectrally resolved provide continuous local information of the probe fluorescence profiles upon exposure to a given stimulus. We used a confocal array upgraded with a spectral detector unit having a 32-channel photomultiplier tube assembly. Thus, using a λ_{exc} = 488 nm, the mitochondria to nucleoli probe redistribution upon $^1O_2$–**CC334** interaction was spectrally-resolved, observing an important increment in the vis-emission band while a slight decrease in the NIR-emission band, Fig. S4 (ESI†), which is in full agreement with the $^1O_2$–**CC334** fluorescence profile discussed in Fig. 2E.

The observed *in vitro* fluorescence response of **CC334** and the unequivocal data interpretation can evidently be extremely difficult. The problem is that the photophysical properties of **CC** probes (including **CC334**) can be modulated by several inputs. One of the main disadvantages of **CC** probes is that they can be used as all, pH, metal ion, ROS, local polarity, local microviscosity sensors by using the same fluorescence response channel. Their Vis-NIR emission properties can originate from the combination of different activation pathways, *i.e.* acid–base equilibrium, intramolecular charge transfer, intramolecular proton transfer, photoacid generation, Kasha's rule breaking, chelation-enhanced fluorescence, site-specific-solvation, among others in such a way that either one or both Vis and NIR channels can be activated. To gain deep insight into the response scheme of **CC334** in highly heterogeneous media, the deactivation pathways present in the molecule were explored. Time-resolved fluorescence spectroscopy was carried out using the time correlated single-photon counting technique (TCSPC); solvents such as acetone and acetonitrile only favor the blue-shifted absorption band at 405 nm, although the emission spectra exhibit the characteristic dual-emission band pattern, λ_1 = 488 nm and λ_2 = 710 nm, see Fig. S5 (ESI†). Non-monoexponential decay life-times were mostly found, Fig. 5. BG40 and LPF 655 filters were used to isolate the emission from the blue and red bands, respectively. In acetone, the blue emission presented two life-times of τ_1 = 3.7 and a fast $\tau_2 < 1$ ns while the red band was short-lived and mono-exponential with 0.7 ns. One of the blue components can be attributed to the locally excited state while the red one is assigned to an ICT state. A similar scheme was found in acetonitrile, with lifetimes of τ_1 = 3.8 and $\tau_2 < 1$ ns in the blue emission and τ = 0.5 ns in the red emission. When testing a non-protic non-polar solvent such as cyclohexane the locally excited (LE) state was evidenced, finding a lifetime of τ = 2.9 ns in the blue emission band. However, in solvents such as methanol and water a more complex behaviour of **CC334** arises.

In methanol, the absorption spectrum exhibits a strong red-shifted band and a dual-emission band pattern as well. Being polar protic solvents, comparison with the polar non-protic features of acetone and acetonitrile the first hypothesis is that the red-shifted band comes from a proton transfer excited state. Thus, lifetimes of 3.8 and 0.5 ns were found for the blue component in methanol, while the red emission presented a

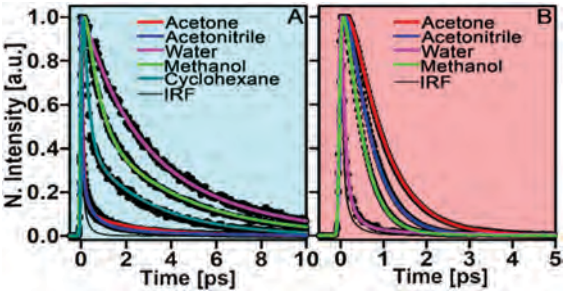

Fig. 5 Nanosecond fluorescence decay curves of **CC334** at the blue emission band (A); and at the red emission band (B) in different solvents, IRF: instrument response function.

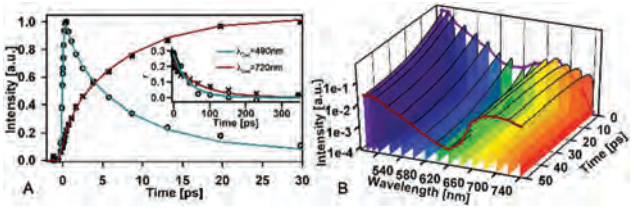

Fig. 6 (A) Normalized fluorescence up-conversion transients detected at 490 nm (blue) and 720 nm (red) for **CC334** in acetone; the inset shows the corresponding anisotropy decays. (B) Obtained ultrafast Time-Resolved Emission Spectra (TRES) in acetone.

0.3 ns lifetime, which in principle involves the closed-spirolactone and the open-acid forms, respectively. When changing from methanol to water the red band decreased, and the lifetimes were 4.3 and 0.9 ns for the blue emission and 2.9 and <0.1 ns for the red emission. Table S1 and Fig. S5 (ESI†) summarize the TCSPC results.

As noticed, the locally excited, charge transfer and proton transfer states can be activated by simple medium effects. However, those states define how much interference a **CC** probe will present *vs.* one specific analyte. Then, ultrafast time dynamics studies were implemented to study the excited state population of **CC334**, and femtosecond fluorescence up-conversion experiments were carried out in acetone and methanol. In acetone the probe only shows a blue absorption band at 438 nm and a dual emission band at 488 and 710 nm (Fig. S6A, ESI†), showing high Stokes shifts that are typical for photoinduced ICT states.[23] The formation of the ICT state is further supported since negligible absorption at longer wavelengths (>600 nm) is observed, and as can be seen in the excitation spectra (Fig. S6B, ESI†) the fluorescence of both the blue and red bands comes from the absorption band at 438 nm. As mentioned before, the dual-emission of **CC334** is a powerful tool in dual-channel confocal microscopies. Two representative results of the ultrafast photophysics for such emission patterns are presented in Fig. 6. There is a clear decay of 8 ps in the 490 nm transient and an accumulation with the same time constant is found at 720 nm, indicating that the locally excited state forms the ICT state in a kinetic scheme A $\rightarrow$ B with a rate constant of 1.25×10^{10} s^{-1}.

As mentioned, the molecular geometry in the excited state is crucial in the photophysical scheme of **CC** fluorophores and thus fundamental for the photophysical scheme to be properly interpreted. Then, to gain more insight into the molecular geometry dynamics at the excited state by means of the transition moment direction changes, we determined the fluorescence anisotropy $r(t)$ of **CC334**. The inset of Fig. 6A shows the anisotropy decays for the two detected states (bands). The blue band anisotropy presents an initial value of $r = 0.3$ and is lost in 40.5 ± 0.3 ps (Fig. S7, ESI†), which is typical for fluorescent probes that only have one emissive state. This indicates that the angle between the excited and the emissive transition dipole moments is around 24°, suggesting that the pumped state (locally excited) is the same as the one detected at 490 nm. The red band, however, presents an $r = 0.2$, which means that the angle between the excited and the ICT transition dipole moments is 35°. Overall this indicates the formation of a different molecular species in the excited state, probably, due to a conjugation and/or planarization of the whole molecule, which is further supported by a higher rotational diffusion constant in the ICT state. The ultrafast temporal evolution of the LE and the ICT states of the molecule is seen in the semi-logarithmic Time-Resolved Emission Spectrum (TRES), Fig. 6B.

In the blue region of the TRES, the LE state quickly decays (in 8 ps) to a relaxed state that lives 2.92 ns (obtained from the TCSPC experiments), while the red band accumulates also in 8 ps and reaches equilibrium between the two species; from the TCSPC results we obtained that the lifetime of this state is 0.69 ns. At 50 ps the temporal spectrum totally resembles the static emission spectrum (Fig. S6A, ESI†) indicating that the LE state relaxation is reached and ICT state is formed.

As mentioned before, the absorption spectrum of the molecule in methanol shows a maximum at 650 nm and some minor features at shorter wavelengths that correspond to higher singlet states (S_n) (Fig. S8A, ESI†). The emission spectrum presents a dual-band pattern when excited at these higher states, similar to the spectrum in acetone. Both bands come from different states as can be seen from the excitation spectra (Fig. S8B, ESI†), the red band corresponds to the S_1 state while the blue band corresponds to the emission from higher singlet excited states or to the coumarin moiety coming from the molecular population that can be found in the spirolactone form. These signatures are indicative that the kinetics of the excited state must be different. The ultrafast temporal behaviour (Fig. 7) indicates that S_n relaxes to S_1 in less than 500 fs, which is a typical time constant for an internal conversion process. This process is further confirmed since the red band is formed at the same time scale. The population of the S_n state that does not convert to the S_1 state reaches equilibrium as long as the pumped state lives (4.08 ns). The anisotropy value near $t = 0$ for the blue band ($r = 0.25$) indicates that the angle between the dipole moment of the pumped and the detected state is about 31° and the loss of the anisotropy occurs in 76.9 ± 0.4 ps (Fig. S9A, ESI†). The rotational diffusion presents a similar time constant to the photoinduced ICT state detected in acetone, which again suggests the extended conjugation of the **CC334** probe. On the other hand, the anisotropy of the S_1 state (Fig. S9B, ESI†) presents an initial value of -0.03, indicating that the angle between the dipole moments of

(B) Obtained ultrafast Time-Resolved Emission Spectra (TRES) of **CC334** in methanol, obtained from the fluorescence up-conversion transient fits.

the higher singlet state and the S_1 states is around 58°. This strong variation in the angle indicates that the nature of the pumped state is completely different from the detected state, confirming that the initial state is a higher singlet excited state. Since this value of the anisotropy is very low, it remains difficult to extract the rotational diffusion constant from the experimental data. The TRES of the **CC334** probe in methanol at early times is presented in Fig. 7B. The molecule reaches the equilibrium between the S_n and the S_1 state in this time scale. The internal conversion process is nicely visualized as an ultrafast decay in the blue region and an accumulation in the red part of the spectrum. The long lifetimes of the bands were determined by the TCSPC technique described before: 4.08 ns and 0.32 ns for the blue and red bands, respectively. The different behaviour observed for the two bands in different environments is a clear indication of the highly complex and versatile molecular scenario that arises when using **CC334** as a fluorescent probe in cellular studies.

In order to schematize the photophysical dynamics of **CC334**, we optimized the molecular structures (open-acid and closed spirolactone forms, Fig. S10, ESI†) which were corroborated by a frequency analysis having no imaginary points at a PBE0/G-31+G(d,p)/IEF-PCM (water) level of theory. We analysed the electron density characteristics upon excitation[24] of the probe and the Natural Transition Orbital (NTO) analysis,[25] which provides a compact orbital representation of the electronic transition through a single configuration of a hole and electron interaction. Then, the NTO interactions show that the probe involves a different electronic distribution between open and closed forms when analysing the HONTO–LUNTO pair. The NTO eigenvalues (w) that represent the extent to which the electronic interaction can be written as a single excitation are 0.98 in both the open and closed forms. While the closed form has a non-planar conformation, which disrupts any electron communication in the conjugated molecular axis, the open form favours a highly planar conformation in this conjugated axis, enabling a pseudo-quadrupole moment with $\pi \rightarrow \pi^*$ charge transfer features, Fig. S10 (ESI†).

To study the effect of **CC334** probe incubation, *in vivo* imaging experiments in live Danio rerio (Zebrafish) embryos were performed. The localization studies were done in several stages of development. Fig. 8 shows 4 and 40 hpf (hours post fertilization) incubation with **CC334** before (panels A) and after (panels B) exposure to an oxidative stimulus induced by *in situ*

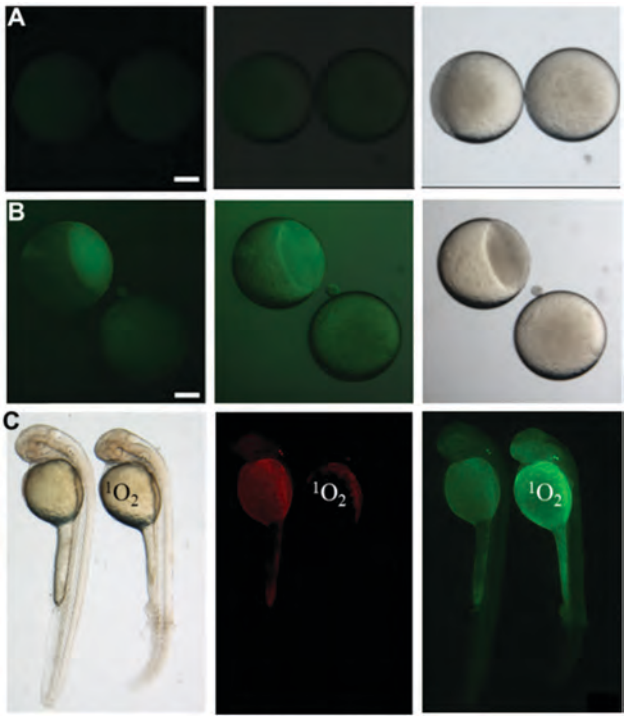

Fig. 8 Fluorescence microscopy of Zebrafish embryos at (A) sphere stage (4 hours post fertilization, hpf) incubated with **CC334** for 30 minutes followed by (B) *in situ* $^1O_2$ stimulation for 10 minutes. After washing excess **CC334** three times for 10 min, specimens were imaged. Left and middle panels show the green channel using 10 μM and 20 μM **CC334**, respectively. The right modules show the bright-field views. Panel C shows 40 hpf Zebrafish before (left) and after (right) $^1O_2$ stimulation in the bright, red and green channels. Scale bars represent 200 μm.

formed $^1O_2$ (preparation of $^1O_2$ and other ROS reagents is described in the ESI† file). These experiments revealed that **CC334** is a permeable fluorescent probe, which, due to the optical transparency of Zebrafish, makes it ideal for imaging single cell stages and subcellular dynamics *in vivo* and in real time.[26] Therefore, we tested whether the selective singlet oxygen **CC334** response could be observed in this model. Interestingly, the epidermis of the developing Zebrafish contains several specialized cell types that allow for the exchange of oxygen, ions and macromolecules, similar to mammalian bilayered epithelia.[27,28]

Stimulation by *in situ* $^1O_2$ generation for 10 minutes resulted in detectable changes of the **CC334** fluorescence, Fig. 8 and 9. The green-channel was enhanced after exposure to the oxidative stimuli, particularly in the embryonic cells composing the sphere, where the latter exhibited a high fluorescence distribution, Fig. 8. Then, confocal imaging of 72 hpf embryos allowed us to visualize the mitochondrial-nuclear redistribution observed in tissue culture cells after exposure to $^1O_2$ oxidative stimuli. Fig. 9 shows clear mitochondria to nucleoli re-localization, where the former was observed using the green and red confocal channels and the nucleoli were observed using the green-channel, indicating that **CC334** could be used in living epithelium to track mitochondrial nuclear redistribution dynamics during exposure to oxidative stimuli with $^1O_2$.

Conclusions

CC334 is a representative probe from the chromenylium-cyanine (**CC**) family of fluorophores. This versatile probe enables bioanalytical sensing and analysis of different species and local microenvironment parameters. Potential interfering factors present in living systems prevents **CC** probes to provide a selective recording of fluorescence. Here, singlet oxygen $^1O_2$, Fe^{2+} ions, pH and polarity/polarizability exert a strong influence on **CC334**, a common problem in the **CC** family. However, we demonstrate that understanding the **CC334** photophysics for all the possible excited-state dynamics (LE, ICT, and IPT) and how the change in molecular nature between the S_1 and S_n excited states governs its reactivity not only facilitates a correct and interference-free bioanalytical analysis but also allows the study of subcellular dynamics *in vivo*. With this study we also clarify that **CC** dual emission behaviour originates from a kinetic process involving the formation of the ICT state by the locally excited state. The dual emission is intrinsic to the **CC** probes regardless of whether the absorption bands have dual-absorption characteristics or not. This advantage is unique to **CC** probes and confers important properties in the analysis of living systems. Spectrally resolved confocal microscopy facilitated the interference-free analysis of $^1O_2$ providing continuous information of the probe emission during measurements. Using **CC** probes in different media inducing redox, pH, polarity and specific ionic interactions for super-resolution microscopy and upconversion luminescence imaging will provide a new avenue for the interference-free analysis of subcellular chemistry.

Abstract

The study of Hutchinson–Gilford progeria syndrome (HGPS) has provided important clues to decipher mechanisms underlying aging. Progerin, a mutant lamin A, disrupts nuclear envelope structure/function, with further impairment of multiple processes that culminate in senescence. Here, we demonstrate that the nuclear protein export pathway is exacerbated in HGPS, due to progerin-driven overexpression of CRM1, thereby disturbing nucleocytoplasmic partitioning of CRM1-target proteins. Enhanced nuclear export is central in HGPS, since pharmacological inhibition of CRM1 alleviates all aging hallmarks analyzed, including senescent cellular morphology, lamin B1 downregulation, loss of heterochromatin, nuclear morphology defects, and expanded nucleoli. Exogenous overexpression of CRM1 on the other hand recapitulates the HGPS cellular phenotype in normal fibroblasts. CRM1 levels/activity increases with age in fibroblasts from healthy donors, indicating that altered nuclear export is a common hallmark of pathological and physiological aging. Collectively, our findings provide novel insights into HGPS pathophysiology, identifying CRM1 as potential therapeutic target in HGPS.

1 | INTRODUCTION

Aging is a universal process that occurs across all living species; in humans, aging is characterized by a gradual decline in physical and psychological capacities that in turn cause morphological, metabolic, and cognitive alterations that limit the quality of life and ultimately provoke death. Premature aging syndromes, a group of extremely rare but devastating disorders that mimic physiological aging, have been proposed as models to decipher the molecular mechanisms underlying aging (Kubben & Misteli, 2017).

Hutchinson–Gilford progeria syndrome (HGPS), the most well-studied progeroid syndrome, is typically caused by a silent point mutation (1824C > T) that activates a cryptic splicing site within exon 11 of the *LMNA* gene, resulting in the synthesis of a prelamin A mRNA that contains an internal deletion of 150 base pairs. Consequently, this leads to the translation of a mutant lamin A termed progerin, which harbors a deletion of 50 amino acids within its C-terminus. Progerin is permanently farnesylated because the deletion eliminates the cleavage site for Zmpste24, the enzyme that removes the C-terminal farnesyl group from prelamin A to render mature lamin A (Eriksson et al., 2003; De Sandre-Giovannoli et al., 2003).

Progerin acts in a dominant gain-of-function manner by anchoring to the nuclear envelope and perturbing nuclear lamin function, thereby inducing a plethora of cellular defects, including aberrant nuclear morphology, altered DNA repair and gene expression, and telomere instability (Gonzalo, Kreienkamp, & Askjaer, 2017). The complex network of downstream effects by which progerin exerts its toxicity is far from understood; it is thought that progerin impacts on central cellular process, which in turn triggers a cascade of noxious downstream effects that ultimately cause aging.

Owing to the deleterious effect exerted by progerin on nuclear envelope, we hypothesized that the nucleocytoplasmic transport of proteins through the nuclear pore complex (NPC) (Christie et al., 2016) could be a primary target of progerin. Supporting our hypothesis, perturbation in the Ran GTPase gradient affecting nuclear import of specific proteins, namely Ubc9, and nucleoporin TPR was previously reported in HGPS cells (Cobb et al., 2016; Snow, Dar, Dutta, Kehlenbach, & Paschal, 2013). Furthermore, the nonclassic transport pathway mediated by transportin-1 (TNPO1) is impaired in HGPS cells, due to cytoplasmic sequestration of TNPO1 by the microtubule network (Larrieu et al., 2018).

In this study, we aimed to analyze whether nuclear protein export is impaired in HGPS. Exportin-1 (XPO1), also known as chromosomal region maintenance 1 (CRM1), binds to cargo proteins through a leucine-rich nuclear export signal (NES) and transports the proteins across the NPC via a Ran-GTP gradient (Ishizawa, Kojima, Hail, Tabe, & Andreeff, 2015; Kirli et al., 2015). We show for the first time that the CRM1-driven nuclear protein export mechanism is abnormally enhanced in HGPS fibroblasts and that this novel hallmark is critically involved in the disease, because pharmacological inhibition of CRM1 rescues the HGPS cellular phenotype and exogenous overexpression of CRM1 recapitulates HGPS in normal fibroblasts.

2 | RESULTS

2.1 | Enhanced CRM1-driven nuclear protein export is a novel hallmark of HGPS cells

To ascertain whether the CRM1-mediated nuclear protein export mechanism is impaired in HGPS, we evaluated the subcellular distribution of six different proteins whose nuclear export depends on NES recognition by CRM1 (STAT3, B23, ZO-2, cyclin B1, Dp71, and HDAC1). Two different HGPS fibroblast cultures (HGPS-1 and HGPS-2) and a passage-matched fibroblast control culture (WT) were examined using confocal laser scanning microscopy (CLSM). There was a significant decrease in the nuclear localization with a concomitant increase in the cytoplasmic labeling for all the analyzed proteins in both HGPS cell cultures, with the exception of HDAC1 that was found to be mislocalized only in HGPS-2 cells (Figure 1a and Figure S1). Quantitative analysis of the fluorescence nuclear/cytoplasmic ratio (Fn/c) corroborated these observations (see graphs). Nuclear accumulation of NES-containing proteins was restored to a similar level to that of WT cells upon treatment of HGPS cells for 1 day with 1 nM leptomycin B (LMB), a specific CRM1 inhibitor (Figure 1a and Figure S1). This clearly indicates that their nuclear depletion is caused by enhanced nuclear export activity rather than nuclear import failure. Next, we analyzed the expression of NES-containing proteins in HGPS cells. The levels of STAT3 and B23 were similar between WT and HGPS cells, while an apparent increase for ZO-2 was observed only in HGPS-2 fibroblasts (Figure 1b).

2.2 | Enhanced nuclear protein export in HGPS cells is caused by progerin-induced CRM1 overexpression

We hypothesized that the exacerbated nuclear export activity of HGPS cells might be consequence of CRM1 overexpression. Consistent with this idea, elevated CRM1 protein levels were found in HGPS cells (Figure 1c,d), with qRT-PCR experiments showing a corresponding increase in CRM1 mRNA levels (Figure 1e). Given that CRM1 overexpression is primarily regulated at the transcriptional level, we next analyzed CRM1 promoter activity in HGPS cells by promoter reporter assays. An increase in CRM1 promoter activity was found in HGPS-2 but not HGPS-1 cells, compared with WT cells (Figure 1f).

INFORME DE LABORES 2019

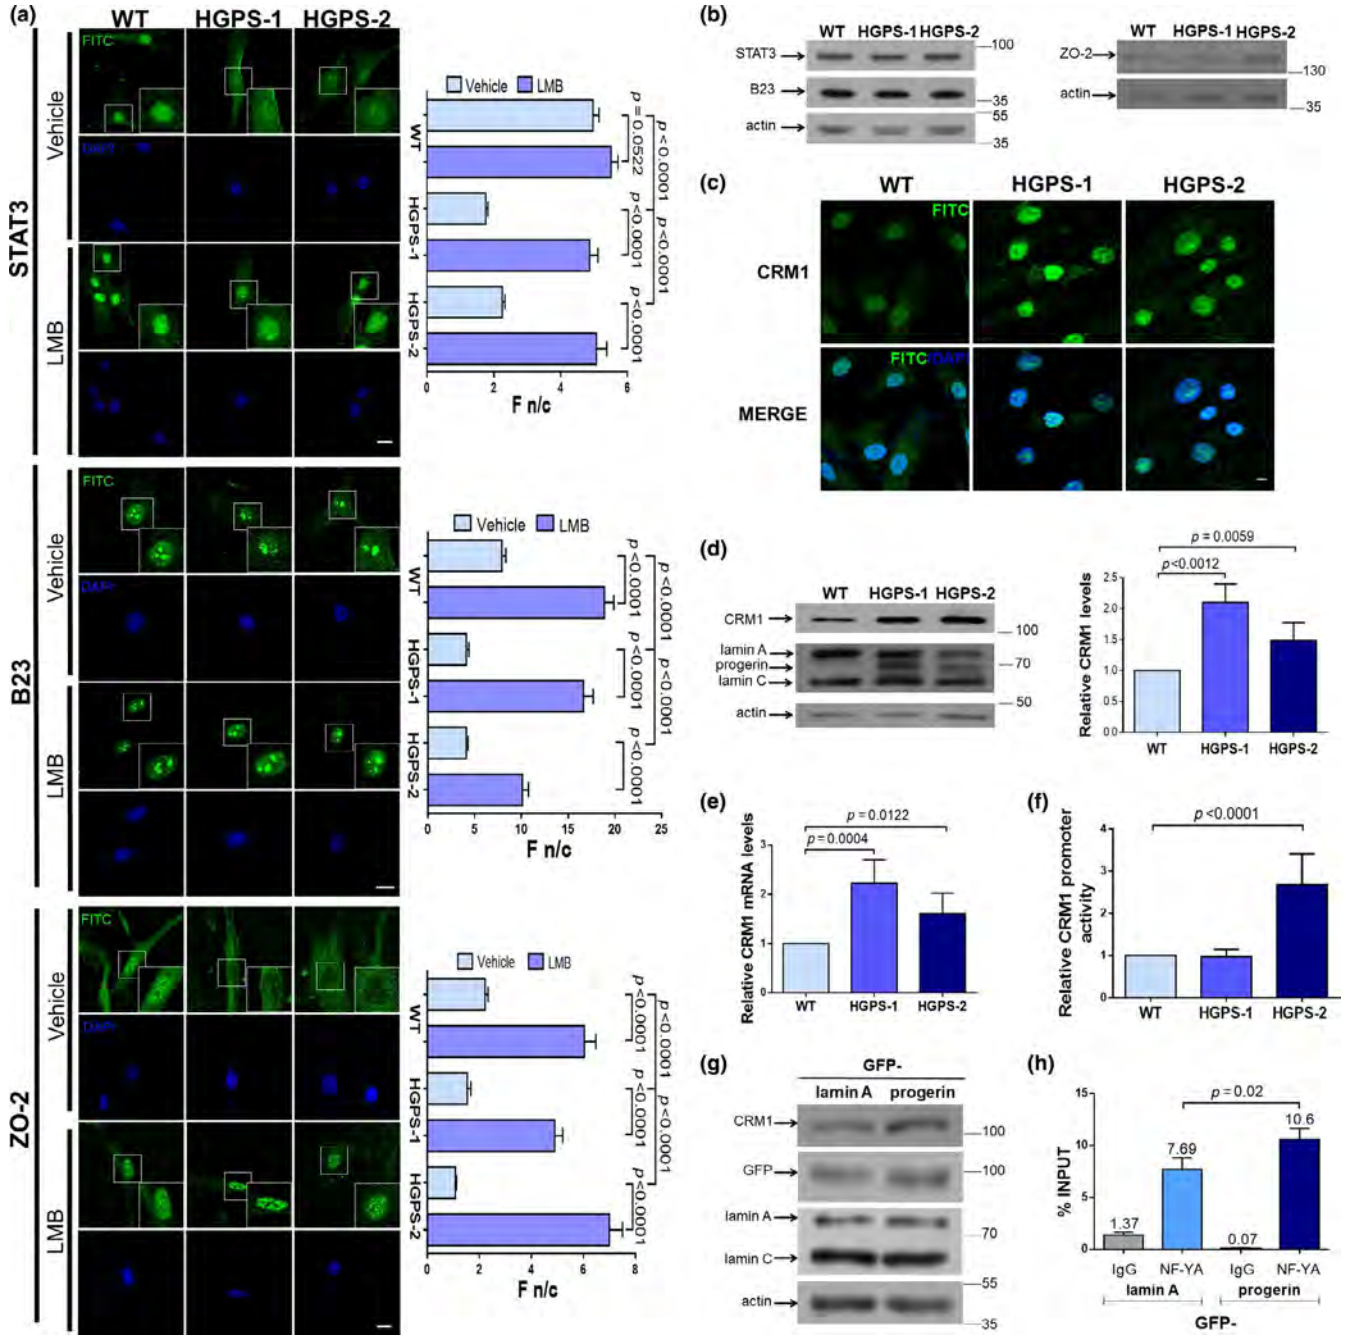

FIGURE 1 Mislocalization of NES-containing proteins is caused by progerin-mediated overexpression of CRM1. (a) Wild-type (WT) and HGPS cells, treated for 24 hr with 10 nM LMB or vehicle alone, were immunolabeled for the indicated proteins (bar, 10 μm). The Fn/c ratio was calculated (n = 50 cells), and significant differences were determined by Mann–Whitney U test (graphs). (b) Protein levels of STAT3, B23, ZO-2, and actin (loading control) were analyzed, and typical gels from two independent experiments are shown. (c) WT and HGPS cells were immunolabeled for CRM1 and analyzed by CLSM. Typical images from 3 independent assays are shown (bar 10 μm). (d) Lysates from WT and HGPS cells were subjected to Western blot using antibodies against CRM1, lamin A/C, or actin (loading control), and relative CRM1 levels were obtained (graph). (e) CRM1 messenger RNA expression was examined by qRT-PCR. (d-e) Significant differences were determined by unpaired t test. (f) WT and HGPS cells were transfected with both Luciferase reporter construct containing the human CRM1 promoter and Renilla luciferase vector, which was used to normalize transfection efficiency. Enzymatic activities were estimated after incubation for 48 hr as described in Methods. Data represent mean ± SEM of three independent experiments (unpaired t test). (g) Lysates from HeLa cells stably transfected to express GFP-lamin A or GFP-progerin were subjected to Western blotting using antibodies against CRM1, GFP, or actin (loading control). (h) HeLa cells expressing GFP-lamin A or GFP-progerin were subjected to chromatin immunoprecipitation (ChIP) with anti-NF-YA antibodies followed by PCR for the CRM1 promoter region. Data correspond to two independent experiments in triplicate

To ascertain whether CRM1 overexpression is causally linked to progerin, we evaluated whether exogenous expression of progerin is sufficient to elicit increased CRM1 levels in HeLa cells. Expression of GFP-progerin but not GFP-lamin A resulted in nuclear morphology aberrations (Figure S2a), decreased H3K9m3 levels (Figure S2b), and increased CRM1 levels (Figure 1g); the latter appears to provoke in turn cytoplasmic mislocalization of the NES-containing STAT3 (Figure S2c). We then evaluated whether exogenously expressed progerin induces CRM1 promoter activity, using ChIP-qPCR assays to assess binding activity of NF-YA, a transcription factor that positively regulates the CRM1 promoter (van der Watt & Leaner, 2011). The binding activity of NF-YA to the CRM1 promoter region was found to be augmented by ~30% in GFP-progerin-expressing cells, compared with those expressing GFP-lamin A (Figure 1h).

Because progerin toxicity is attributed at least in part to its farnesyl moiety, we next examined whether inhibition of progerin farnesylation using the farnesyltransferase inhibitor (FTI) lonafarnib would reduce overexpression of CRM1 in HGPS cells. As previously reported (Noda et al., 2015), treatment with 25 μM of lonafarnib for 3 days elicited a significant decrease in both nuclear blebbing (Figure S3a) and progerin levels (Figure S3b). Supporting our idea, the decrease in progerin levels resulted in CRM1 downregulation (Figure S3b).

2.3 | Pharmacological attenuation of CRM1 activity rescues premature senescence in HGPS cells by improving lamin B1 levels

We wondered whether enhanced CRM1 activity might be part of the molecular basis underlying HGPS. To address this, we evaluated whether amelioration of CRM1 activity through LMB treatment has an impact on cellular senescence. Remarkably, LMB treatment for 2 days resulted in a significant reduction of senescence cells in HGPS cultures, as determined by senescence-associated β-galactosidase (SA-β-gal) staining (Figure 2a). Consistent with this, the percentage of HGPS-1 and HGPS-2 cells arrested at G0/G1 phase of the cell cycle decreased upon treatment with LMB, as revealed by flow cytometry analysis (Figure S4a). We next analyzed the effect of LMB on cell proliferation. Treatment with LMB for 3 days resulted in significantly decreased cell growth in both WT and HGPS cells; however, it provoked only a slight increase in cell death by the third day, as shown by MTT and annexin V assays (Figure S4b,c, respectively). Since decreased lamin B1 expression is associated with senescence (Freund, Laberge, Demaria, & Campisi, 2012; Shimi et al., 2011), we were prompted to analyze whether treatment with LMB has a positive effect on lamin B1 levels. A ~80% decrease in lamin B1 levels was observed in HGPS cells incubated with vehicle alone. Nevertheless, partial restitution of lamin B1 expression was obtained after incubation of HGPS fibroblasts with LMB (50 nM) for 6 days, while no changes were found in WT cells upon treatment (Figure 2b). Redistribution of lamin B1 into distinct nucleoplasmic foci was observed in LMB-treated HGPS cells (Figure 2c). It is thought that nucleoplasmic foci of lamin B1 correspond to nascent lamin B1 incorporated in the nucleoplasmic reticulum in interphase nuclei (Drozdz, Jiang, Pytowski, Grovenor, & Vaux, 2017).

We considered that restoration of lamin B1 levels might consequently reduce those HGPS characteristics governed by lamin B1 (Camps et al., 2014). We then examined the impact of LMB treatment on heterochromatin organization using the heterochromatin marker H3K9me3. Supporting our idea, recovery of both nuclear staining and protein levels of H3K9me3 was evidenced in HGPS cells after LMB treatment (Figure 2d,e, respectively).

We next examined the effect of LMB on nuclear morphology, using nuclear morphometric analyses. Nuclear defects were commonly found in vehicle-treated HGPS fibroblasts immunostained for lamin A/C, compared with WT cells (Figure 3a and graphs). Remarkably, ovoid-shaped nuclei devoid of irregularities that resemble WT nuclei were evident after treatment of HGPS cells for 3 days with LMB (Figure 3a). Nuclear morphometric analyses confirmed significant differences between vehicle- and LMB-treated HGPS cells (right graphs). Collectively, these data indicate that mitigation of CRM1 activity through LMB treatment delayed the progression of HGPS cells to senescence by preventing lamin B1 downregulation.

2.4 | Pharmacological modulation of CRM1 activity ameliorates aging features of HGPS cells

To analyze in depth the effect of LMB-mediated CRM1 inhibition on senescence, two distinctive features of senescent cells, namely enlarged nucleolar morphology and senescent cellular morphology, were examined in HGPS fibroblasts. As reported previously, (Buchwalter & Hetzer, 2017), a single or two prominent nucleoli with increased nucleolar area were observed in most HGPS cells (Figure 3b). Notably, administration of LMB to HGPS cultures for 3 days resulted in increased number of nucleoli per cell (Figure 3b), with smaller nucleolar area (right graphs), which were comparable in size to wild-type nucleoli. Previously, the expansion of nucleoli was linked to elevated protein synthesis in HGPS cells (Buchwalter & Hetzer, 2017). Therefore, we were prompted to analyze whether alleviation of nucleolar expansion by LMB treatment has an effect on global protein synthesis by monitoring the phosphorylation state of the α subunit of eukaryotic initiation factor 2 (eIF2α), the p70 ribosomal protein S6 kinase (p70 S6K) and its substrate, and the ribosomal protein S6 (rpS6). Consistent with elevated protein synthesis, HGPS-1 cells treated with vehicle alone showed decreased p-eIF2a levels but elevated levels of p-p70 S6K and p-rpS6K (Figure 3c). By contrast, LMB treatment for 3 and 6 days resulted in increased p-eIF2α levels but reduced phosphorylated levels of both p70 S6K and rpS6 in HGPS-1 cells (Figure 3c), which is consistent with a translational repression effect mediated by LMB. With respect to the senescent cell morphology, LMB-mediated

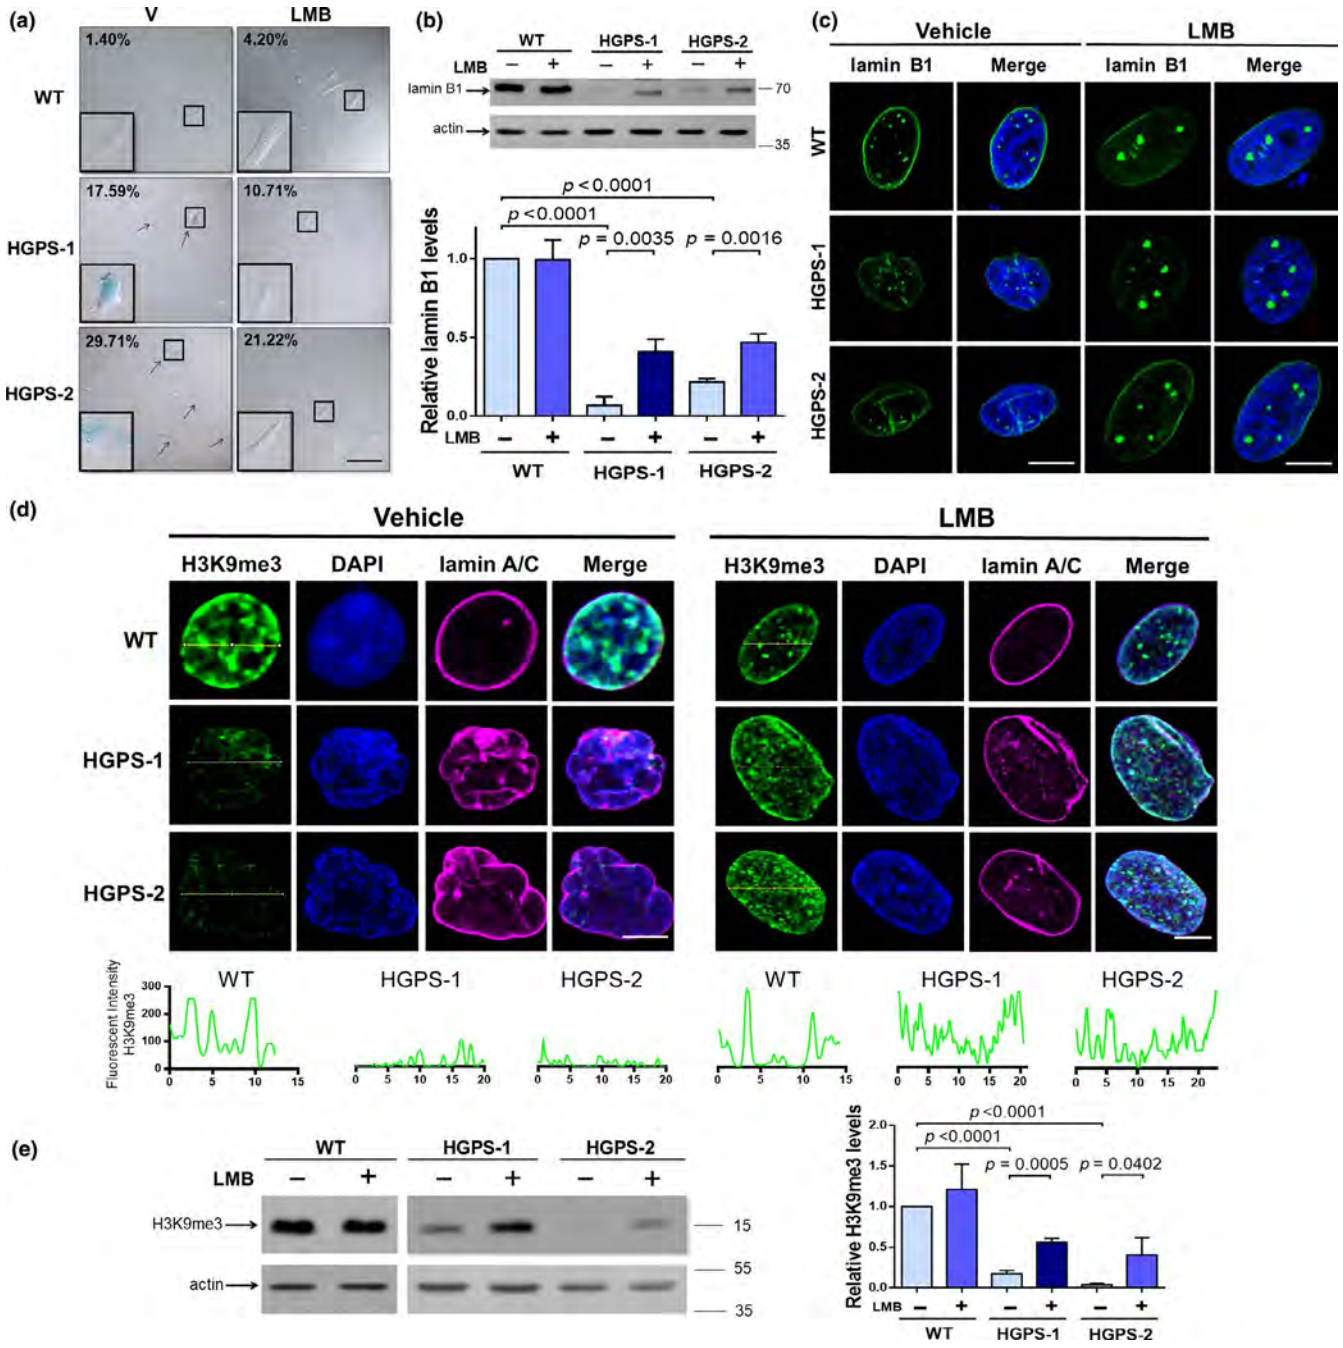

FIGURE 2 LMB-mediated inhibition of CRM1 prevents cellular senescence by improving lamin B1 levels. (a) WT and HGPS fibroblasts were treated for 2 days with 1 nM LMB or vehicle alone. The activity of β-galactosidase was assessed, and representative images are shown. Bar = 100 μM. The percentage of senescent cells was calculated from 3 separate experiments (n = 300 cells for each condition). (b) Lysates from WT and HGPS fibroblasts, previously treated for 6 days with 50 nM LMB or vehicle, were analyzed by Western blotting using antibodies against lamin B1 and actin (control). Lamin B1 levels were assessed (bottom panel). (c) WT and HGPS fibroblasts treated with 50 nM LMB or vehicle alone for 3 days were immunostaining for lamin B1, and typical images are shown. Bar, 10 μm. (d) WT and HGPS fibroblasts treated with 50 nM LMB or vehicle for 6 days were analyzed by CLSM, using antibodies against H3K9me3 and lamin A/C. Representative images are shown. B Bar, 10 μm. *Bottom*. Line profile analysis showing H3K9me3 fluorescence pattern. (e) Lysates from HGPS cells treated as peer C were analyzed by Western blotting using antibodies against H3K9me3 and actin (control). Relative H3K9me3 levels are shown (right graph). (b and e) Significant differences were determined by unpaired t test

inhibition of CRM1 activity shifted the flattened and expanded morphology of HGPS fibroblasts to the typical fusiform morphology of WT fibroblasts (Figure 3d), with a concomitant decrease in cell size (right graph).

Finally, we assessed whether treatment with LMB has an effect on progerin expression. Interestingly, progerin levels were found to significantly decrease in HGPS-2 cells but not HGPS-1 cells upon LMB treatment (Figure S4c).

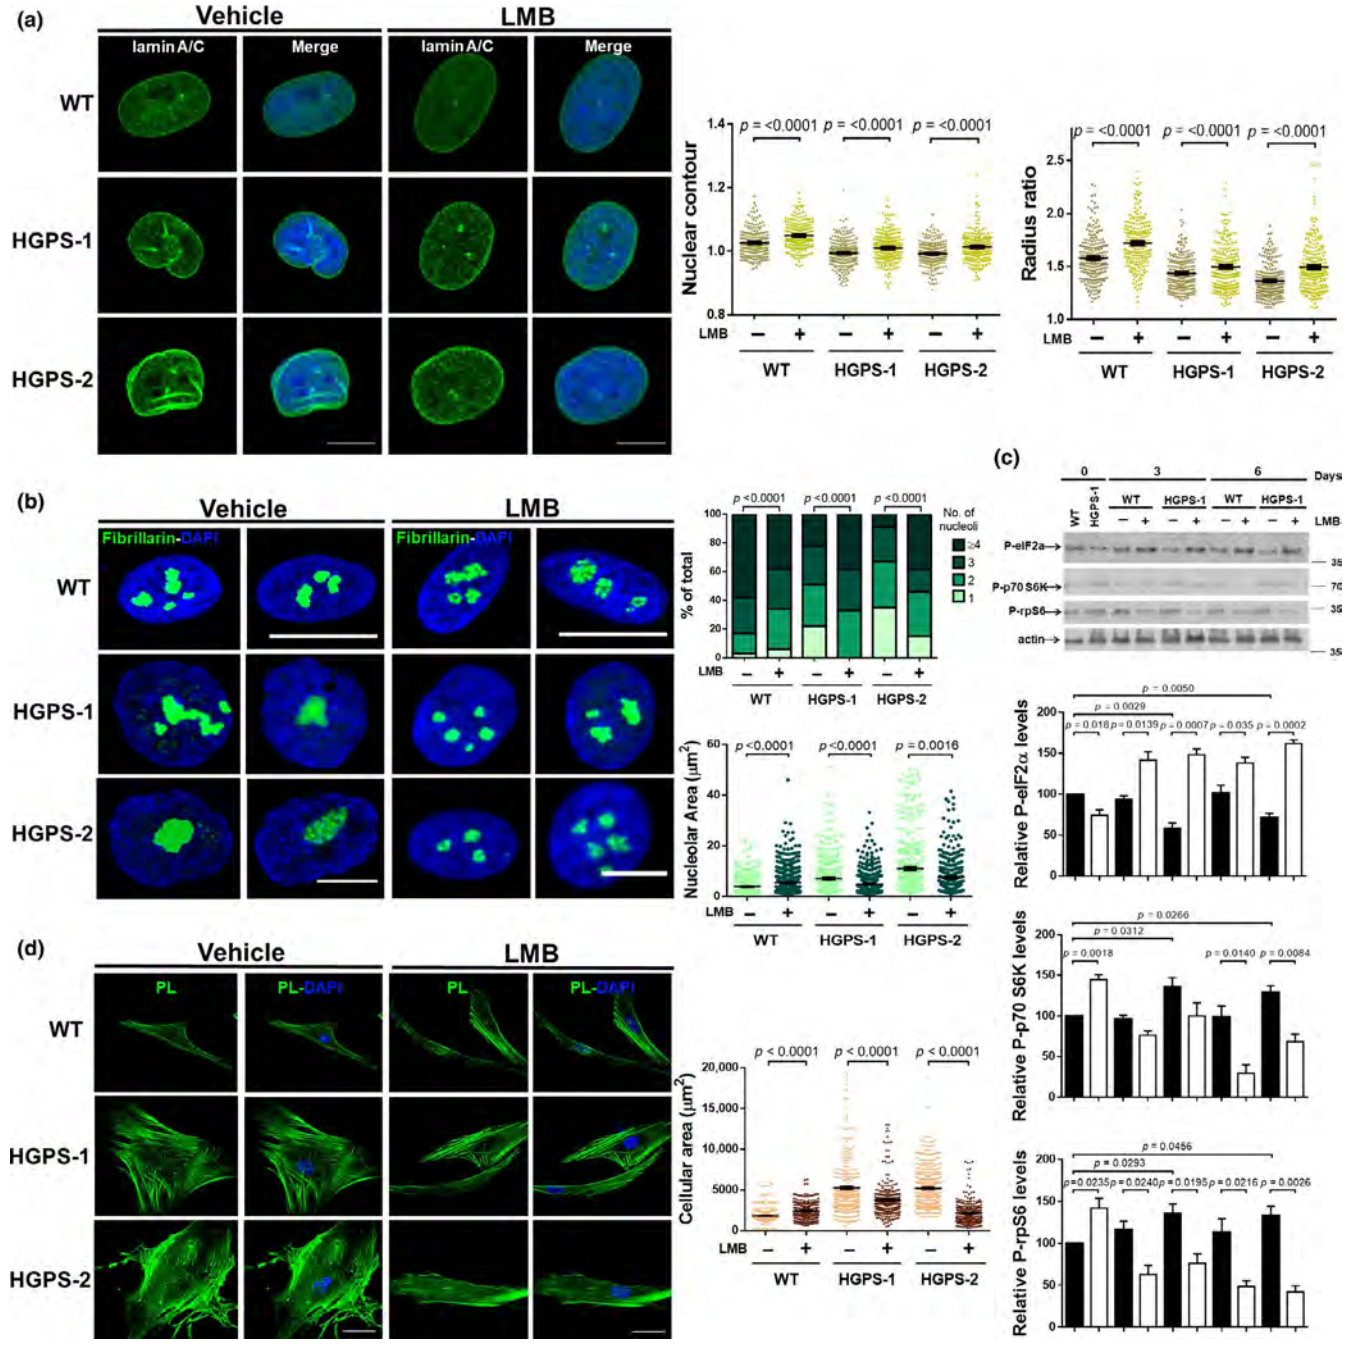

FIGURE 3 LMB-mediated inhibition of CRM1 alleviates aging features of HGPS cells. (a) WT and HGPS fibroblasts were treated for 3 days with 50 nM LMB or vehicle alone. Cells were immunolabeled for lamin A/C before being analyzed by CLSM, and representative images are shown. Bar, 10 μm. *Right*. Nuclear morphometric analysis was carried out as described in Methods (n = 200 nuclei for each condition), with significant differences determined by Mann–Whitney U test. (b) WT and HGPS fibroblasts, treated as peer A, were immunostained for fibrillarin to decorate nucleoli. Bar, 10 μm. *Right*. Nucleolar area was determined as described in Methods (n > 600 nucleoli per condition). Number of nucleoli per cell was estimated (bottom panel; n > 80 cells per sample), and significant differences were determined by Mann–Whitney U test. (c) Lysates from WT and HGPS-1 fibroblasts, previously treated for 0, 3, or 6 days with 1 nM LMB or vehicle, were analyzed by Western blotting using antibodies against the indicated proteins. Relative protein levels from three independent experiments are shown (bottom graphs), with significant differences determined by unpaired t test. (d) WT and HGPS fibroblasts were treated as peer A. Cells were labeled with phalloidin to visualize actin cytoskeleton. Bar, 50 μM. *Right*. The cellular area was estimated (n > 300 cells), with significant differences determined by Mann–Whitney U test

2.5 | Ectopic overexpression of CRM1 recreates the HGPS phenotype in normal human fibroblasts

Next, we ascertained whether exogenous overexpression of CRM1 is sufficient to mimic progeroid hallmarks in normal fibroblasts. A ~100% increase in CRM1 levels was observed after stable transfection of WT fibroblasts with a vector expressing FLAG-CRM1, compared to WT cells expressing FLAG alone (Figure 4a). Cytoplasmic mislocalization of the NES-containing protein STAT3 confirmed accelerated nuclear export activity in cells overexpressing CRM1

INFORME DE LABORES 2019

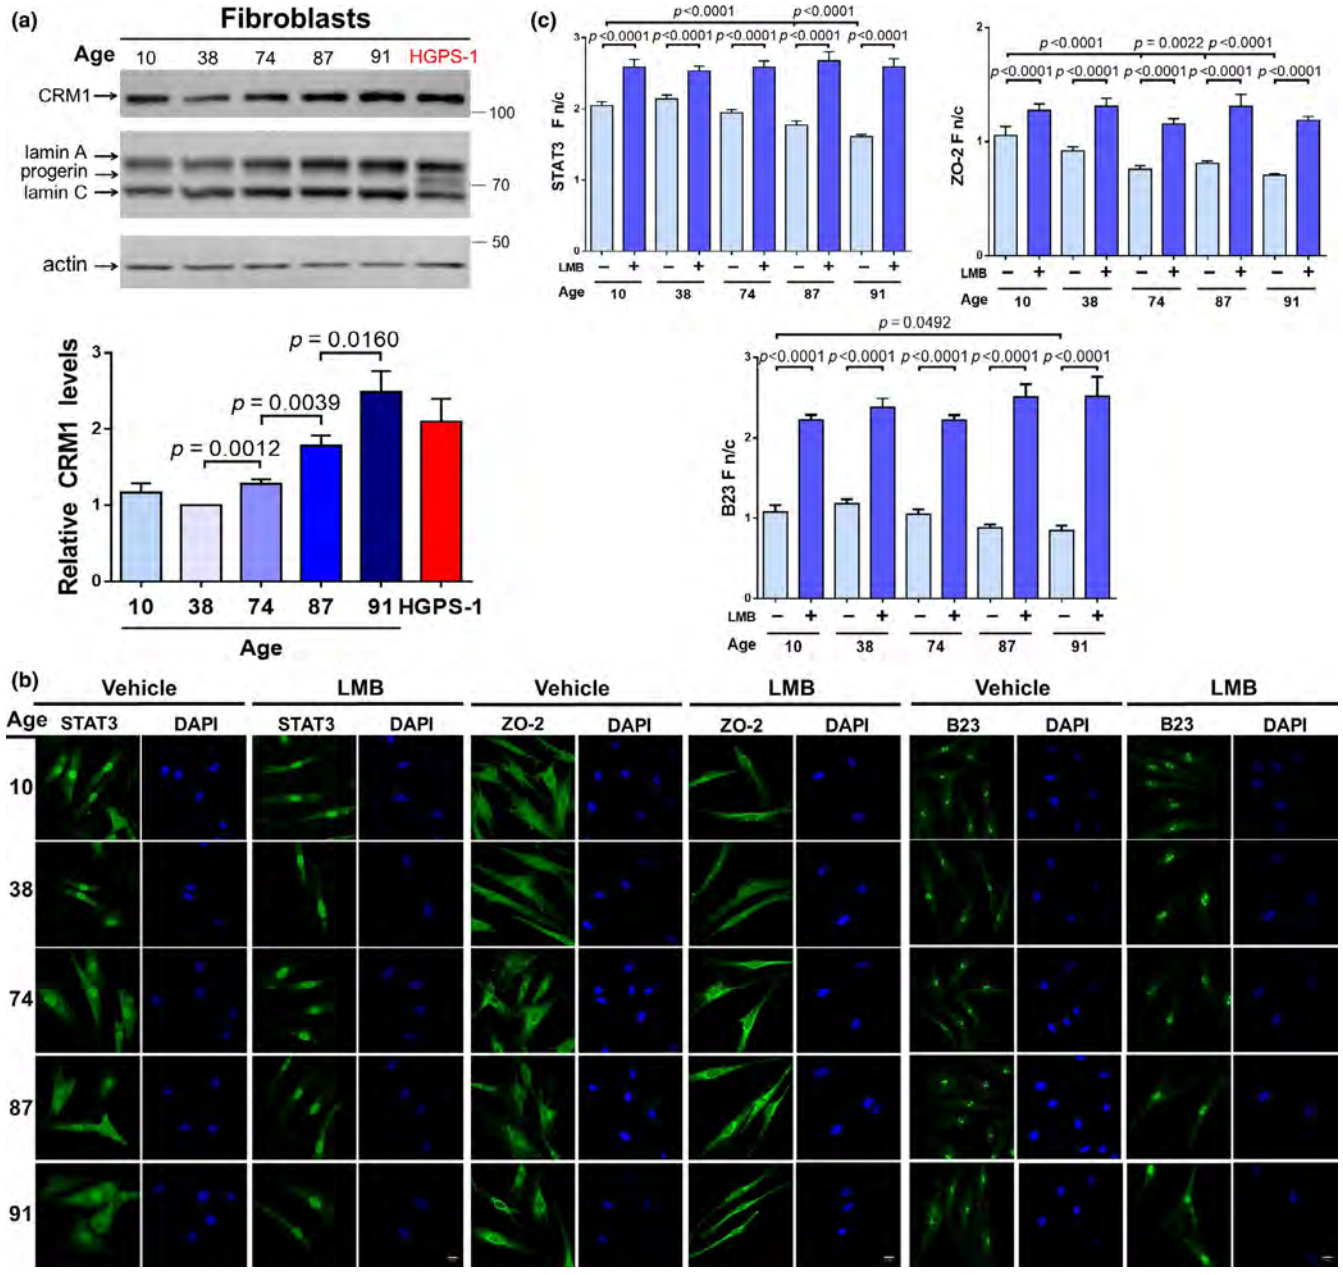

FIGURE 6 CRM1 expression and activity increased during normal aging. (a) Primary human fibroblast from healthy individuals of varying ages or HGPS-1 fibroblasts were analyzed by Western blotting using antibodies against CRM1, lamin A/C, and actin (control). CRM1 expression is shown (bottom panel; unpaired *t* test). (b) Localization of the NES-containing proteins STAT3, Z0-2, and B23 was evaluated in the indicated fibroblast cultures, treated with LMB or vehicle alone for 24 hr. Typical images are shown. Bar, 20 μM. (c) The n/c ratio of STAT3, Z0-2, and B23 was calculated as peer Methods (n = 50 cells; Mann–Whitney U test)

(Figure 4b). Remarkably, most of CRM1-overexpressing WT fibroblasts became senescent (75%), as shown by SA-β-gal staining and the acquisition of a flattened and extended cellular morphology (Figure 4c,d, respectively). Furthermore, forced overexpression of CRM1 in WT fibroblasts resulted in decreased lamin B1 levels (Figure 4e–f), with the consequent loss of H3k9m3 (Figure 4g–h). Interestingly, pharmacological inhibition of CRM1 in FLAG-CRM1-expressing fibroblasts alleviated the senescent morphology (Figure 4d) and prevented both lamin B1 downregulation (Figure 4e,f) and the loss of heterochromatin (Figure 4g,h).

The gradient of Ran, a key regulator of nucleocytoplasmic transport, was previously reported as disrupted in HGPS cells (Datta, Snow, & Paschal, 2014). We therefore investigated whether enhanced nuclear export activity via CRM1 overexpression can occur in cells with a deficient Ran gradient. Since depletion of the Ran import factor NTF2 (nuclear transport factor 2) is sufficient to disrupt the Ran gradient (Datta et al., 2014; Dworak et al., 2019), HeLa cells were double-transfected to express CRM1 and a shRNA against NTF2. Interestingly, stably transfected HeLa cells having both overexpressed levels of CRM1 and depleted levels of NTF2 (Figure 5a) still

showed elevated nuclear export activity, as shown by cytoplasmic mislocalization of the NES-containing protein STAT3 (right panel). Consequently, these cells acquired different aging marks, including depleted levels of lamin B1 and H3K9m3 (Figure 5b). Collectively, these data imply that enhancing CRM1 activity is necessary and sufficient to induce the cells to age prematurely.

2.6 | Exogenous restoration of lamin B1 levels partially alleviates the HGPS phenotype

To ascertain whether improvement of lamin B1 levels by LMB treatment is the basis of the HGPS phenotype rescue, the expression of lamin B1 was exogenously restored in HGPS-1 cells by stably transfecting a vector expressing GFP-lamin B1. GFP-lamin B1 was properly targeted to the nuclear envelope, while GFP alone was localized throughout all the cells (Figure 5c). Remarkably, HGPS cells expressing GFP-lamin B1 showed improved nuclear morphology (Figure 5d) and recovery of peripheral heterochromatin (Figure 5e), compared with HGPS-1 cells expressing GFP alone. However, restoration of lamin B1 expression failed to alleviate the senescent morphology (data not shown).

2.7 | The expression and activity of CRM1 increase during normal aging

We hypothesized that the CRM1-mediated nuclear export system could be dysregulated during normal aging as well. Thus, we analyzed expression and activity of CRM1 in a panel of primary human fibroblasts from healthy individuals ranging from 10 to 91 years of age. Interestingly, we found a significant and direct correlation between aging and increased CRM1 levels in individuals between 38 and 91 years of age (Figure 6a). Cytoplasmic mislocalization of the NES-containing proteins STAT3, Z0-2, and B23 was evident in fibroblasts from 74- to 91-year-old individuals (Figure 6b), with Fn/C analysis corroborating these observations (Figure 6c); further treatment with LMB restored predominant nuclear localization of NES-containing proteins, similar to that observed in fibroblasts from 10- to 38-year-old individuals (Figure 6b-c). Altogether, these data suggest that enhanced CRM1 activity is a hallmark of physiological aging.

3 | DISCUSSION

In this study, we show for the first time that the CRM1-driven nuclear protein export mechanism is abnormally enhanced in HGPS cells due to overexpression of CRM1. We revealed that upregulation of CRM1 in HGPS cells is controlled at the transcriptional level through induction of CRM1 promoter activity, at least for HGPS-2 cells. Furthermore, a causal link between progerin and CRM1 overexpression was demonstrated because ectopic expression of progerin in HeLa cells elicited elevated CRM1 levels, at least in part through enhancing the binding activity of NF-YA (a positive transcription factor) to the CRM1 promoter region, and because treatment of HGPS cells with FTI that decreased progerin levels resulted in turn in downregulation of CRM1. We speculated that exacerbated nuclear export activity might be part of the molecular basis underlying HGPS. As proof of concept, we evaluated whether inhibition of CRM1 activity by pharmacological treatment with LMB has a therapeutic effect on the HGPS phenotype. Remarkably, we found alleviation of virtually all HGPS hallmarks upon treatment with LMB, including reduced number of SA-β-gal positive cells, recovery of peripheral heterochromatin, and rescue of lamin B1 downregulation, nucleolar expansion, augmented protein synthesis, and the senescent cellular morphology. Furthermore, ectopic overexpression of CRM1 enabled normal fibroblasts to acquire all the aging marks aforementioned. Thus, CRM1 overexpression is sufficient to recapitulate an aging phenotype in the absence of progerin, which indicates that a dysregulated nuclear protein export is an early key event in the pathway leading to HGPS.

Most of the cellular processes rescued by LMB treatment are intimately related to lamin B1, including nuclear morphology (Vergnes, Peterfy, Bergo, Young, & Reue, 2004), organization of peripheral heterochromatin, nucleolar plasticity (Camps et al., 2014), and cellular senescence (Dreesen, Ong, Chojnowski, & Colman, 2013; Freund et al., 2012; Lukasova, Kovarik, & Kozubek, 2018; Shimi et al., 2011). Therefore, it is likely that rescue of the HGPS phenotype by treatment with LMB relies mainly on the improvement of lamin B1 levels. Consistent with this, exogenous expression of lamin B1 resulted in improved nuclear morphology and the recovery of peripheral heterochromatin, but failed to alleviate the senescent morphology of HGPS cells. Thus, alleviation of the HGPS aging marks appears to occur through more than one mechanism; further experiments are required to fully delineate pathways underlying the correction of aging marks in response to CRM1 inhibition.

A broad spectrum of treatments against HGPS has been tested in HGPS fibroblasts (Harhouri et al., 2018), and most of these are designed to target progerin. Blocking of progerin farnesylation by administration of farnesyltransferase inhibitors corrected nuclear structure but failed to alleviate other aging-associated marks (Glynn & Glover, 2005; Toth et al., 2005), while depletion of progeria via rapamycin-mediated activation of autophagy improved nuclear morphology and delayed the onset of senescence (Cao et al., 2011). In a similar manner, proteasome inhibitor MG132 enhanced proliferation and decreased cellular senescence by promoting progerin degradation (Harhouri et al., 2017). Finally, treatment with the chemical JH4 ameliorated nuclear defects and prevented premature senescence by interfering with the harmful interaction between progerin and lamin A (Lee et al., 2016). Alternative strategies aimed to repair downstream effects of progerin have been proposed as well; treatment with methylene blue rescued not only nuclear morphology and heterochromatin loss but also mitochondrial function (Xiong et al., 2016), while administration of the ROCK inhibitor Y-27632 ameliorated nuclear morphology defects and DNA double-strand breaks along with decreased ROS

levels and improvement of mitochondrial function (Kang et al., 2017). In this scenario, pharmacological modulation of CRM1 using selective inhibitors clearly provides a viable and promising therapy against HGPS, because this treatment specifically targets and corrects the nuclear export mechanism and, more importantly, because it alleviates the largest number of HGPS cellular characteristics (Graphical abstract), compared with the aforementioned treatments. Furthermore, synthetic selective inhibitors of CRM1 with pharmacological properties superior to LMB (selinexor/KPT-330), which have shown to be well-tolerated in human cancer clinical trials (Mahipal & Malafa, 2016), would facilitate future in vivo evaluation of this therapy in HGPS animal models.

Interestingly, we found increased CRM1 levels in primary fibroblast from healthy aged donors; however, no progerin was detected in these cell cultures. In analogy to the mechanism underlying CRM1 overexpression in cancer cells (van der Watt & Leaner, 2011), we hypothesized that upregulation of CRM1 in fibroblasts from aged individuals could be controlled by modulation of the binding activity of transcription factors involved in CRM1 promoter activity. Thus, enhanced CRM1-mediated nuclear export activity appears to be a key converging mechanism in both pathological and physiological aging. Consistent with this notion, silencing or pharmacological inhibition of CRM1 resulted in extended lifespan in *C. elegans* (Silvestrini et al., 2018).

In conclusion, we reveal that enhanced nuclear protein export is a new hallmark of both HGPS and normal aging. Furthermore, we provide evidence that pharmacological inhibition of CRM1 activity alleviates the progeroid cellular phenotype (Graphical abstract), which delineates CRM1 as potential therapeutic target for HGPS and other aging-related diseases.

4 | EXPERIMENTAL PROCEDURES

4.1 | Cell culture, treatments, and transfection

Primary human dermal fibroblasts from patients with HGPS and healthy donors (see Table 1) were cultured in MEM (Invitrogen) supplemented with 15% FBS (Invitrogen), nonessential amino acids, and antibiotics. All experiments were carried out with fibroblast cultures at passage numbers 12–16. Where indicated, fibroblasts were treated with 1 nM leptomycin B (LMB; Sigma-Aldrich) for 1, 3, or 6 days diluted in ethanol to a final concentration of 0.1% in the culture medium, or with 25 μM of the farnesyl transferase inhibitor (FTI) lonafarnib (Sigma-Aldrich) for three days. Fibroblasts were transfected with Lipofectamine 3,000 following manufacturer's protocol (Invitrogen). Stably transfected fibroblasts were obtained by culturing them for 12 days with 200 μg/ml G418 (Invitrogen). HeLa cells were double-transfected with pFlag-CRM1 vector and vector expressing either a short hairpin RNA (shRNA) specific for the human nuclear transport factor 2 gene (NUTF2) or a scrambled shRNA control (GeneCopoeia, Inc.), using Lipofectamine 2000 (Invitrogen). Stably transfected HeLa cells were obtained by culturing them for 6 days in the presence of 1 μg/ml puromycin and 800 μg/ml G418. Cloning strategies to obtain vectors pEGFP-C1-LB1, pFLAG-CRM1, and pCRM1 promoter are provided under request.

4.2 | Promoter reporter assays

WT, HGPS-1, and HGPS-2 fibroblasts were transfected as above with both the CRM1 promoter vector, which expresses Firefly luciferase under the control of human CRM1 promoter, and the Renilla luciferase vector as a control to normalize for differences in transfection efficiency. After 48 hr, the luciferase activity was measured using Dual Luciferase Assay kit (Promega).

4.3 | Quantitative chromatin immunoprecipitation (Q-ChIP) assays

Q-ChIP assays were performed as reported previously (Morales-Lazaro et al., 2010), using 7.8 μg of mouse anti-NF-YA antibodies or 7.8 μg of mouse IgG (irrelevant control). 20 ng of DNA was used to perform quantitative PCR (qPCR) using SYBR Green and primers specific to amplify the CRM1 promoter region (van der Watt & Leaner, 2011).

4.4 | Indirect immunofluorescence and confocal microscopy analysis

Immunostaining and CLSM analyses were carried out following standard techniques, using the appropriate primary antibodies (Table 2) and the corresponding secondary fluorochrome-conjugated antibodies (Jackson ImmunoResearch Laboratories). Images were acquired with the confocal laser system TCS-SP5, Leica. Quantification of nucleus/cytoplasm fluorescence intensity was performed as reported previously (Aguilar et al., 2015). Morphometric analysis of nuclei was performed with software

ImageJ 1.46j. Nucleolar area was quantified by measuring the cross-sectional area occupied by a mark corresponding to fibrillarin stain, with software ImageJ 1.46j.

4.5 | Senescence-Associated β-Galactosidase (SA-β-Gal) Assay

Fibroblasts seeded on coverslips were stained with SA-β-Gal following manufacturer's instructions (Senescent Cell Histochemical Staining Kit, Sigma-Aldrich). Blue-stained cells expressing β-galactosidase (senescent cells) were observed under bright-field microscopy.

4.6 | Western blotting

Immunoblotting analyses were carried out following standard protocol. Specific proteins were visualized using the Enhanced Chemiluminescence (ECL™) Western blotting detection system (Amersham Pharmacia, GE Healthcare), according to the manufacturer's instructions.

INFORME DE LABORES 2019

4.7 | Flow cytometry and cell proliferation assays

The analysis of cell cycle was carried out on a BD LSRFortessa flow cytometer (BD Biosciences), using the ModFit LT software (Verity Software House). Cell proliferation was assessed by the 3-(4,5-dimethylthiazole-2–5-diphenyl tetrazolium bromide (MTT) assay, as reported previously (Velez-Aguilera et al., 2018).

4.8 | Quantitative reverse transcription PCR (RT-qPCR)

Total RNA was isolated from fibroblasts using the Direct-zol™ RNA MiniPrep Kit (Zymo Research), according to the manufacturer's instructions. RT-qPCR was carried on the StepOnePlus Real-Time PCR System (Applied Biosystems), using the KAPA SYBR Fast One-Step qRT-PCR system (Kapa Biosystems) and following a standard protocol. The expression levels for *CRM1* mRNA were measured by the $2^{\Delta\Delta ct}$ method and normalized to *GAPDH* mRNA values. Primer sequences for CRM1 and GAPDH amplification will be provided under request.

4.9 | Statistical analysis

Statistical analyses were performed by the two-tailed unpaired Student's *t* test. Data represent the mean ± SEM from a series of three separate experiments, and *p* values < 0.05 are indicative of statistical significance. Where indicated, statistical analysis was carried out using exact nonparametric Mann–Whitney U test or unpaired *t* test and data were summarized by the mean ± SEM or the mean ± *SD* from a series of three separate experiments. *p* values < 0.05 were considered as significant. All statistical analyses were performed using GraphPad Prism 5 software (San Diego).

ACKNOWLEDGMENTS

We thank Gómez-Islas J. P. (CINVESTAV) for technical support. This project was supported by a grant from the Bilateral Agreement CNR (Italy)/CINVESTAV (Mexico) #CNR2018/4 to BC, and a grant from the Secretaria de Educación, Ciencia, Tecnología e Innovación de la Ciudad de México SECITI/042/2018 (INGER-DI-CRECITES-008-2018) "Red Colaborativa de Investigación Traslacional para el Envejecimiento Saludable de la Ciudad de México (RECITES)."

Genetic Knockdown of mGluR5 in Striatal D1R-Containing Neurons Attenuates L-DOPA-Induced Dyskinesia in Aphakia Mice

Abstract

L-DOPA is the main pharmacological therapy for Parkinson's disease. However, long-term exposure to L-DOPA induces involuntary movements termed dyskinesia. Clinical trials show that dyskinesia is attenuated by metabotropic glutamate receptor type 5 (mGluR5) antagonists. Further, the onset of dyskinesia is delayed by nicotine and mGluR5 expression is lower in smokers than in non-smokers. However, the mechanisms by which mGluR5 modulates dyskinesia and how mGluR5 and nicotine interact have not been established. To address these issues, we studied the role of mGluR5 in D1R-containing neurons in dyskinesia and examined whether nicotine reduces dyskinesia via mGluR5. In the aphakia mouse model of Parkinson's disease, we selectively knocked down mGluR5 in D1R-containing neurons (aphakia-mGluR5$^{KD\text{-}D1}$). We found that genetic downregulation of mGluR5 decreased dyskinesia in aphakia mice. Although chronic nicotine increased the therapeutic effect of L-DOPA in both aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ mice, it caused a robust reduction in dyskinesia only in aphakia, and not in aphakia-mGluR5$^{KD\text{-}D1}$ mice. Downregulating mGluR5 or nicotine treatment after L-DOPA decreased ERK and histone 3 activation, and FosB expression. Combining nicotine and mGluR5 knockdown did not have an added antidyskinetic effect, indicating that the effect of nicotine might be mediated by downregulation of mGluR5 expression. Treatment of aphakia-mGluR5$^{KD\text{-}D1}$ mice with a negative allosteric modulator did not further modify dyskinesia, suggesting that mGluR5 in non-D1R-containing neurons does not play a role in its development. In conclusion, this work suggests that mGluR5 antagonists reduce dyskinesia by mainly affecting D1R-containing neurons and that the effect of nicotine on dyskinetic signs in aphakia mice is likely via mGluR5.

Keywords Basal ganglia · Dyskinesia · mGluR5 · Nicotine · Parkinson's disease

Introduction

Parkinson's disease (PD) is characterized by the loss of dopaminergic neurons in the *substantia nigra pars compacta* and is associated with a reduction of dopaminergic tone in the striatum that correlates with the motor symptomatology. The dopamine precursor L-3,4-dihydroxyphenylalanine (L-DOPA) provides the most effective symptomatic treatment for PD [1, 2]. However, chronic L-DOPA administration together with the progression of PD induces motor side effects, such as dyskinesia. Strong evidence demonstrates that the dopamine D1 receptor (D1R) is critical for the development of dyskinesia [3–5]. For instance, L-DOPA and D1R agonists induce dyskinesia [6], and increased activation of D1R is associated with enhanced expression of extracellular-signal-activated kinases (ERK), phospho-acetylated histone 3 (pAcH3) and FosB [7–12]. These findings indicate that reduction of D1R-dependent signaling may help to alleviate dyskinetic symptoms [8, 13, 14]. Previous evidence demonstrated that glutamatergic and cholinergic transmission modulate the D1R signaling pathway [15, 16]. In fact, glutamatergic transmission in the basal ganglia is increased in dyskinesia [17–20]. Interestingly, this overactivation could be reversed in animal

models by modulating the metabotropic glutamate receptor type 5 (mGluR5) [21].

The mGluR5 is highly expressed in striatal D1R- and D2R-containing neurons but also in cholinergic, parvalbumin, and somatostatinergic interneurons as well as in corticostriatal and thalamostriatal pathways [22, 23]. Several lines of evidence implicate mGluR5 in the development of dyskinesia [24–29]. First, L-DOPA treatment increases mGluR5 binding in the striatum of dyskinetic MPTP-treated monkeys and 6-OHDA-lesioned rats [28, 30]. Second, clinical and preclinical studies show that mGluR5 antagonists have moderate to mild antidyskinetic effects but at the expense of the therapeutic efficacy of L-DOPA [31–33]. Because mGluR5 is so widely distributed on striatal neurons, it is possible that these effects reside in different populations. Therefore, before dismissing mGluR5 as a potential therapeutic target for treatment or prevention of dyskinesia, it is important to determine if the antidyskinetic role of mGluR5 antagonists reside in a specific striatal population.

Previous studies have shown that dyskinesia is less frequent in PD patients who smoke compared to those who do not [34]. Although tobacco smoke contains many chemical components, it is possible that nicotine plays a role, since previous studies show that nicotine has antidyskinetic effects in rodents and non-human primates [35–38]. Nicotine actions are mediated by nicotinic acetylcholine receptors (nAChR) that are highly expressed in the striatum and modulate dopaminergic transmission. In the striatum, the two most abundant nicotine receptors are the β2* (α4β2*, α6β2*) and the α7 [39]. These receptors modulate the release of dopamine and glutamate in the striatum [3, 40]. Interestingly, previous studies showed that α7 receptor-specific binding is increased in the putamen of dyskinetic MPTP-treated monkeys and PD patients [41]. It is noteworthy that mGluR5 expression is downregulated in smokers, specifically in the caudate nucleus and putamen, suggesting that nicotine may be the cause of this downregulation [42]. Moreover, other previous studies suggest that the antidyskinetic effect of nicotine may be the result of targeting glutamatergic inputs [18, 43, 44].

Because D1R-containing neurons are strongly implicated in the development of dyskinesia, our aim in this study was to investigate the role of mGluR5, in direct pathway neurons, in dyskinesia. To produce a parkinsonian mouse model with D1R-specific reduction of mGluR5, we crossed transgenic mice, with a selective reduction of mGluR5 in D1R-containing neurons ($mGluR5^{KD\text{-}D1}$), with aphakia mice, a genetic model of PD [45, 46]. To understand the function of mGluR5 in direct pathway neurons in dyskinesia, we compared the effect of L-DOPA treatment in these mice to aphakia mice [46]. We also studied the dyskinetic effect of nicotine in these mice to determine if mGluR5 on D1R-containing neurons plays a role.

Methods

Mice

Female and male mice (22–30 g) were housed under 12-h light-dark cycle with food and water ad libitum, temperature 22 °C, and humidity 44%. $mGluR5^{KD\text{-}D1}$ mice were generated by homologous recombination and kindly provided by Dr. Bilbao and Dr. Spanagel, from the Central Institute of Mental Health, Manheim Germany [45]. Aphakia mice and C57BL/6J mice were obtained from our own facility. Aphakia mice with a selective knockdown of mGluR5 in D1R-containing neurons were created by crossing aphakia mice with $mGluR5^{KD\text{-}D1}$ mice. All mice were on a C57BL/6J background, and the genotype was determined by PCR analysis of tail-tip DNA as described previously [45, 46].

Drugs

L-DOPA, benserazide, and 1-methyl-3-(4-methylpyridin-3-yl)-6-(pyridin-2-ylmethoxy)-1H-pyrazolo-[3,4-b]pyrazine (PF470) were purchased from Sigma–Aldrich (Spain). (−)-Nicotine ditartrate was purchased from Tocris-Bioscience (UK).

Nicotine and L-DOPA Treatment

Half of the mice were randomly assigned to control (sweetened water) or nicotine groups. Nicotine was supplied in drinking water (300 μg/mL in 2% saccharine vehicle) for 8 weeks. This concentration corresponds to a level similar to that found in long-time smokers [3]. Chronic nicotine treatment in the drinking water was initiated a month before the chronic administration of L-DOPA. Mice received a daily injection of benserazide (10 mg/kg i.p.) followed, 20 min later, by L-DOPA (10 mg/kg i.p) (Fig. 1(a)) [47]. To assess the non-D1R role of mGluR5 in dyskinesia, a highly potent negative allosteric modulator, PF470 (1 mg/kg s.c.), was used (Ki = 0.9 nM vs MTEP Ki = 16 nM) together with benserazide.

Behavioral Analysis

Following injections, mice were placed individually in glass cylinders and were video-recorded for 4 min, beginning 30 min after L-DOPA or saline injection. Three and four paw dyskinesia (3–4 paw dyskinesia) was scored as described previously. Briefly, 3–4 paw dyskinesia was noted when mice stood on their hind paws and reared against the wall of the cylinder, moving both front paws and repeatedly lifting the hind paws up and down [47–49].

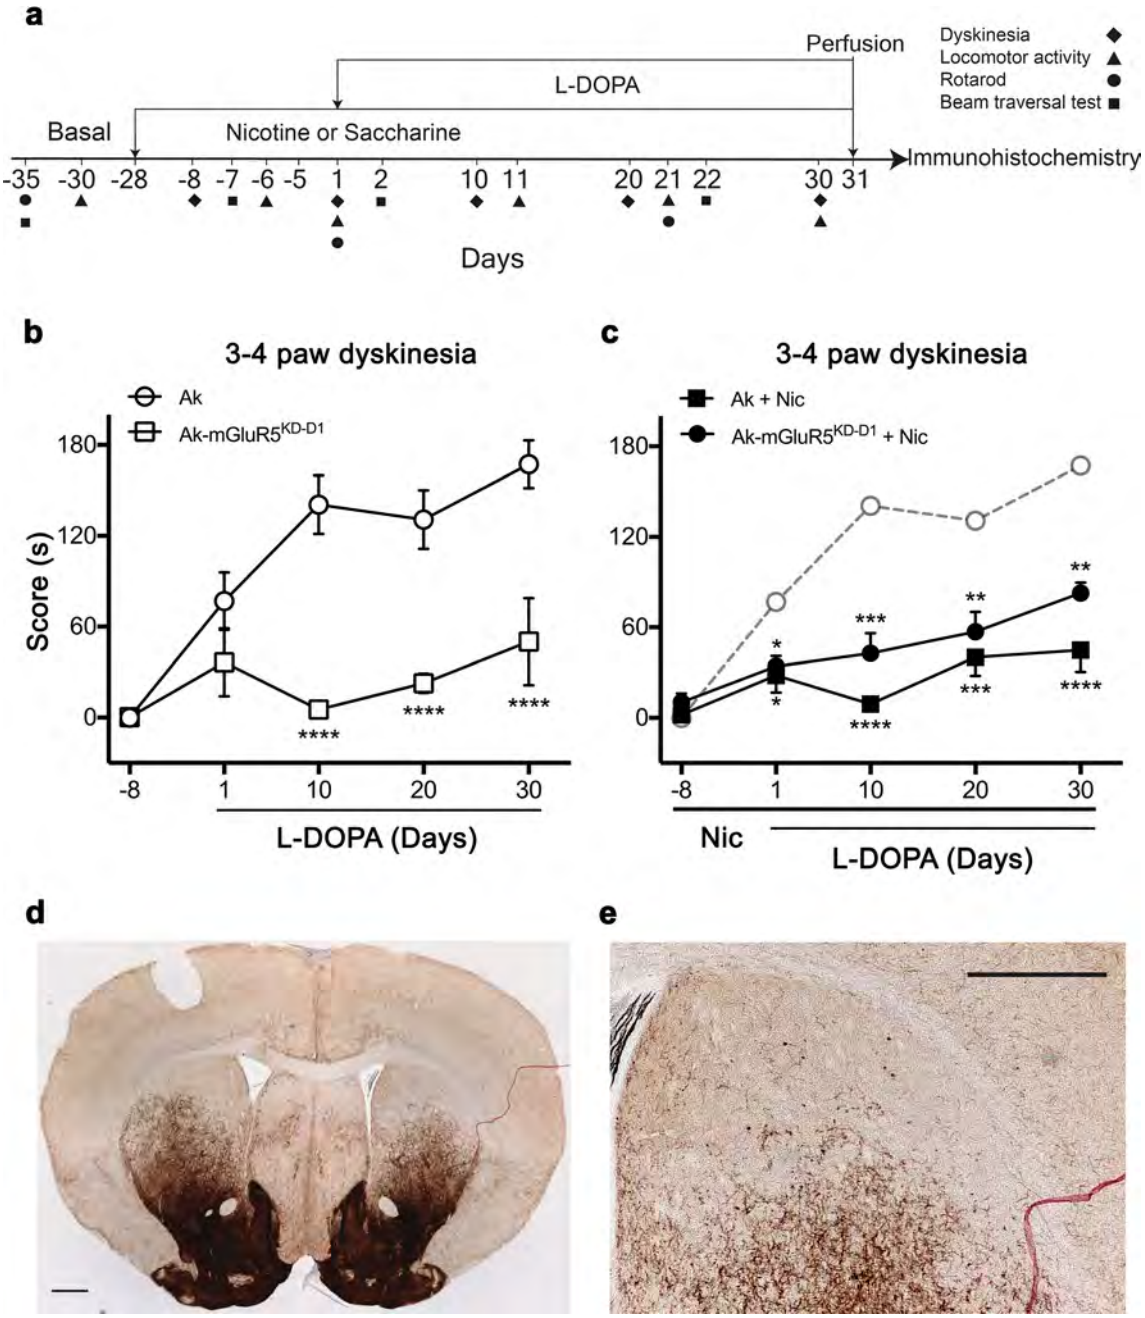

Fig. 1 Selective reduction of mGluR5 in D1R-containing neurons diminishes L-DOPA-induced dyskinesia in aphakia (Ak) mice. *a* Schematic view of the experimental timeline. *b*, *c* Scores of 3–4 paw dyskinesia in Ak and Ak-mGluR5^{KD-D1} mice treated with L-DOPA *b* and nicotine + L-DOPA *c*. *d* Coronal section from an Ak mouse immunostained for TH. *e* High magnification image from *d* showing a gradient of TH loss in dorsolateral striatum. Scale bar = 500 μm. Data are expressed as mean ± SEM, $n = 9–15$ per group. Two-way ANOVA followed by Bonferroni's post hoc test showed significant differences for *b* [genotype, $F_{1,102} = 48.95$, $p < 0.0001$; time, $F_{4,102} = 10.04$, $p < 0.0001$; interaction, $F_{4,102} = 5.21$, $p = 0.0007$] and for *c* [treatment, $F_{4,146} = 16.83$, $p < 0.0001$; time, $F_{2,146} = 40.3$, $p < 0.001$; interaction, $F_{8,146} = 4.35$, $p = 0.0001$]. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$ vs. L-DOPA-treated Ak (dotted line in *c*). Nic nicotine

Basal motor behavior was evaluated 1 to 2 weeks before L-DOPA administration. Locomotor activity was assessed in activity cages (AccuScan instruments, Inc.) as previously described [13]. We measured the total distance (cm) traveled during a 30-min period, beginning 30 min after L-DOPA injection. Motor coordination and balance were measured in the challenging beam traversal test as previously described [50]. Briefly, before treatments, mice were trained to cross the beam, and once trained, they were videotaped. We measured the total time it took the mice to cross the beam. The beam traversal test was evaluated 45 min after L-DOPA

INFORME DE LABORES 2019

injection, when dyskinesia is higher. Motor coordination was evaluated using the rotarod test (UgoBasile, Varese, Italy), following an accelerating protocol with increasing speed from 4 to 40 rpm over a 5-min period and measuring latency up to the first fall off the rod [47]. Mice were tested in six consecutive trials, 20 min apart. All behavioral experiments were assessed by observers who were blind to mouse genotypes and treatment.

Immunohistochemistry

One hour after the last L-DOPA injection, animals were anesthetized with an overdose of pentobarbital (Normon Labs, Madrid Spain) and perfused with saline solution, followed by 4% paraformaldehyde in phosphate-buffered saline. The brains were post-fixed overnight and transferred to a solution of 0.1 M phosphate buffer. The brains were cut into 30-μm coronal sections with a vibratome (Leica, Wetzlar, Germany), and immunohistochemistry was performed on free-floating sections. To stain sections of striatum, we used the standard avidin-biotin immunohistochemical protocol with the following primary antibodies: tyrosine hydroxylase (TH, 1:1000; Chemicon), FosB (1:15000; Santa Cruz Biotechnology), pERK (1:250; Cell Signaling Technology), and pAcH3 (1:10000; Millipore). For immunofluorescence, we used mGluR5 antibody (1:100; Alomone labs) revealed with Alexa fluor 647-conjugated secondary antibody (1:500; Invitrogen). Quantification of FosB, pAcH3, and pERK, TH and mGluR5 expression levels were carried out using ImageJ [51]. The number of immunolabeled cells were determined using two-three serial rostrocaudal sections (+ 1.10 to + 0.14 mm relative to bregma) per animal from the lesioned dorsolateral striatum as previously described. The digital images were obtained under a Leica microscope using a × 40 objective. The data are presented as the number of stained nuclei per square millimeter in the denervated striatum as previously reported [14]. We conducted fluorescence analyses of mGluR5 by using ImageJ to calculate the signal intensity contained in the double stained microphotographs obtained with confocal microscope using a × 60 objective as previously described [52]. Fluorescence intensity results are expressed as percentage of control (C57BL/6J mice).

Statistical Analysis

All values are given as mean ± SEM. Statistical analyses were performed using GraphPad Prism 6. Statistical analysis was assessed by using two-way ANOVA or repeated measures, followed by the appropriate post hoc comparisons. A level of $p < 0.05$ was considered statistically significant.

Results

Knockdown of mGluR5 in D1R-Containing Neurons Ameliorates L-DOPA-Induced Dyskinesia

The aphakia mice lack nigrostriatal innervation in both hemispheres (Fig. 1(d, e)) and, therefore, display bilateral dyskinetic symptoms after L-DOPA treatment as shown previously [46, 48]. To evaluate the role of mGluR5 in direct pathway neurons in dyskinesia, we used the aphakia-mGluR5$^{KD\text{-}D1}$. Aphakia-mGluR5$^{KD\text{-}D1}$ and aphakia mice were chronically treated with L-DOPA (10 mg/kg) for 31 days, (Fig. 1(a)), and 3–4 paw dyskinesia was evaluated at regular intervals by a researcher blinded to treatment and genotype [46, 47]. L-DOPA increased 3–4 paw dyskinesia in aphakia mice, while in aphakia-mGluR5$^{KD\text{-}D1}$ mice, dyskinetic scores were significantly lower ($p < 0.001$) (Fig. 1(b)). Because nicotine attenuates and delays the onset of dyskinetic symptoms [34–36, 53], and also reduces brain mGluR5 [42], we wanted to address if nicotine's effect on dyskinesia is related to reduced mGluR5 expression on D1R-containing neurons. Chronic treatment with nicotine robustly and significantly reduced dyskinesia in aphakia mice ($p < 0.01$), similar to its previously published effects in unilateral 6-OHDA-lesioned mice and in MPTP-treated monkeys [38, 40, 54]. In aphakia-mGluR5$^{KD\text{-}D1}$ mice, nicotine treatment did not further reduce dyskinetic symptoms. In fact, the aphakia-mGluR5$^{KD\text{-}D1}$ mice showed slightly higher dyskinetic scores compared with aphakia mice treated with nicotine (Fig. 1(c)).

Knockdown of mGluR5 in D1R-Containing Neurons Does Not Affect L-DOPA's Therapeutic Efficacy

To check that the antidyskinetic effects of mGluR5 knockdown were not due to a reduction in the therapeutic effect of L-DOPA, we compared motor behavior in L-DOPA-treated aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ mice. In this experiment, we used activity cages that measure spontaneous locomotor activity as reflected by sequential horizontal beam breaks, computing the total distance traveled during each trial. We found no difference between aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ mice in horizontal movements or the distance traveled under basal conditions or after chronic L-DOPA treatment (Fig. 2(a, b)). Chronic nicotine treatment also had no effect in motor activity in the L-DOPA-treated or naïve aphakia or aphakia-mGluR5$^{KD\text{-}D1}$ mice (Fig. 2(a', b')).

We then challenged the mice for finer motor coordination and activity using the beam traversal and rotarod tests before and after L-DOPA treatment. The time to cross the beam was similar in aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ mice after saline. Chronic L-DOPA significantly reduced the time

INFORME DE LABORES 2019

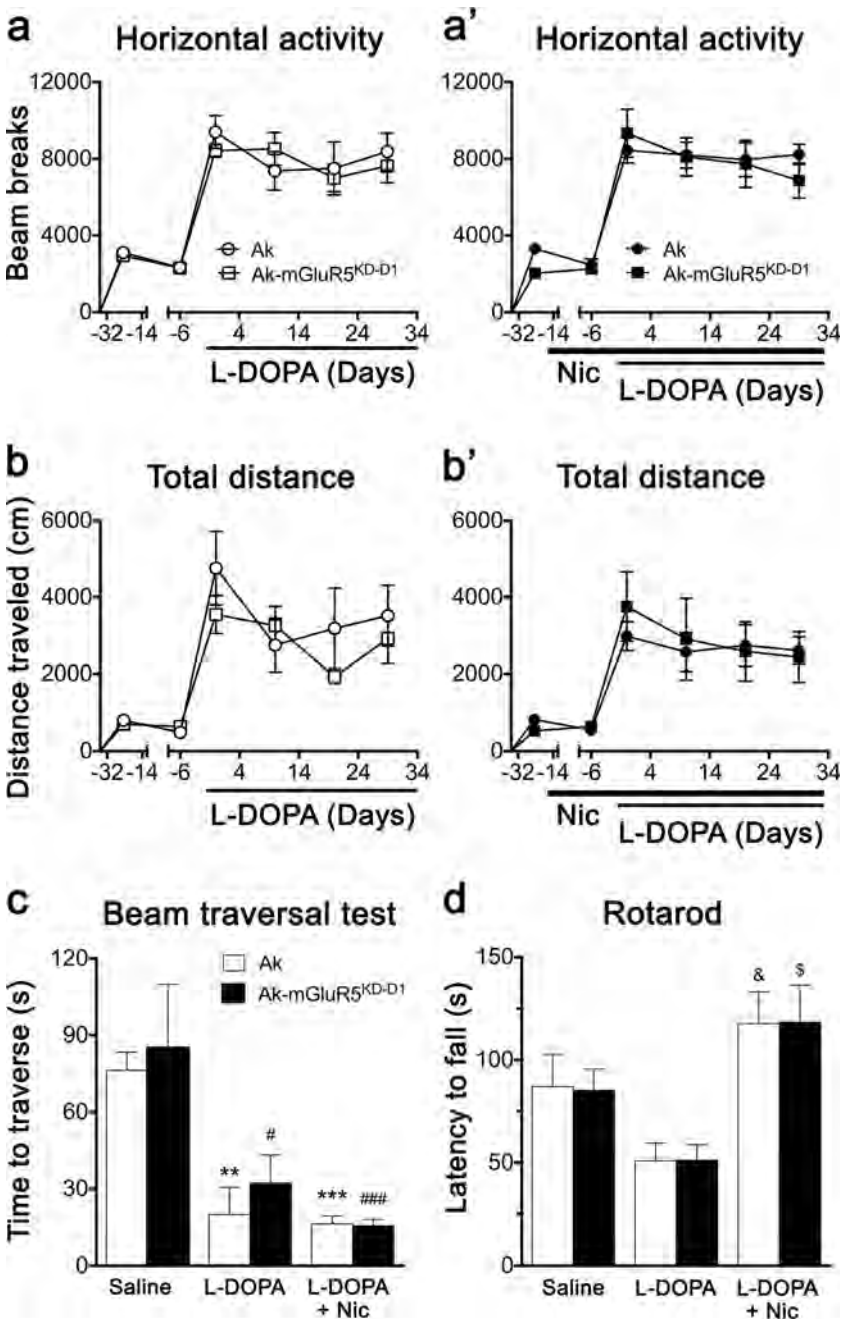

Fig. 2 Selective reduction of mGluR5 in D1R-containing neurons does not alter the therapeutic effect of L-DOPA. (a, a'). Horizontal locomotor activity and (b, b') total distance traveled were measured 30 min after L-DOPA administration for 30 min. Note that no differences were found between Ak and Ak-mGlur5^{KD-D1} neither in basal conditions nor with L-DOPA (a, b) or L-DOPA + nicotine (a', b'). Motor coordination and performance were measured in the beam traversal (c) and in the rotarod (d) tests at different time points: 5 weeks before any treatment (saline), or 45 min after L-DOPA administration (see timeline in Fig. 1(a)). Two-way ANOVA followed by Bonferroni's post hoc test showed significant differences for treatment [$F_{2,42} = 25.26$, $p < 0.001$ for (c); $F_{2,50} = 12.15$, $p = 0.0001$ for (*d*)]. $^{**}p < 0.01$, $^{***}p < 0.001$ vs. Ak saline, $^{\#}p < 0.05$, $^{\#\#\#}p < 0.001$ vs. Ak-mGlur5^{KD-D1} saline, $^{\&}p < 0.05$ vs. Ak L-DOPA, $^{\$}p < 0.05$ vs. Ak-mGlur5^{KD-D1} L-DOPA. Data are expressed as mean ± SEM, $n = 6$–11 per group. Nic nicotine

to cross beam in both groups of mice ($p < 0.01$), with no significant difference between genotypes. Chronic nicotine treatment did not further reduce the time to cross the beam (Fig. 2(c)). In terms of motor coordination, dyskinesia reduced the latency to fall from the rod in both aphakia and aphakia-mGluR5^{KD-D1} mice (Fig. 2(d)). Interestingly, chronic treatment with nicotine in addition to L-DOPA significantly potentiated L-DOPA's motor coordination effect in both aphakia and aphakia-mGluR5^{KD-D1} mice ($p < 0.01$) (Fig. 2(d)).

Molecular Markers as Cue in the Effect of Nicotine in Aphakia Mice Lacking mGluR5 in D1R-Containing Neurons

We then investigated whether the decrease in L-DOPA-induced dyskinesia in aphakia-mGluR5^{KD-D1} mice is accompanied by a reduction of molecular markers of L-DOPA-induced dyskinesia—pERK, pAcH3, and FosB. As expected, L-DOPA induced the expression of molecular markers selectively in the completely denervated striatal areas in both hemispheres (e.g. see FosB

inset in Fig. 3(c)). Chronic L-DOPA treatment significantly increased the expression of FosB, pAcH3, and pERK in aphakia mice compared to the saline- and nicotine-treated aphakia animals ($p < 0.001$) (Fig. 3). Interestingly, in aphakia-mGluR5^{KD-D1} mice, the number of neurons immunoreactive for pERK was reduced by 66% ($p < 0.01$), pAcH3 activation was reduced by 33% ($p < 0.05$, $p < 0.01$, $p < 0.001$), and FosB expression by 39% ($p < 0.05$) (Fig. 3(a'–c')) compared to aphakia mice. Consistent with its effect on dyskinesia signs, chronic treatment with nicotine resulted in a significant decrease of pERK- and pAcH3-induced by L-DOPA in aphakia ($p < 0.01$) (Fig. 3(a', b')) but not in aphakia-mGluR5^{KD-D1} mice. However, nicotine did not alter L-DOPA-induced FosB expression in either aphakia or aphakia-mGluR5^{KD-D1} mice (Fig. 3(c, c')).

The Antidyskinetic Effect of the mGluR5 Negative Allosteric Modulator Is Primarily Mediated by mGluR5 on D1R-Containing Neurons

Because mGluR5 is similarly expressed in D1R- and D2R-containing striatal neurons, and in most interneurons [22], we then tested if the antidyskinetic effects of the negative

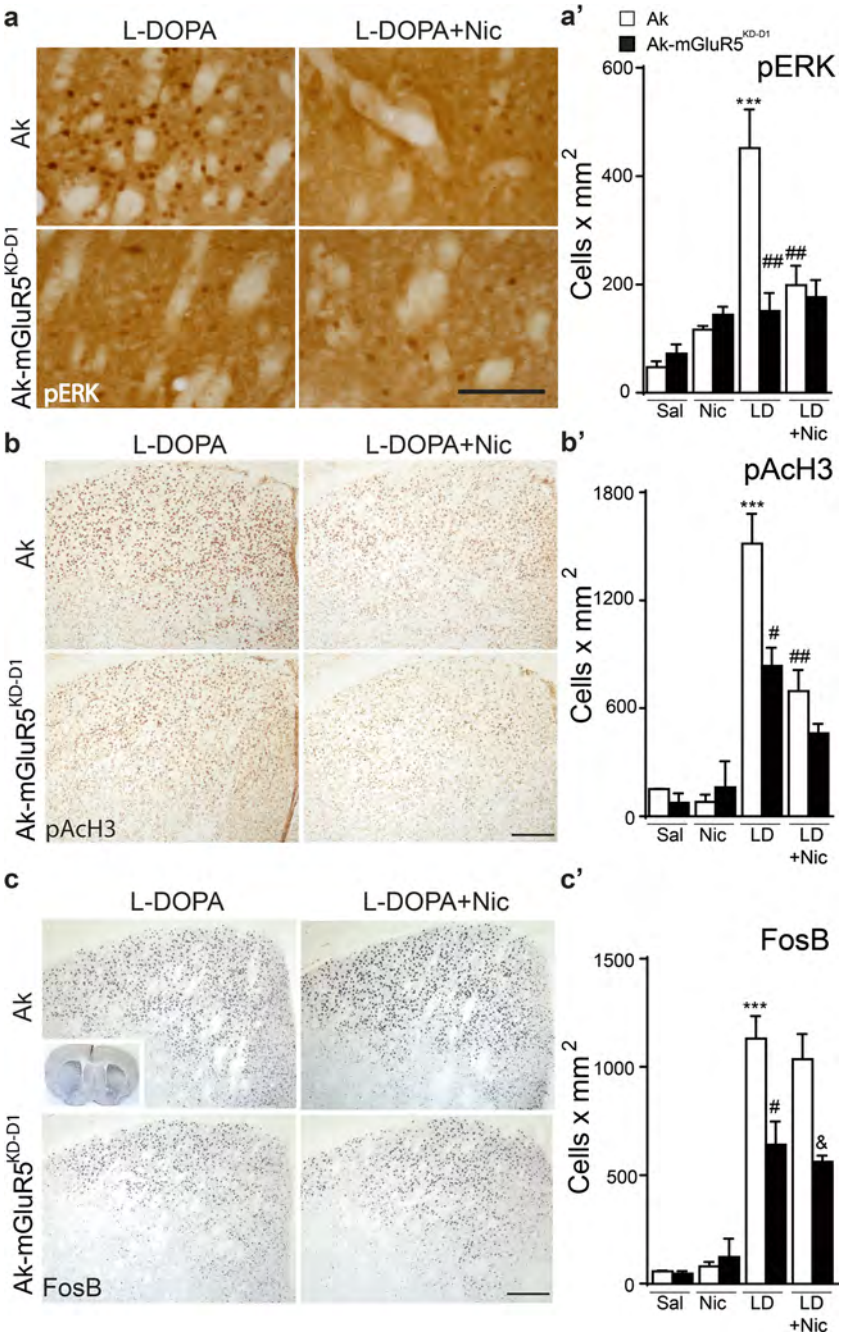

Fig. 3 Downregulation of mGluR5 in D1R neurons reduces L-DOPA-induced molecular markers of dyskinesia. (a, b, c) Microphotographs of striatal coronal sections from Ak and Ak-mGluR5^{KD-D1} mice sacrificed 1 h after the last L-DOPA injection, immunostained for pERK, pAcH3, and FosB. Scale bar = 100 μm, 200 μm. (a', b', c') Histograms represent the quantification of pERK, pAcH3, and FosB immunoreactive positive cells. Note that all molecular markers are expressed in the completely denervated striatal areas, see FosB image in (c). Two-way ANOVA followed by Bonferroni's post hoc test showed significant differences for genotype [$F_{1,26} = 4.49$, $p = 0.04$ for pERK; $F_{1,26} = 7.02$, $p = 0.01$ for FosB] and treatment [$F_{3,26} = 10.15$, $p = 0.0001$ for pERK; $F_{3,27} = 16.93$, $p = 0.0001$ for pAcH3; $F_{3,26} = 26.04$, $p = 0.0001$ for FosB]. ***$p < 0.001$ vs. Ak saline, $^{\#}p < 0.05$, $^{\#\#}p < 0.01$ vs. Ak L-DOPA. $^{\&} < 0.05$ vs. Ak-mGluR5^{KD-D1} L-DOPA + nicotine. allosteric modulators in aphakia-mGluR5^{KD-D1} mice were mediated by the mGluR5 expressed in D1R-containing neurons. Previous studies showed a marked antidyskinetic effect of the highly selective and efficacious mGluR5 negative allosteric modulator, PF470 [55]. To assess the specific contribution of mGluR5 on D1R-containing neurons, we compared the effect of PF470 on L-DOPA-induced dyskinesia in aphakia and aphakia-mGluR5^{KD-D1} mice. We treated mice with PF470 20 min before the last dose of L-DOPA (Fig. 4(a)). Our results showed that a single dose (1 mg/kg, i.p.) of PF470 decreased dyskinetic behavior in aphakia mice by about 80% ($p < 0.05$), as expected [56]. However, acute PF470 had no significant effect on dyskinetic behavior in aphakia-mGluR5^{KD-D1} mice (Fig. 4(b)), suggesting that the effect of the mGluR5 antagonists on dyskinesia is primarily due to its action on mGluR5 located in D1R-containing neurons. Similarly, PF470 did not further reduce the antidyskinetic effects of nicotine in aphakia or aphakia-mGluR5^{KD-D1} mice (Fig. 4(b)).

We next compared the effect of PF470 on expression of molecular markers of dyskinesia in aphakia and aphakia-

INFORME DE LABORES 2019

mGluR5$^{KD\text{-}D1}$ mice. PF470's effect on molecular markers of dyskinesia mirrored its effects in the behavioral assays of dyskinesia. Thus, PF470 decreased pERK and pAcH3 in both aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ groups (Fig. 4(c, d')). In the mice chronically treated with nicotine, PF470 did not further alter pERK and pAcH3 in aphakia or aphakia-mGluR5$^{KD\text{-}D1}$ mice. Although PF470 treatment decreased FosB expression induced by L-DOPA in aphakia and aphakia-mGluR5$^{KD\text{-}D1}$ mice, as expected, in the nicotine-treated mice, this reduction occurred in the aphakia-mGluR5$^{KD\text{-}D1}$ mice only (Fig. 4(e, e')).

mGluR5 Expression in D1R-Containing Neurons

Previous studies showed that mGluR5 is downregulated in mGluR5$^{KD\text{-}D1}$ mice [15, 45]. Since aphakia mice express the tomato fluorescent protein in D1R-containing neurons, we were able to measure by immunofluorescence the expression of mGluR5. As expected, we found that saline-treated aphakia-mGluR5$^{KD\text{-}D1}$ mice display lower expression of the mGluR5 in D1R-containing neurons compared to aphakia mice ($p < 0.01$) in the denervated striatum. This pattern of expression was similar in the nicotine-treated animals. Next, we asked whether L-DOPA is able to increase the expression of mGluR5 in striatal D1R-containing neurons in the aphakia-mGluR5$^{KD\text{-}D1}$ mice, and second, if nicotine could further reduce mGluR5 in D1R-containing neurons. We found that L-DOPA increased the expression of mGluR5 in D1R-containing neurons in aphakia mice relative to saline-treated aphakia mice. This L-DOPA-induced increase in mGluR5 expression was prevented in aphakia-mGluR5$^{KD\text{-}D1}$ animals ($p < 0.01$), although the expression was slightly higher compared to saline aphakia-mGluR5$^{KD\text{-}D1}$ mice. Nicotine reduced mGluR5 fluorescence intensity in D1R-containing neurons in aphakia mice but not in aphakia-mGluR5$^{KD\text{-}D1}$ (Fig. 5).

Discussion

The present study demonstrates that selective knockdown of mGluR5 in D1R-containing neurons decreases L-DOPA-induced dyskinesia in aphakia mice, an established genetic mouse model of PD [46–49]. We observed that aphakia-mGluR5$^{KD\text{-}D1}$ mice, showed a robust decrease in dyskinesia but retained full therapeutic efficacy of L-DOPA compared to aphakia mice. Importantly, this reduction in behavioral indicators of dyskinesia was accompanied by reduced activation of the pERK/pAcH3/FosB signaling pathway, a known molecular cascade associated with L-DOPA-induced dyskinesia. Furthermore, administration of the highly selective mGluR5 negative allosteric modulator (PF470) reduced dyskinesia in aphakia but did not further modify dyskinetic behavior in apahakia-mGluR5$^{KD\text{-}D1}$ mice, suggesting that the effect of PF470 on dyskinesia is primarily mediated by its action on mGluR5 in D1R-containing neurons. Given that nicotine has been shown to regulate glutamate neurotransmission, we also asked whether nicotine was able to further reduce dyskinesia in aphakia-mGluR5$^{KD\text{-}D1}$ mice. Our results suggest that the effect of nicotine on dyskinesia is also mediated through mGluR5 in D1R direct pathway neurons. Chronic nicotine decreased dyskinesia in aphakia mice, but was unable to produce a further reduction of dyskinetic signs in aphakia-mGluR5$^{KD\text{-}D1}$. Interestingly, animals that received nicotine showed no reduction in the antiparkinsonian effect of L-DOPA and exhibited improvement in motor performance.

Previous research shows that striatal mGluR5 are increased when dyskinetic movements induced by L-DOPA appear [57]. In addition, it was demonstrated that there is a cross talk between D1R- and mGluR5-signaling pathways in direct pathway neurons that leads to ERK activation in the dopamine-depleted striatum [15], and it has been suggested that this modulation of the D1R signaling cascade mediates dyskinesia [8]. In our study, we found that aphakia-mGluR5$^{KD\text{-}D1}$ mice display fewer dyskinesia than aphakia mice (Fig. 1), but still exhibit the full therapeutic efficacy of L-DOPA (Fig. 2). This is in line with previous findings showing that mGluR5 antagonists such as MPEP, MTEP, fenobam, and MRZ-8676 reduce dyskinesia in 6-OHDA-lesioned rats and MPTP-lesioned non-human primates [6, 58, 59].

Chronic L-DOPA treatment causes long-term modification of synaptic activity in dyskinesia. For instance, there is an increase in D1R-mediated response, leading to enhanced activation of ERK, histone 3, and FosB expression in the dopamine-denervated striatum [60–62]. The exact mechanisms underlying the reduction of dyskinesia in aphakia-mGluR5$^{KD\text{-}D1}$ mice are not completely understood. One possible mechanism is that decreased levels of mGluR5 lead to a reduction in D1R signaling. A recent study demonstrated a cross talk between mGluR5 and D1R in the dopamine-depleted striatum by showing that mGluR5 modulates SKF38393-induced ERK activation [15]. Previous studies suggest at least two ways in which knocking down mGluR5 could affect D1R-dependent signaling pathway via ERK [15]: first, by decreasing diacylglycerol, which leads to lower activation of protein kinase C, which in turn reduces ERK signaling and second, by reducing intracellular calcium release, which reduces calcium calmodulin kinase II and ERK activation (Fig. 6) [63]. Here, we report that the reduced development of dyskinesia in aphakia-mGluR5$^{KD\text{-}D1}$ mice is associated with a decrease in the molecular markers pERK, pAcH3, and FosB (Fig. 3). These results are in agreement with previous studies showing that mGluR5 antagonist reduced L-DOPA-induced ERK activation and FosB expression in the 6-OHDA rat model of dyskinesia [26, 64]. The reduced pERK, pAcH3 activation, and FosB expression induced by L-DOPA in aphakia-mGluR5$^{KD\text{-}D1}$ mice suggests cooperation

Nuclei are visualized via DAPI staining. Arrows indicate examples of dual D1R-positive and mGluR5-positive neurons. Scale bar = 100 μm. Two-way ANOVA followed by Bonferroni's post hoc test showed significant differences for genotype [$F_{1,46} = 43.9$, $p = 0.0001$] and treatment [$F_{3,46} = 13.2$, $p = 0.0001$]. $^{\#\#}p < 0.01$, $^{\#}p < 0.05$ vs. Ak saline, $^{***}p < 0.001$ vs. Ak L-DOPA. $n = 4$–8 per group

between D1R and mGluR5 in the D1R-dependent signaling pathway in dyskinesia. Our finding that PF470 does not further modify dyskinesia in aphakia-mGluR5^{KD-D1} mice (Fig. 4) rules out a role of mGluR5 in non-D1R-containing neurons in the development of dyskinesia.

Nicotinic receptors have recently emerged as a potential therapeutic target to treat dyskinesia. nAChR are ionotropic receptors widely expressed in the central nervous system. The striatum expresses two nAChR implicated in regulating the release of different neurotransmitters: the most abundant is the *β2 (α4β2*, α6β2*), which is implicated in dopamine release, while α7 is preferentially located in glutamatergic terminals [3, 37, 53]. The location of nicotinic receptor in striatal projection neurons remains controversial. For instance, electrophysiological recordings using the puff technique revealed that 32% of striatal projection neurons respond to nicotine. In this study, we tested whether nicotine could modulate dyskinesia via mGluR5 using the aphakia-mGluR5^{KD-D1} mice. We found that nicotine robustly reduced L-DOPA-induced dyskinesia in aphakia mice, but was unable to modify the already reduced dyskinetic signs in the aphakia-mGluR5^{KD-D1} mice. These results suggest that nicotine effects and mGluR5 blockade function via a similar mechanism.

◀ **Fig. 6** Schematic diagram illustrating the molecular changes induced by L-DOPA and nicotine in aphakia and aphakia-mGluR5^{KD-D1} mice. Chronic nicotine treatment desensitizes presynaptic nAchR, decreasing L-DOPA-induced pERK and pAcH3 expression in dyskinetic Ak mice. mGluR5 genetic downregulation on D1R-containing neurons also reduces L-DOPA-induced pERK, pAcH3, and FosB expression in dyskinetic Ak mGluR5^{KD-D1} mice. Half-tones represent genetic manipulation in Ak mGluR5^{KD-D1} mice

The reduction of dyskinetic behavior in aphakia mice was accompanied with attenuation of the associated molecular markers pERK and pAcH3, but surprisingly not of FosB expression. A possible explanation for the unaltered FosB expression is that chronic nicotine treatment induces striatal FosB accumulation following dopamine receptor activation [16]. It is possible that in our nicotine-treated animals, FosB expression occurs, in part, independently of the ERK/pAcH3 pathway. However, future studies are needed to explore these possibilities.

The molecular mechanisms underlying the ability of nicotine to reduce dyskinesia in aphakia mice are not completely understood. There is evidence of pharmacological modulation of mGluR5 in the striatum by nicotine [18, 41, 42]. For instance, mGluR5 expression is downregulated in the caudate nucleus and putamen of smokers, suggesting an interaction between nicotine receptor and mGluR5 [42, 65]. This could be one of the reasons why we observed that nicotine did not further decrease the dyskinetic response to L-DOPA in aphakia-mGluR5^{KD-D1} mice. In fact, we found that nicotine treatment prevented the L-DOPA-induced mgluR5 expression in the denervated striatum (Fig. 5). Another possible explanation could involve the modulation of the nitrergic system by nicotine. Nicotine increases nitric oxide synthase expression in the striatum, which is involved in the development of dyskinesia [66–68]. We, and others, have shown that increasing nitric oxide signaling by administering a nitric oxide donor or a phosphodiesterase inhibitor decreases dyskinesia [47, 69, 70]. However, more studies are needed to clarify whether nicotine alleviates dyskinesia by modulating the nitrergic system. In addition, our results also showed that the antidyskinetic effect of nicotine is accompanied by a better performance of motor tasks, thus increasing the therapeutic effect of L-DOPA independently of mGluR5 in D1R-containing neurons.

In summary, the current study demonstrates the role of mGluR5 in D1R-containing neurons on dyskinesia. We found that the specific reduction of mGluR5 in direct pathway neurons reduces L-DOPA-induced dyskinesia in aphakia mice and the associated molecular markers. In support to this, we found that the antidyskinetic effect of a mGluR5 negative allosteric modulator is mainly due to the blockade of those receptors expressed in D1R-containing neurons. On the other hand, our results also indicate that the antidyskinetic effect of nicotine might be mediated by a downregulation of mGluR5 expression, because the combination of nicotine and reduction (or blockade) of mGluR5 did not have an added antidyskinetic effect. Further studies are needed to determine if combining subthreshold doses of these drugs might have an additive antidyskinetic effect. Our data suggest that therapies based on targeting mGluR5 (specifically expressed in D1R-containing neurons) or nicotine would be an efficient clinical approach to treat dyskinesia.

Summary

***Pseudomonas aeruginosa* is a widely distributed environmental bacterium but is also an opportunistic pathogen that represents an important health hazard due to its high intrinsic antibiotic resistance and its production of virulence factors. The genetic structure of *P. aeruginosa* populations using whole genome sequences shows the existence of three clades, one of which (PA7 clade) has a higher genetic diversity. These three clades include clinical and environmental isolates that are very diverse in terms of geographical origins and isolation date. Here, we report the characterization of two distinct clonal *P. aeruginosa* groups that form a part of the PA14 clade (clade 2) sampled from the Churince system in Cuatro Ciénegas Basin (CCB). One of the clonal groups that we report here was isolated in 2011 (group 2A) and was displaced by the other clonal group (2B) in 2015. Both Churince groups are unable to produce pyoverdine but can produce other virulence-associated traits. The existence of these unique *P. aeruginosa* clonal groups in the Churince system is of ecological and evolutionary significance since the microbiota of this site is generally very distinct from other lineages, and this is the first time that a population of *P. aeruginosa* has been found in CCB.**

Introduction

Pseudomonas aeruginosa is an environmental bacterium that has been considered ubiquitous since it is present in a wide range of environments, but it is also an opportunistic pathogen that represents an important health hazard due to its high intrinsic antibiotic resistance, the high frequency of multi-resistant strains (Castañeda-Montes *et al.*, 2018) and its production of virulence-associated traits (Gellatly and Hancock, 2013).

P. aeruginosa genomics has revealed the existence of three main clades (Freschi *et al.*, 2015) that include clinical and environmental isolates (Grosso-Becerra *et al.*, 2014; Stewart *et al.*, 2014; Diaz *et al.*, 2018). The geographical origin and date of isolation of the strains belonging to these three clades vary widely (Pirnay *et al.*, 2009; Castañeda-Montes *et al.*, 2018). One of the clades (the PA7 clade) presents a much higher genetic variability (Roy *et al.*, 2010), and a member of this clade (strain ATCC 9027) has been reported to produce low levels of virulence factors and to be non-virulent in a mouse model (Grosso-Becerra *et al.*, 2016).

The production of the siderophore pyoverdine is characteristic of all fluorescent *Pseudomonas*, including clinical and environmental *P. aeruginosa* isolates (Lamont and Martin, 2003; Ravel and Cornelis, 2003; Schalk and Guillon, 2013). The chemical structure of these siderophores consists of a dihydroxyquinoline chromophore attached to a 6 to 12 variable peptide chain with a sequence that is species- and even strain-specific (Meyer, 2000).

P. aeruginosa produces three types of pyoverdines, and their ferric ion specificity is around 10^{32} M^{-1}. These siderophores are also able to bind other metals, but with

a much lower affinity (Braud *et al.*, 2009). FpvA is the specific outer-membrane receptor for pyoverdine-iron complexes and is indispensable for its uptake (Schalk *et al.*, 2001). It has been reported that the production of pyoverdine is important for the pathogenesis of *P. aeruginosa*, but clinical isolates that do not produce this siderophore can be isolated (Tasake *et al.*, 2000; Visca *et al.*, 2006; Kirienko *et al.*, 2013; López-Medina *et al.*, 2015; Granato *et al.*, 2016).

P. aeruginosa is able to produce other non-fluorescent siderophores, such as piochelin that plays an ecological important role in the competition of this bacterium in environments where soluble iron is very low (Schiessi *et al.*, 2017).

Another conserved characteristic among the three described *P. aeruginosa* clades is the regulation at the transcriptional level of the production of most of the virulence factors by a complex regulatory network called quorum-sensing response (QSR) that depends on the production of autoinducers (AIs) that interact with transcriptional regulators (Williams and Cámara, 2009; Grosso-Becerra *et al.*, 2016).

P. aeruginosa QSR modulates the expression of several virulence factors such as pyocianin (PYO), elastase and rhamnolipids (RL) through the activity of two transcriptional regulators (LasR and RhlR) that interact with their cognate AIs 3-oxo-dodecanoyl-homoserine lactone (3O-C12-HSL) with LasR and butanoyl-homoserine lactone (C4-HSL) with RhlR. *P. aeruginosa* clades 1 and 2 share the secretion of toxins through the type III secretion system (T3SS), which is also an important virulence associated trait (Dacheaux *et al.*, 1999; Berube *et al.*, 2017). Strain PA14 and other members of clade 2 secrete ExoU and ExoT effectors through the T3SS (Miyata *et al.*, 2003).

P. aeruginosa is a very well-studied species, but in order to explore the possibility of isolating new *P. aeruginosa* lineages and to understand the origin of its pathogenic potential, we have characterized isolates from diverse environments (Grosso-Becerra *et al.*, 2014). In this work, we explore the Cuatro Ciénegas Basin (CCB) located in the Chihuahuan Desert in the Mexican State of Coahuila, a place previously referred as a lost world due to the presence of ancient bacterial lineages (Souza *et al.*, 2018). We have observed that in CCB microbial diversity is extremely high (Souza *et al.*, 2018) and a large portion of it seems to include direct descendants of marine organisms (Souza *et al.*, 2006; Alcaraz *et al.*, 2008) including marine virus (Desnues *et al.*, 2008; Taboada *et al.*, 2018), which is atypical for lagoons and springs outside CCB. We think that this is given in part by the ion composition of its water that is rich in sulphur and magnesium salts and poor in phosphorous and iron. Moreover, the extreme unbalanced nutrimental stoichiometry where the ratio of nitrogen/phosphorous is very high (Elser *et al.*, 2005; Lee *et al.*, 2015, 2017) can explain most of the endemicity due to extreme selective pressure. It has been proposed that within CCB, oligotrophy not only forces the collaboration within the community to optimize its nutrient cycling (Tapia-Torres *et al.*, 2016; Gomez-Lunar *et al.*, 2018; Rodríguez-Torres *et al.*, 2017), but it acts as an effective sieve against migration (Souza *et al.*, 2012, 2018).

Within the diverse and particular CCB water bodies, the most distinct site is the hydrological system of Churince, a particularly vulnerable site due to the overexploitation of its aquifer by alfalfa agriculture (Souza *et al.*, 2007; De Anda *et al.*, 2018; Souza *et al.*, 2018). Churince was composed of three interconnected sections: large lagoon, intermediate lagoon and a spring. In 2004, the lagoon farthest from the spring, the desiccation lagoon (large lagoon), began to shrink and completely dried in 2006 (Alcaraz *et al.*, 2008). Later, the intermediate lagoon began to shrink in 2011 and completely dried in 2017 (Souza *et al.*, 2018), now only the main spring maintains some water.

Given its cultivable nature, several studies at CCB water bodies have been focused in the genus *Pseudomonas* and hundreds of novel isolates have been identified (Escalante *et al.*, 2009; Toribio *et al.*, 2011; Bonilla-Rosso *et al.*, 2012; Rodríguez-Verdugo *et al.*, 2012; Ponce-Soto *et al.*, 2015). Twice each year for more than ten years, samples have been obtained from defined points in the Churince system to study the stability of different bacterial communities, and in the case of Pseudomonads it has also been determined the effect in their composition of fluctuations in temperature along the year (Rodríguez-Verdugo *et al.*, 2012), and of nutrient availability, for example (Ponce-Soto *et al.*, 2015). It is interesting that despite extensive sampling effort, only one *P. aeruginosa* strain (M10) was isolated from the Churince spring in 2008, which was very similar to the PAO1 type strain (Grosso-Becerra *et al.*, 2014). It is possible that strain M10 is an introduced *P. aeruginosa* clone and not a member of a CCB bacterial population.

However, as the system declined due to the severe overexploitation of the aquifer, both by superficial channels and deep wells, the community conditions changed and we started to isolate more *P. aeruginosa* strains. Herein, we report the isolation and phenotypic characterization of 49 *P. aeruginosa* isolates from the Churince system, 44 of them in October 2011 when intermediate lagoon started to dry, and 5 in October 2015 on an even more dry condition. The analysis of the genome sequence of 10 isolates from the 2011 sample and the 5 isolates from 2015 showed that they represent two novel *P. aeruginosa* clonal groups of the PA14 lineage that are indigenous to CCB. All the isolates studied in this

work were able to produce virulence-associated traits with the exception of pyoverdine and are virulent when tested in the *Galleria mellonella* model. The ecological significance of the existence of these new *P. aeruginosa* clonal groups that were native to CCB is discussed.

Results and discussion

Phylogenetic analysis of P. aeruginosa *strains isolated from intermediate lagoon in 2011 and 2015 using whole genome sequencing*

The water level of intermediate lagoon started to lower in October 2011 (date of the first sampling presented in this article) after a particularly hot summer where the diminishing water supply by the deep aquifer met with a larger evaporation. Due to the protected status of CCB (Área de Protección de Flora y Fauna) and the endangered lagoon, in coordination with federal authorities and with the local users, we were able to close for a year the canal located in La Becerra (an important spring close to Churince) from early 2013 to the fall of 2014, restoring, temporarily, the water levels of intermediate lagoon (de Anda *et al.*, 2018), therefore allowing the microbiota to recover, while the water levels increased. However, in our second sampling shown in this work in October 2015, the lagoon was dryer than in 2011.

In order to understand the evolutionary effect of the lowering water level on the population of aquatic microbes, we compared genomes of the 2011 sample with the genomes of bacteria isolated in a new survey of different *Pseudomonas* species in October 2015. Among the recovered strains 44 *P. aeruginosa* isolates were obtained in 2011 and only 5 in 2015. In order to study the population genetics of the two collections, we obtained the whole genome sequence of 10 strains isolated in 2011 and the 5 strains isolated in 2015 (Supporting Information Table S1) and their phylogeny was determined (Fig. 1).

Unexpectedly, we observed that the sequenced strains from each sampled year formed a distinct clonal group closely related to the PA14 clade 2: one contains the 10 strains isolated in 2011 (defined as *P. aeruginosa* group 2A) and the other contains the 5 strains isolated in 2015 (*P. aeruginosa* group 2B).

The result obtained (Fig. 1) through the phylogenetic analysis of the whole genome sequence of the 15 *P. aeruginosa* strains of clonal groups 2A and 2B, compared to 24 *P. aeruginosa* whole-genome sequences (5 members of PAO1 clade 1 including M10 strain; 17 belonging to the PA14 clade 2; and 2 to the PA7 clade 3), show that the 10 strains isolated in 2011 and the 5 strains isolated in 2015 form two distinct clonal groups (2A and 2B, respectively) within the PA14 clade 2 (Fig. 1).

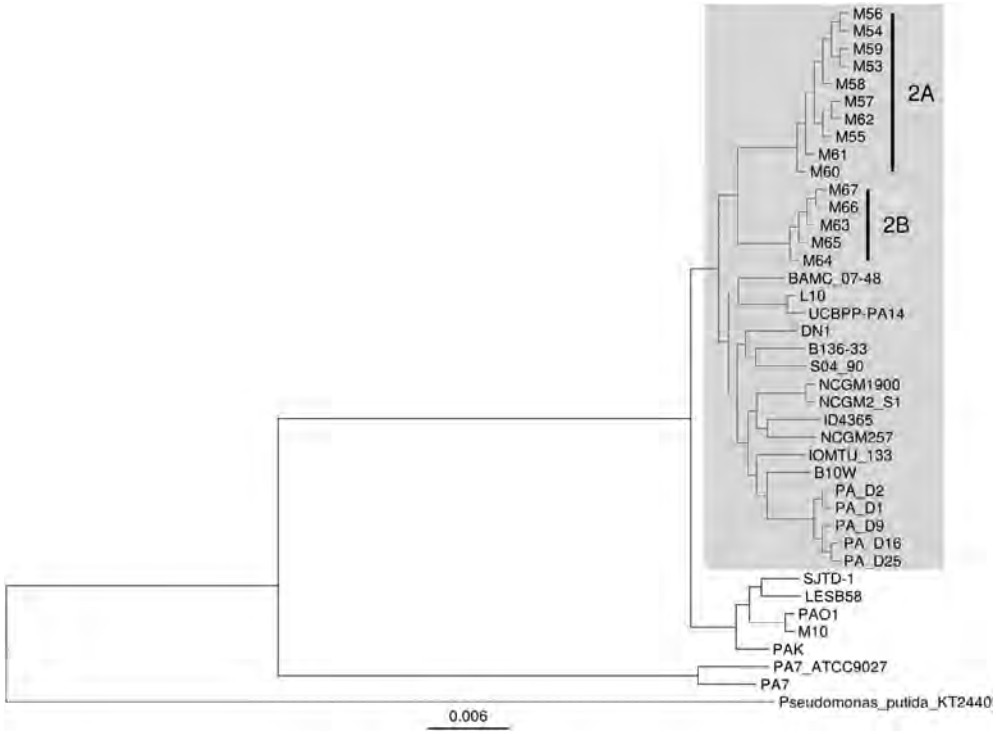

Fig. 1. Core genome phylogeny of the 15 sequenced *P. aeruginosa* strains isolated from the intermediate lagoon. The phylogeny was constructed with FastTree 2.0 (Price *et al.*, 2010) and annotated with the R package *ggtree* (Yu *et al.*, 2018). Clade 2 is highlighted in grey and clonal groups 2A and 2B are indicated with black bars. *Pseudomonas putida* KT2440 was used as outgroup.

The existence of two distinct clonal groups in Churince was further confirmed by the analysis of the phylogenetic tree constructed based on the MLST data of 2953 *P. aeruginosa* strains including the strains isolated in 2011 and 2015, and the M10 strain isolated previously, together with the data available on the PubMLST *Pseudomonas aeruginosa* database. This phylogenetic analysis of nearly 3000 strains confirmed the existence of the two indigenous CCB clonal groups (2A and 2B) in two distinct branches both presenting a 100% bootstrap support (Fig. 2). These results suggest that the wetland brief recovery in 2013 selected against the early *P. aeruginosa* clonal group 2A allowing the succession process of another, not previously seen group 2B in the drying lagoon.

The analysis of the genome assemblies of the 15 sequenced strains showed slight differences in genome size and GC content between the two clonal groups, but more interestingly, different number of CRISPR arrays, which can be used for differentiating *P. aeruginosa* strains (Van Belkum *et al.*, 2015); clonal group 2A has one CRISPR array, while group 2B has two (Supporting Information Table S1). In addition, we found that clonal group 2A has a genome size of 6.44–6.46 Mb with a GC content of 66.43%–66.46%, while group 2B has a slightly larger genome size (6.49–6.53 Mb) with a GC content of 66.31%–66.34% (Supporting Information Table S1). Thus, the two described clonal groups are indistinguishable using their size or GC content. However, the previously isolated M10 strain has more diverse genomic characteristics; it has a genome size of 6.20 Mb with a GC content of 66.56% and no CRISPR arrays (Supporting Information Table S1), features closer to those found on the PAO1 strain (Stover *et al.*, 2000; Grosso-Becerra *et al.*, 2014). Moreover, even though the novel strains that belong to each clonal group have a high genomic similarity and are closely related to PA14 clade 2 (Fig. 1), they are unique as can be concluded by the analysis of the structure of their *pvd* genes discussed below.

The finding of two Churince native clonal groups of *P. aeruginosa* was unexpected, since this is the first time

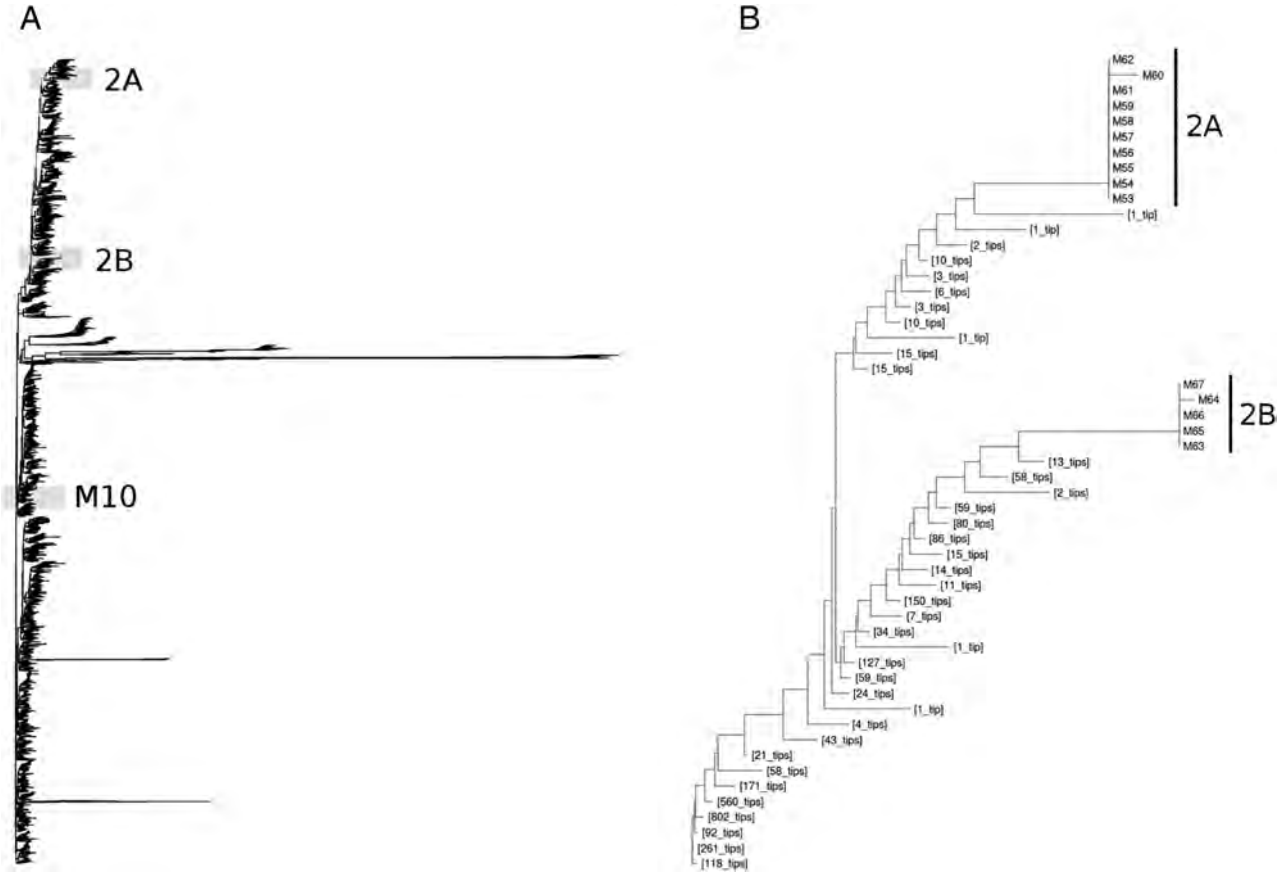

Fig. 2. MLST neighbour-joining phylogenetic reconstruction. 2953 *P. aeruginosa* concatenated MLST sequences from the PubMLST *Pseudomonas aeruginosa* Database alongside the 10 and 5 MLST from members of clonal groups 2A and 2B, respectively, and strain M10, whose positions are highlighted in grey, were used for the phylogenetic reconstruction shown in Fig. 2A. A total of 1000 bootstrap replicates were performed using MEGA7 (Kumar *et al.*, 2016); branches corresponding to clonal groups 2A and 2B are 100% supported. A summarized subtree of clonal groups 2A and 2B is shown in Fig. 2B and indicated with black bars was extracted from the complete phylogeny using the R package *ggtree* (Yu *et al.*, 2017).

that lineages that are particular to a determined environment and time of isolation have been described in this well-studied species. All the previously reported collections contain clinical and environmental representatives and are in no way related to any specific environmental parameter (Freschi *et al.*, 2015; Mosquera-Rendón *et al.*, 2016; Castañeda-Montes *et al.*, 2018).

In agreement with the ubiquitous character of the three previously reported *P. aeruginosa* clades and the typical cosmopolitan way of life of this bacterial species, we isolated in 2008 from Churince spring, the M10 strain belonging to clade 1, which is very similar to the PAO1 strain (Grosso-Becerra *et al.*, 2014).

Nevertheless, the indigenous character of *P. aeruginosa* clonal groups 2A and 2B reported here was not surprising, since most of the microbiota studied in the Churince system seems to be unique (Souza *et al.*, 2018). We hypothesize that *P. aeruginosa* clonal groups 2A and 2B represent populations that belong to Churince communities, but that their population size was very small to be detected in previous samplings and that they were able to thrive in perturbed conditions. Our results suggest that the conditions found in the desiccating intermediate lagoon were favourable for *P. aeruginosa* clades 2A and 2B, and that the constant follow-up of Churince microbiota sampling, allowed us to pick up these rare inhabitants that could not be found before and not even in the 2016–2017 samplings.

Antibiotic resistance of P. aeruginosa *strains belonging to the 2A and 2B clonal groups*

It has been reported previously that the production and resistance to antibiotics are ecologically significant traits in the Churince system not only in sediment-associated *Bacillus* (Pérez-Gutiérrez *et al.*, 2012) but also in the water column Pseudomonads inhabitants (Aguirre-von-Wobeser *et al.*, 2014; Ponce-Soto *et al.*, 2015). Therefore, we determined the antibiotic resistant profile of the 15 strains studied in this work against carbenicillin (500 μg/ml), tetracycline (150 μg/ml), kanamycin (200 μg/ml), streptomycin (200 μg/ml), chloramphenicol (200 μg/ml), gentamycin (150 μg/ml), and apramycin (100 μg/ml). In agreement with previous results for *Pseudomonas* isolated from the intermediate lagoon (Ponce-Soto *et al.*, 2015), we found that the 15 analysed strains are resistant to carbenicillin and kanamycin and sensitive to the rest of the antibiotics tested. This, along with their unique phylogenetic position reinforces the idea of these two clonal groups being native to the Churince system. Meanwhile, strain M10, a typical environmental *P. aeruginosa*, is sensitive to all antibiotics tested, which is consistent with it being an introduced bacterium to the Churince system.

In addition, we determined the antibiotic resistance profile of these 15 strains to the antibiotics that are commonly used against *P. aeruginosa* infections and found that all of them are sensitive with only one exception (strain M58 has an intermediate resistance to aztreonam; supplementary information Table S2).

Virulence-factors production of P. aeruginosa *strains belonging to the 2A and 2B groups*

We carried out the phenotypic characterization of the *P. aeruginosa* strains belonging to clonal groups 2A and 2B with respect to the production of virulence factors

Table 1. Phenotypic characterization of *P. aeruginosa* CCB isolates analysed in this work compared to PAO1-type strain.

Strain	PYO (μg/ml)	RL (μg of rhamnose)	Elastase (Units)	3O-C12-HSL (Miller Units)	C4-HSL[a]	Virulence in *G. mellonella* model[a]
PAO1	3.46 ± 0.9	108.3 ± 5.24	1.41 ± 0.02	6658.7 ± 300	+	+

+ means that it was detected. A + sign in the virulence in the *G. mellonella* model means that the five tested larvae were dead at 24 h of injection of 10^5 CFU.

a. The production of C4-HSL was determined using the qualitative bioassay based on the production of violacein by *Chromobacterium violaceum* strain CV026.

regulated by the QSR and the production of the AIs C4-HSL and 3O-C12-HSL that participate in this complex regulatory network (Table 1).

We found that the production of the QSR-regulated virulence-factors (PYO, RL, and elastase) and the production of the AIs C4-HSL and 3O-C12-HSL of strains belonging to the *P. aeruginosa* 2A and 2B clonal groups (Table 1) are very similar to the QSR presented by strains belonging to clades 1 (including PAO1 strain), 2 (including PA14 strain) and 3 (including ATCC 9027 strain, analysed by Grosso-B*ecerra et al.*, 2016). The only strain with an atypical QSR is strain M66 of clonal group 2B, which has a high PYO production and a low production of the AI 3O-C12-HSL (Table 2). Strains with atypical QSR have been previously reported (Grosso-Becerra *et al.*, 2014; Morales *et al.*, 2017).

Furthermore, *P. aeruginosa* strains that belong to 2A and 2B clonal groups produce the two types of RL: mono-RL that contains one rhamnose moiety and di-RL, which contains two molecules of rhamnose (Supporting Information Fig. S1). Strains belonging to clade 3, as PA7 (Roy *et al.*, 2010) and ATCC 9027 (Grosso-Becerra *et al.*, 2016) only produce mono-RL.

We also found that all the strains belonging to clonal groups 2A and 2B secrete ExoU and ExoT effectors by the T3SS (Supporting Information Fig. S2), as has been reported for PA14 and other strains of clade 2. In addition we found that the two clonal groups studied here are pathogenic when tested in the *Galleria mellonellamodel* (Table 1), even though they are unable to produce pyoverdine as discuss below. These results suggest that these two lineages diverged from a clade 2 *P. aeruginosa* common ancestor that was able to establish pathogenic interactions.

Analysis of pyoverdine genes of P. aeruginosa *strains belonging to clonal groups 2A and 2B*

Many strains belonging to species of the fluorescent *Pseudomonas* isolated from the Churince system are unable to produce fluorescent siderophores even belonging to fluorescent *Pseudomonas* species (Escalante *et al.*, 2009; Toribio *et al.*, 2011; Bonilla-Rosso *et al.*, 2012; Rodríguez-Verdugo *et al.*, 2012; Ponce-Soto *et al.*, 2015), and the same is true for *P. aeruginosa* strains isolated in 2011 (44 strains) and 2015 (5 strains) analysed in this work.

In order to determine whether the lack of pyoverdine production reflected a specific arrangement of the *pvd* genes in the 15 *P. aeruginosa* isolates that were sequenced in this work, we analysed these loci and compared them with the *pvd* genes of the PAO1-type strain (Fig. 3).

Our results show that all the sequenced strains that belong to the 2A group contain a deletion spanning from the PA2403 ORF to the *pvdE* gene (including the gene encoding for the pyoverdine receptor FpvA), while the five strains belonging to clade 2B have deletions including the *pvdD* gene, but retaining *fpvA* (Fig. 3). In addition, strains M63 and M65 lack the *pvdI* gene and strain M65 also lacks *pvdJ* (Fig. 3). Thus among the five strains belonging to clonal group 2B, we found three different patterns of deletions affecting the *pvd* gene cluster (Fig. 3). The detected variability of the *pvd* gene cluster among the sequenced strains belonging to clonal groups 2A and 2B suggest that the lack of pyoverdine production is positively selected among *P. aeruginosa* isolates native to intermediate lagoon.

Furthermore, we analysed the *pvd* genes in strain M10 and as expected since it is a fluorescent isolate, we found that it has a very similar pattern of *pvd* genes to strain PAO1 (Fig. 3). These results reinforce the idea that strain M10 is an introduced bacterium to CCB and does not form part of a native *P. aeruginosa* population of the Churince system.

Structure of the pvd *locus among the strains isolated in October 2011 that were not sequenced*

To determine whether the remaining 34 strains isolated in 2011 that were not sequenced have the same structure of the ten 2A clonal group sequenced strains, we designed a series of oligonucleotides to amplify some of the deletions present in the 15 sequenced isolates, using as a positive control the region from *pvdE* to *fpvA* (which is present in the PAO1, M10 and the 5 strains belonging to the clonal group 2B) and oligonucleotides that specifically amplify the 16S rDNA (see Supporting Information Table S3 and Fig. S3).

Table 2. Characterization by PCR of the deletions present in 21 *P. aeruginosa* strains belonging to 2A clonal group that were not sequenced.

PCR product	Strains that present the PCR product	Type of deletion*
pvdE to PA2403	7 strains (they do not present the *pvdE* to *fpvA* PCR product)	Type 1, as in the 10 sequenced strains belonging to 2A clonal group (Fig. 3)
fpvA to *pvdJ*	2 strains (also have the *pvdE* to *fpvA* PCR product)	Type 2, as in strains: M63, M64, M66, M67, belonging to 2B clonal group (Fig. 3)
fpvA to PA2403	12 strains that also have the *pvdE* to *fpvA* PCR product.	Type 3, as strain M65 belonging to 2B clonal group (Fig. 3)

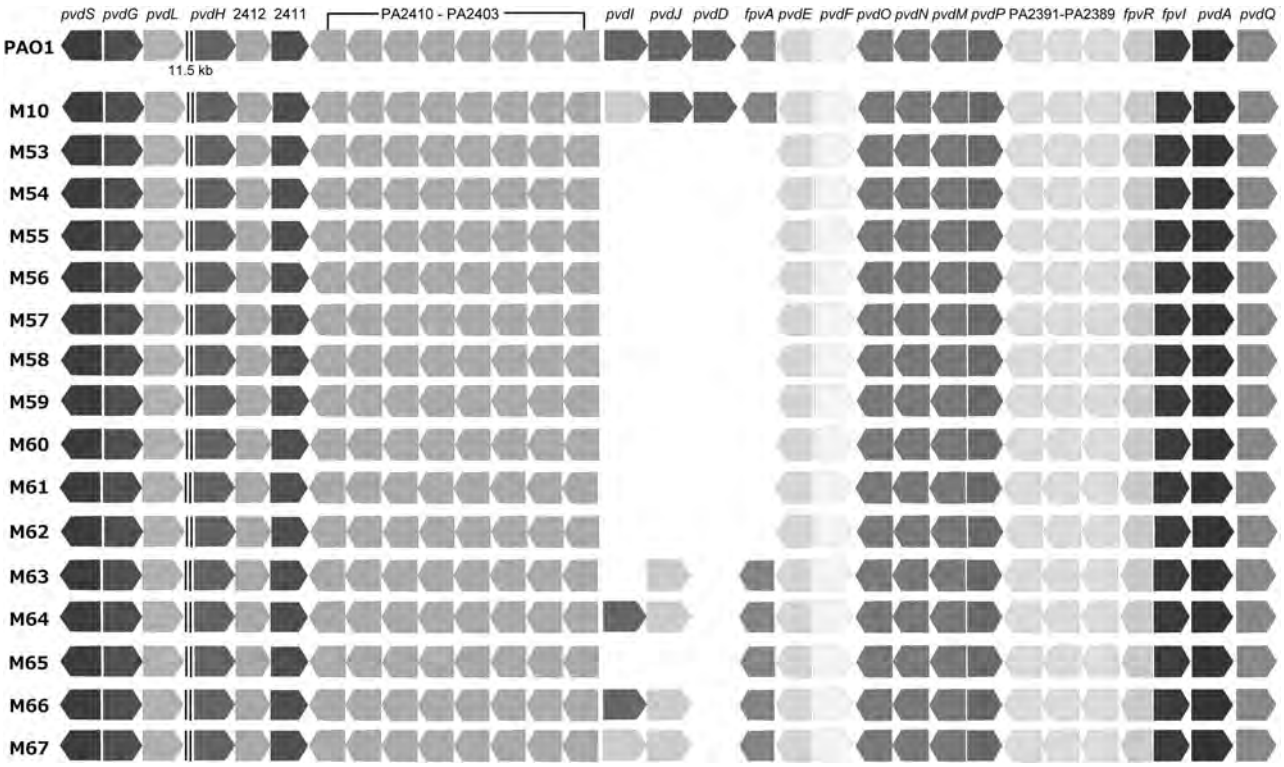

Fig. 3. Schematic representation of the *pvd* gene cluster. This chromosomal region is shown in the *P. aeruginosa* strains isolated from the Churince system compared with *P. aeruginosa* PAO1. Identification of the syntenic genes was done with progressive Mauve (Darling *et al.*, 2010).

Our results show that 13 of the 34 tested strains did not amplify the *pvdE* to *fpvA* region, nor the three types of *pvd* deletions that we screened by PCR (Table 2), even though we were able to amplify the gene encoding 16S rRNA in all of them. These results show that these 13 strains contain an uncharacterized deletion that is not equal to those found in the 10 sequenced strains belonging to 2A group, or to the deletions found in the 5 sequenced strains from clonal group 2B (Fig. 3).

Among the remaining 21 strains, only 7 have the type 1 deletion presented by the 10 sequenced strains belonging to clonal group 2A (Fig. 3 and Table 2). This was determined by the amplification of a PCR product using oligonucleotides from *pvdE* to PA2403 (Table 2; Supporting Information Fig. S3 and Table S3).

Interestingly, we detected among the bacteria that were collected in 2011, 2 strains that have the same deletion as strains M63, M64, M66 and M67 of the clonal group 2B, spanning from *fpvA* to *pvdJ* (type 2 deletion, Table 2), and 12 strains with a similar deletion as strain M65 (type 3 deletion, Table 2) that also belongs to the 2B group (Table 2).

The existence of 27 strains among the 44 strains collected in October 2011 that have a different structure of the deleted *pvd* locus as the 10 sequenced strains belonging to clonal group 2A (Fig. 3) shows that the 44 strains isolated in 2011 that presumably belong to clonal group 2A, are not the same individual that has been sampled twice and led us to the conclusion that the lack of pyoverdine production is positively selected among *P. aeruginosa* isolates indigenous to the intermediate lagoon.

It is possible that *P. aeruginosa* strains that were isolated in October 2011 that present a similar deletion to clonal group 2B strains, in fact belong to this phylogenetic group and not to the 2A group. So it is possible that clonal groups 2A and 2B coexisted in the Churince intermediate lagoon in 2011, but this possibility does not modify the conclusions attained in this work.

The results presented here strongly suggest that the lack of pyoverdine synthesis of *P. aeruginosa* strains endemic to CCB is of ecological significance. It is intriguing though, that pyoverdine deficient strains were selected in the Churince system, an environment with an extremely low iron concentration. A possible explanation for this apparent paradox is that FpvA might be used as the receptor of a common bacterial toxin in Churince, as has been shown in the case of pyocine S2 produced by *P. aeruginosa* (Denayer *et al.*, 2007). If this were the case, the *fpvA* gene present in some of the strains studied in this work (Fig. 3) would not be expressed. It has

been reported that antagonic interactions through diffusible molecules are common among Churince proteobacteria (Aguirre-von-Wobeser *et al.*, 2014).

In this scenario, the production of other siderophores as pyochelin will circumvent the problem of iron starvation, so we hypothesize that Churince *P. aeruginosa* strains belonging to the 2A and 2B clonal groups, that are deficient in pyoverdine production, can produce pyochelin, and possibly other siderophores. In support of this hypothesis, we found that the 15 sequenced *P. aeruginosa* strains have apparently functional *pchA, pchB, pchD, pchR* genes and in addition they present the *pfeA* gene encoding for the ferric enterobactin receptor that might enable them to capture iron coupled with this siderophore produced by other bacterial species.

Moreover, *P. aeruginosa* strains belonging to clonal groups 2A and 2B are pathogenic in the *Galleria mellonella* model (Table 1). These results suggest that pyoverdine deficiency is an ancient phenotype that has been counterbalanced by the production of other virulence-associated traits (Table 1, Supporting Information Fig. S2), since the production of pyoverdine has been reported to be indispensable for the establishment of pathogenic interactions when mutants lacking this siderophore were selected from pyoverdine proficient strains (Kirienko *et al.*, 2019). This rational has been used to select compounds that inhibit the production of this siderophore that block *P. aeruginosa* virulence (Kirienko *et al.*, 2019), but these molecules will not be effective for the treatment of infections caused by naturally occurring pyoverdine deficient strains such as those studied in this work.

Concluding remarks

In this study, we described the characterization of two novel *P. aeruginosa* clonal groups (2A and 2B) that are endemic to the Churince system in the CCB. This is the first time that *P. aeruginosa* isolates have been found to be limited to a particular environment and we think that this situation reflects that these clonal groups were part of this ecosystem, but they need perturbed conditions (low water levels) in order to outcompete the previously diverse bacterial community of Churince.

We have shown here that the two *P. aeruginosa* clonal groups isolated in CCB are virulent and thus capable of infecting the debilitating endemic fishes and turtles, so it is possible that the negative effect to these animals caused by the drought that started in 2011 gave them a proper niche to increase their population size.

Unfortunately the intermediate lagoon is been considered dead, since plants are growing on top of the stromatolites for the first time in the history of this site (Minckley *et al.*, 2019) since the Churince system had no previous record of plant occupation due to the long-term stability and presence of water in the site. Therefore, the 49 *P. aeruginosa* CCB isolates that we report in this work might be the only living representatives of the clonal groups described in this work. A similar fate has had all the bacterial isolates that have been collected over the years in what was a relict of the ancient ocean.

Experimental procedures

Sampling and isolation of P. aeruginosa *strains*

Samples were taken from surface water from all across intermediate lagoon (26°50′53.79″N, 102°08′30.29″W) using sterile BD Falcon vials (BD Biosciences, San Jose, CA). Bacterial colonies were obtained by plating 200 μl of each water sample on PIA medium agar plates, which were further incubated at 32 °C for 1 day. Individual colonies were transferred to new PIA plates and grown at 32 °C for 1 day. Each colony was stored in 30% glycerol solution at −80 °C.

Microbiological methods

The strains and plasmids used in this work are shown in Supporting Information Table S1. The strains were routinely cultured in LB broth (Miller, 1972), or in phosphate-limited peptone-protease, glucose, ammonium salts (PPGAS) medium (Zhang and Miller, 1992) using glucose as a main carbon source. For the analysis of phenotypic traits, the cultures were inoculated to start at the same optical density (0.05 at 600 nm) and were incubated 16 h in continuous shaking (225 rpm) at 37 °C.

Determination of the antibiotic resistance of P. aeruginosa *strains*

In order to compare the resistance profile of the 15 strains studied in this work to the antimicrobials that have been reported to be prevalent among *Pseudomonas* isolated from intermediate lagoon (Ponce-Soto *et al.*, 2015), we determine the antibiotic resistant profile of these isolates against carbenicillin (500 μg/ml), tetracycline (150 μg/ml), kanamycin (200 μg/ml), streptomycin (200 μg/ml), chloramphenicol (200 μg/ml), gentamicin (150 μg/ml) and apramycin (100 μg/ml).

The antibiotic resistance profile to antimicrobials commonly used to treat *P. aeruginosa* infections was done by micro dilution titre in 96-well plaques, according to the CLSI M100-ED28: 2018 Performance Standards for Antimicrobial Susceptibility Testing, 28th Edition. The antibiotics used were amikacin (AK), gentamicin (GN), aztreonam (AZT), ceftazidime (CAZ), cefepime (FEP), ciprofloxacin (CIP), levofloxacin (LVC), doripenem

(DORY), imipenem (IMP), meropenem (MRP), colistin (CL), piperacillin/tazobactam (TZP).

Determination of virulence-factors and autoinducers (AIs) production

PYO concentration was extracted and measured as reported previously (Essar *et al.*, 1990). Elastase activity was determined using Elastin Congo Red protocol (Beatson *et al.*, 2002) with some changes. Briefly, 50 μl of supernatant were added to 5 mg of Elastin Congo Red (Sigma) and 950 μl of a buffer solution containing 20 mM Tris–HCl (pH 7.5) and 1 mM $CaCl_2$. The reaction was incubated in continuous shaking at 37 °C for 30 min. After centrifugation, the absorbance at 495 nm of the supernatant was measured with a spectrophotometer zeroed with a control reaction using LB medium alone. RL were measured as reported (Chandrasekaran and Bemiller, 1980) and were visualized by thin layer chromatography (Matsuyama *et al.*, 1987).

The extracts to determine AIs production were prepared as previously reported (Grosso-Becerra *et al.*, 2014). To perform these determinations cells were grown in PPGAS medium at 37 °C for 24 h. Detection of C12-HSL was assessed by measuring β-galactosidase (β-gal) activity (Miller, 1972) in *E. coli* strain DH5α harbouring a plasmid expressing a *lasB´-lacZ* transcriptional fusion under the control of its transcriptional regulator LasR (plasmid pECP64, Pearson *et al.*, 1997).

Determination of virulence using the Galleria mellonella *assay*

Virulence in *Galleria mellonella* was evaluated according to the protocol described previously (Koch *et al.*, 2014). In brief five larvae with a size of 2.5 to 3 cm were injected with 10 μl of a 10 mM magnesium sulphate solution containing the inoculum of each strain at a concentration of 1×10^5 CFU/ml. As a positive virulence control, we used either PA14 or PAO1 strains (Table 1), and as a negative control, we used the non-virulent ATCC 9027 strain (Grosso-Becerra *et al.*, 2016), and 10 μl of sterile 10 mM magnesium sulphate was used as injection control. The larvae were incubated at 37 °C for 24, 48 or 72 h, and the dead and living organisms were quantified.

DNA extraction, whole genome sequencing and genome assembly

Strains were inoculated into 3 ml LB medium at 32 °C with 200 rpm shaking. Genomic DNA was extracted and purified from 1.5 ml of culture broth using the DNeasy Blood and Tissue Kit (Qiagen). Quality and quantity of purified genomic DNA was tested by using NanoDrop 2000 UV–Vis spectrophotometer (Thermo Scientific, MA). Whole genome sequencing for all 15 isolates was carried out by using the MiSeq 2x300 paired-end platform (Illumina, Inc.). *De novo* genome assembly was performed using MaSuRCa v3.2.2 assembler (Zimin *et al.*, 2013) followed by the *–trusted_contigs* option from SPAdes v.3.10.1 assembler (Bankevich *et al.*, 2012), which showed to improve the final result. Contigs with a length smaller than 600 bp and less than 10x coverage were removed. The quality of the assemblies was assessed with QUAST v4.5 (Gurevich *et al.*, 2013) and BUSCO v3.0.2 (Simão *et al.*, 2015; Waterhouse *et al.*, 2017). CRISPR arrays were detected with MinCED (Bland *et al.*, 2007) (Table 1).

Phylogenetic analysis

Genomic assemblies were aligned using progressiveMauve (Darling *et al.*, 2010), and core genomes were extracted with the stripSubsetsLCBs script. Core genome phylogenies were carried out by using FastTree 2.0 (Price *et al.*, 2010). MLST sequences were extracted from the genome assemblies with *blastdbcmd* command from BLAST+ software (Camacho *et al.*, 2008), concatenated manually and aligned alongside other 2953 MLST sequences from the PubMLST *Pseudomonas aeruginosa* Database with CLUSTAL W (Thompson *et al.*, 1994). The Neighbour Joining MLST phylogeny and 1000 bootstrap replicates were carried out by MEGA7 (Kumar *et al.*, 2016). Both core genome and MLST phylogenies were visualized with FigTree v.1.4.3.

PCR determination of deletions affecting the pvd *genes*

The oligonucleotides used to amplify the *pvd* genes deletion present in the 34 *P. aeruginosa* strains isolated in 2011 from intermediate lagoon (Supporting Information Table S2) were designed based on the alignment of flanking regions sequence present in the genomes of PAO1, M10 and the sequenced CCB isolates studied in this work. The conditions for the PCR assay were determined using one of the sequenced strains that contain each type of deletion.

Sequence accession numbers

The whole-genome sequences of members of 2A and 2B clonal groups and strain M10 were deposited at GenBank under the accession numbers NZ_SDVO00000000 (M10), NZ_SDVN00000000 (M53), NZ_SDVM00000000 (M54), NZ_SDVL00000000 (M55), NZ_SDVT00000000 (M56), NZ_SDVS00000000 (M57), NZ_SDVR00000000 (M58), NZ_SDVQ00000000 (M59), NZ_SDVK00000000

(M60), NZ_SDVJ00000000 (M61), NZ_SDVI00000000 (M62), NZ_SDVH00000000 (M63), NZ_SDVG00000000 (M64), NZ_SDVF00000000 (M65), NZ_SDVP00000000 (M66) and NZ_SDVE00000000 (M67). GenBank accession numbers of the reference strains used in the phylogenetic reconstruction are NC_002947 (*P. putida* KT2440), NC_020912 (*P. aeruginosa* B136-33), NZ_KE137323 (*P. aeruginosa* PAK), NC_011770 (*P. aeruginosa* LESB58), NC_017549 (*P. aeruginosa* NCGM2.S1), NC_009656 (*P. aeruginosa* PA7), NZ_LLKP01000001.1 (*P. aeruginosa* ATCC 9027), NZ_CP015377 (*P. aeruginosa* BAMC_07–48), NZ_CP017099 (*P aeruginosa* DN1), GCA_000647615 (*P. aeruginosa* ID4365), NZ_AP017302 (*P. aeruginosa* IOMTU_133), NZ_CP017969 (*P. aeruginosa* B10W), NZ_CP019338 (*P. aeruginosa* L10), NZ_AP014622 (*P. aeruginosa* NCGM1900), NZ_AP014651 (*P. aeruginosa* NCGM257), NZ_CP012585 (*P. aeruginosa* PA_D1), NZ_CP012581 (*P. aeruginosa* PA_D16), NZ_CP012578 (*P. aeruginosa* PA_D2), NZ_CP012584 (*P. aeruginosa* PA_D25), NZ_CP012580 (*P. aeruginosa* PA_D9), NZ_CP011369 (*P. aeruginosa* S04_90), NZ_CP015877 (*P. aeruginosa* SJTD-1), NC_008463 (*P. aeruginosa* UCBPP-PA14) and NC_002516 (*P. aeruginosa* PAO1).

Acknowledgements

This work represents part of the PhD thesis of Manuel García-Ulloa II in the Programa de Doctorado en Ciencias Biomédicas (PDCB), Universidad Nacional Autónoma de México (UNAM) and received fellowship from Consejo Nacional de Ciencia y Tecnología (CONACYT). We acknowledge Dra. Norma Espinosa Sánchez for technical assistance. This work was supported in part by grant PAPIIT IN201819 (DGAPA-UNAM) and from the 252269 CONACYT-grant. We are grateful to Dr. Rafael Franco Cendejas and M. C Melissa Hernández Durán of the Instituto Nacional de Rehabilitación Luis Guillermo Ibarra Ibarra for the determination of the antibiotic resistance of the Churince *P. aeruginosa* isolates as shown in Supporting Information Table S1.

Conflict of Interest

The authors declare that they do not have a conflict of interest.

Autophagy as a Homeostatic Mechanism in Response to Stress Conditions in the Central Nervous System

Cristian Gerónimo-Olvera [1,2] · Lourdes Massieu [1]

Abstract

Autophagy is considered a major bulk degradation system that helps cells to counteract different intracellular and extracellular stress signals. Several protein complexes integrate multiple signals in order to activate autophagy, which sequesters damaged cellular components and carries them to lysosomes for degradation. This active mechanism is essential to maintain cell homeostasis and particularly in neurons to sustain their viability. Because of their polarized morphology, neurons face special challenges to recycle cellular components through autophagy in dendrites and distal regions of axons. Thus, autophagy is critical in the remodeling of pre- and post-synaptic constituents to sustain neuronal functionality. Under stress conditions, autophagy may play either a cytotoxic or a cytoprotective role. This discrepancy is partly due to the lack of a full characterization of the autophagic process and conclusive evidence to support whether basal autophagy is stimulated or impaired in a particular condition. Moreover, in many studies, only pharmacologic tools have been used to modulate autophagy. Throughout the present review, we go over the literature revealing autophagy induction in the nervous system under diverse stressful conditions, the signaling pathways involved, and its consequences for neuronal homeostasis and survival. We have focused on five particular stress conditions that alter neuronal homeostasis and can induce neuronal death including, starvation, oxidative stress, endoplasmic reticulum (ER) stress, proteotoxic stress, and aging.

Keywords Autophagy · Neurons · Starvation · Oxidative stress · Endoplasmic reticulum stress · Aging

Introduction

Autophagy is an evolutionary conserved mechanism in eukaryotes, considered as the major bulk degradation system where damaged cytoplasmic components are delivered to the lysosome for degradation. Autophagy is also responsible for the turnover and recycling of cytoplasmic materials to produce building blocks and energy to maintain cellular homeostasis [1–3]. Several extracellular and intracellular stimuli promote autophagy representing an essential mechanism by which cells can adapt to stress conditions, particularly to starvation. However, basal levels of autophagy are present in all cells in order to maintain cellular homeostasis and energy balance [4].

Depending on how cytoplasmic material is delivered to the lysosome, autophagy is divided in three classes: macroautophagy, microautophagy, and chaperone-mediated autophagy. In macroautophagy, an isolation membrane (phagophore) sequesters portions of the cytoplasm, including proteins and organelles, to form a double- or multi-membrane structure named autophagosome. The autophagosome fuses with the lysosome to become an autolysosome and degrades its content. Microautophagy involves the engulfment of small portions of the cytoplasm directly by the lysosome membrane to be subsequently degraded [5]. Finally, chaperone-mediated autophagy is a specific type of autophagy, where substrate proteins are targeted one by one toward the lysosome and then translocated across the lysosomal membrane [6]. Macroautophagy has been mostly investigated and is considered as the major subtype of autophagy; thereby, we will refer to macroautophagy as autophagy.

The Autophagy Machinery

The process of autophagy involves the participation of autophagy-related (ATG) proteins, which are recruited to the

phagophore to form the autophagosome. The canonical formation of the autophagosome involves different steps including induction, autophagosome formation, fusion of the autophagosome with the lysosome, and cargo degradation, followed by the release of breakdown products into the cytosol. ATG proteins contribute to these steps and many of them are essential for a proper autophagy function.

A central inhibitor of autophagy is mTOR, a Ser/Thr protein kinase originally recognized as a target of rapamycin, which is involved in numerous cell processes such as protein synthesis, growth, sensing of environmental nutritional changes, and autophagy. mTOR integrates multiple upstream signals which control autophagic activity. Under nutrient-rich conditions, mTOR activation negatively regulates autophagy through inhibition of the ULK1 complex, composed by ULK1, ATG13, FIP200, and ATG101 [7, 8]. In contrast, upon starvation or rapamycin treatment, mTOR inactivation leads to a stable form of the ULK1 complex located at the phagophore to induce autophagy.

In cells undergoing autophagy, autophagosome formation initiates at phagophore assembly sites (PAS), where double-layered membrane elongates to form a phagophore and then an autophagosome [8]. Different organelles are considered as phagophore membrane sources such as endoplasmic reticulum (ER), mitochondria, and the Golgi complex, where multiple PAS can arise [9]. Phagophore formation initiates after ULK1 activation, which in turn targets class III PtdIns3K complex, containing VPS34, BECN1, ATG14, and VPS15, to produce PtdIns3P [7]. After the initiation of the phagophore formation, the elongation of the phagophore membrane that will ultimately become an autophagosome is regulated by two ubiquitin-like reactions. In the first reaction, ATG12 is activated by ATG7 (E1 ubiquitin-activating enzyme) and transferred to ATG10 (E2 ubiquitin-activating enzyme); after these two subsequent reactions, ATG12 is covalently bound to ATG5 to form the ATG12-ATG5 conjugate. This complex interacts with ATG16L1 resulting in a ternary complex ATG12-ATG5-ATG16L1 [8, 10], which localizes to the phagophore membrane and is essential for its elongation. This complex dissociates when the autophagosome is fully formed. The second ubiquitin-like reaction involves the conjugation of ATG8 family, which includes the microtubule-associated protein light chain 3 (MAP-LC3/ATG8/LC3), γ-amino-butyric acid receptor-associated protein (GABARAP), and Golgi-associated ATPase enhancer of 16 kDa (GATE-16), to phosphatidylethanolamine (PE). LC3, the best-characterized ATG8 member, is cleaved by ATG4B to produce the cytosolic form LC3-I [11]. LC3-I is conjugated to PE at the autophagosome membrane through two ubiquitin-like reactions involving ATG7 (E1 like) and ATG3 (E2 like), to form autophagosome-associated LC3-II. The ATG12-ATG5-ATG16L complex regulates the conjugation of LC3-I to PE acting as an E3-like enzyme, although it is not essential for conjugation to occur [8]. LC3-II is associated to both sides of the autophagosome and regulates its size due to its ability to determine membrane curvature.

Autophagosomes are mobilized toward lysosomes along microtubules through dynein-dependent transport; then, the outer membrane of the autophagosome fuses with the lysosome to form an autolysosome, a process that requires the lysosomal membrane protein LAMP-2 and the small GTPase Rab7 [12]. Soon after the fusion, LC3-II attached to the outer membrane is delipidated by ATG4B to recycle LC3-I [13]. Proper function and integrity of the lysosome are essential for successful fusion to occur. Degradation of the inner membrane and autophagosome content including LC3-II is dependent on lysosomal hydrolases such as cathepsin B, D, and L. Degraded autolysosome content is released into the cytosol for protein synthesis and maintenance of cellular homeostasis.

On the other hand, non-canonical pathways of autophagy have been discovered, whereby autophagosome formation occurs in the absence of some key autophagy proteins such as ATG7, ATG5, LC3, and BECN1. These non-canonical pathways have been identified under certain cellular circumstances and their role in cellular homeostasis is not completely clear [14]. For instance, BECN1-independent autophagy contributes to apoptosis in cortical neurons exposed to the pro-apoptotic agent staurosporine [15]. On the other hand, mouse embryonic fibroblast lacking ATG5 or ATG7 can undergo autophagy when exposed to certain stressors such as etoposide, staurosporine, and even nutrient deprivation. Interestingly, under these conditions, lipidation of LC3 does not occur, suggesting that ubiquitin-like proteins are not required for alternative autophagy. However, some conventional autophagy-related proteins including ULK1, BECN1, and VPS34 are required for alternative autophagy. These findings suggest that under certain stress conditions, an alternative autophagy can occur in order to overcome stress. Although, conventional autophagy is necessary for the clearance of protein aggregates in neurons [16].

Autophagy can be either nonselective or selective. Selectivity is mediated by autophagy receptors that recognize both, the tagged cargos with degradation signals and the autophagosome membrane through the LC3-interacting region [17]. The ubiquitin-binding protein p62/SQSTM1 is the best-characterized autophagy receptor and its degradation into the autolysosome has been widely used as a measure of the autophagic flux.

Autophagy in the CNS

In mammalian adult brain, neurogenesis is limited to selected regions, namely, the dentate gyrus of the hippocampus and the subventricular zone. Thus, there is no turnover of dysfunctional neurons and they ought to survive an entire lifetime. As

INFORME DE LABORES 2019

post-mitotic cells, neurons rely on autophagy for the maintenance of protein and organelle homeostasis and thus neuronal viability.

The relevance of autophagy as a quality control mechanism in the CNS is evidenced in animal models where essential autophagy genes are genetically suppressed. Mice lacking Atg5 [18], Atg7 [19], and FIP200 [20], specifically in the CNS, show neurological and behavioral defects, including abnormal limb-clasping reflexes, locomotor ataxia, and deficits in motor coordination that result in early death. Deficiency of these autophagy-related genes causes the accumulation of polyubiquitinated proteins in almost all brain regions, forming inclusion bodies that increase in size and number with age [18, 19]. Moreover, animals exhibit axonal degeneration and neuronal loss in the cerebral and cerebellar cortices. These findings highlight the importance of a continuous clearance of cytosolic proteins through basal autophagy, in order to prevent the accumulation of abnormal proteins, which might impair neuronal function.

Autophagy plays a housekeeping role degrading aggregate-prone proteins including polyglutamine-expanded huntingtin (mHTT) and mutant α-synuclein (PD) [21]. In agreement, autophagy dysfunction, leading to the accumulation of pathogenic proteins and autophagy vacuoles, has been reported in neurodegenerative disorders [22]. Conversely, stimulation of autophagy reduces the accumulation of mHTT and α-synuclein, protects against cell death, and reduces behavioral alterations in different animal models of neurodegenerative diseases [23–25].

Besides a housekeeping role, autophagy functions as an adaptive response exerting cytoprotective and anti-inflammatory actions under stress conditions [9]. Pharmacological or genetic inhibition of autophagy diminishes neuronal capacity to respond to nutritional, physical, and chemical insults, suggesting an adaptive role that contributes to reestablish physiological conditions [26]. In contrast, there is also evidence supporting that autophagy can lead to cell death, named autophagic cell death, under certain conditions such as starvation and hypoxia/ischemia [27]. Thus, autophagy may exert a cytotoxic rather than a cytoprotective action under some circumstances [28]. The differential role of autophagy as an adaptive response or a mechanism contributing to cell death is related to the intensity and the duration of the stress stimulus (Fig. 1).

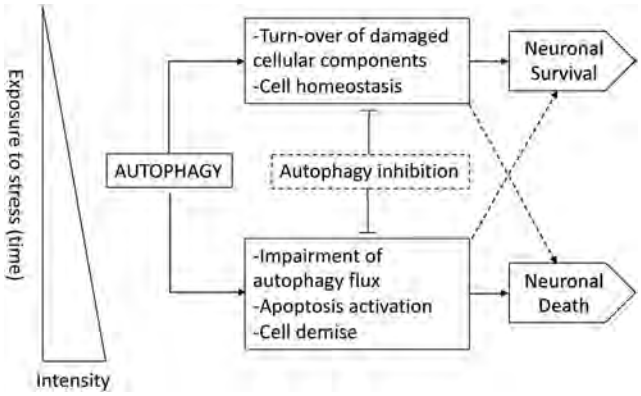

Fig. 1 Stress stimuli induce autophagy that depending on the duration and intensity can elicit different responses. Mild and short stress induce autophagy-dependent turnover of damaged cellular components to restore cell homeostasis that ultimately promote neuronal survival. Prolonged and intense stress induce autophagy dysfunction and apoptosis activation, which in turn causes neuronal death. Inhibition of neuroprotective autophagy leads to accumulation of damaged cellular components and cell homeostasis disruption. By contrast, inhibition of neurotoxic autophagy prevents apoptosis activation and autophagy-dependent cell demise

Autophagy Takes Place in Specific Neuronal Compartments

Neurons are polarized cells with unique morphology. The axon is a specialized compartment that can reach up long distances from the soma, the main site of protein degradation and synthesis. How autophagy regulates protein homeostasis along the different cell compartments is a challenging question [29]. Live-cell imaging studies indicate that autophagosomes are formed at the distal end of the axon. Autophagy core proteins are recruited to ER membranes present at the distal axon, where autophagosomes are generated [27, 28]. Then, autophagosomes travel by retrograde transport toward the soma and fuse with late endosomes or lysosomes, forming autolysosomes as they reach the soma [30, 31]. This process regulates axonal homeostasis and maintains the quality control of proteins present in nerve terminals. On the other hand, in the case of dendrites, it has been suggested that autophagosome biogenesis can occur locally or autophagy vesicles can be recruited to this compartment in a synaptic activity-dependent manner [32].

Synapses are critical neuronal compartments for brain function. Synaptic activity requires the participation of a large amount of proteins, which are highly susceptible to damage that leads to their accumulation and function impairment. Autophagy-recycling plays a crucial role in removing damaged proteins and maintaining homeostasis also in synapses [33]. In addition, autophagy regulates presynaptic structure and function. It has been reported that autophagy deficiency in dopaminergic neurons results in enhanced dopamine secretion in response to stimulation and accelerated presynaptic recovery due to the lack of the turnover of neurotransmitter vesicles [34]. Conversely, enhanced autophagy induced by rapamycin decreased dopaminergic synaptic vesicle density [35]. This suggests that autophagy regulates neurotransmission through the degradation of synaptic vesicles, altering synaptic terminal volume and the release of neurotransmitter. Also, autophagy is involved in synaptic plasticity. After chemical long-term depression, autophagosomes accumulate within dendrites and spines, and partially contribute to AMPA

receptor degradation. Under these conditions, ATG7 knockdown recovers AMPA protein levels only partially, suggesting the involvement of other degradation systems [36].

Starvation and Nutrient Deprivation

Neurons are highly metabolically active with a limited nutrient storage capacity; thereby, they are particularly sensitive to energy fluctuations. Glucose is the obligatory substrate for adult brain and a continuous supply of glucose and oxygen is required during development for normal brain function. Under prolonged fasting, which can lead to moderate hypoglycemia, or during pathological conditions such as ischemia and severe hypoglycemia, the brain is deprived from glucose. In these conditions, autophagy may be triggered in neurons in order to reestablish the energy status.

Metabolic stimuli that lead to autophagy activation are canonically integrated by the master regulator mTOR. However, depending on the stimuli, the upstream signaling can vary. For instance, growth factor deprivation, such as insulin, activates autophagy through PI3K/Akt signaling and subsequent inhibition of mTOR (reviewed in [37]). On the other hand, amino acid starvation is sensed by Rag GTPases that regulate the inhibition of mTOR and consequently ULK1/2 activation leading to autophagy [38]. Under these conditions, ablation of ULK1/2 completely abrogates autophagy activation [39]. Moreover, autophagy induced by glucose starvation also depends on mTOR-ULK1/2 but the upstream signaling involves AMPK activation [40]. Thus, cells can respond to a variety of metabolic challenges inducing autophagy in order to maintain the energy status. Nonetheless, severe conditions that lead to energy depletion result in autophagy impairment. This is because some autophagy steps are ATP-dependent such as lysosomal v-ATPase functioning, which is essential for the autophagosome-lysosome fusion and autolysosome degradation [41].

It is well known that food restriction induces autophagy in many organs. However, pioneer studies in mice exposed to food deprivation during 48 h showed no increase in brain autophagy [42]. The authors hypothesized that under these conditions, other organs could supply the brain with nutrients such as glucose and ketone bodies. However, more recent studies revealed that short-term fasting induces the upregulation of autophagy in cortical neurons and Purkinje cells, mediated by the decreased activation of neuronal mTOR in vivo [43]. In hypothalamic neurons, autophagy is induced by free fatty acids under fasting conditions in order to modulate food intake and long-term energy homeostasis [44]. Inhibition of hypothalamic autophagy alters energy balance and potentiates the development of metabolic diseases. Thus, autophagy within hypothalamic neurons is crucial for the control of food intake, energy and body weight balance [45].

Data on autophagy activation during nutrient stress in cultured neurons are still controversial. It has been observed that deprivation of growth factors and hormones in cortical cultures activates autophagy via mTOR inactivation [46]. In this condition, activation of autophagy protected neurons against proteotoxicity induced by polyQ-expanded huntingtin, suggesting an adaptive role. Conversely, in hippocampal-cultured neurons, nutrient or glucose deprivation markedly decreased mTOR signaling but it was not sufficient to activate autophagy. However, glucose deprivation attenuates retrograde transport of autophagosomes due to ATP depletion [47]. The authors hypothesized that autophagy has a key function regulating neuronal homeostasis, rather than providing amino acids in response to starvation. Likewise, we have recently demonstrated the impairment of the autophagy flux and the accumulation of autophagosomes in response to glucose deprivation in cortical-cultured neurons, due to lysosomal damage [48]. However, the autophagy flux can be restored upon glucose replenishment or when an alternative fuel such as the ketone body beta-hydroxybutyrate is added [49]. Similarly, long-term exposure to glucose deprivation during 18 h induces the accumulation of autophagy markers in the mouse neuroblastoma cell line Neuro2a suggesting the impairment of the autophagy flux [50].

Several molecules regulate autophagy under nutrient-deficient conditions, AMPK is one of the best characterized. AMPK monitors the energy homeostasis of the cells by sensing the AMP/ATP ratio. In addition, different upstream kinases can regulate AMPK activation including, LKB1 (liver kinase B1), CaMKKB (calcium/calmodulin kinase kinase B), and TAK-1 (TGFB-activated kinase-1) [51]. Autophagy is induced by AMPK-mediated mTOR inhibition, via phosphorylation of TSC2 and Raptor; however, AMPK can directly phosphorylate ULK1 and initiate autophagy [52] (Fig. 2a). Hypothalamic AMPK integrates diverse hormonal signals and plays an important role in the regulation of food intake. In hypothalamic cell lines exposed to low glucose or in animals treated with 2DG, autophagy is induced via AMPK activation, which increases the expression of NPY and decreases that of POMC stimulating food intake. Conversely, knockdown of AMPK within the hypothalamus induces the opposite changes in NPY and POMC expression leading to a reduction in food intake and body weight [53].

Under more severe conditions such as cerebral ischemia, morphological and biochemical markers of autophagy have been observed in several studies (reviewed [54]). However, whether autophagy plays a neuroprotective or neurotoxic role is still controversial [55]. Particularly, in ischemic injury, AMPK leads to autophagy activation, and inhibition of the AMPK-autophagy pathway confers protection against brain damage through the restoration of mTOR activity [56]. In contrast, it has been reported that metformin preconditioning

INFORME DE LABORES 2019

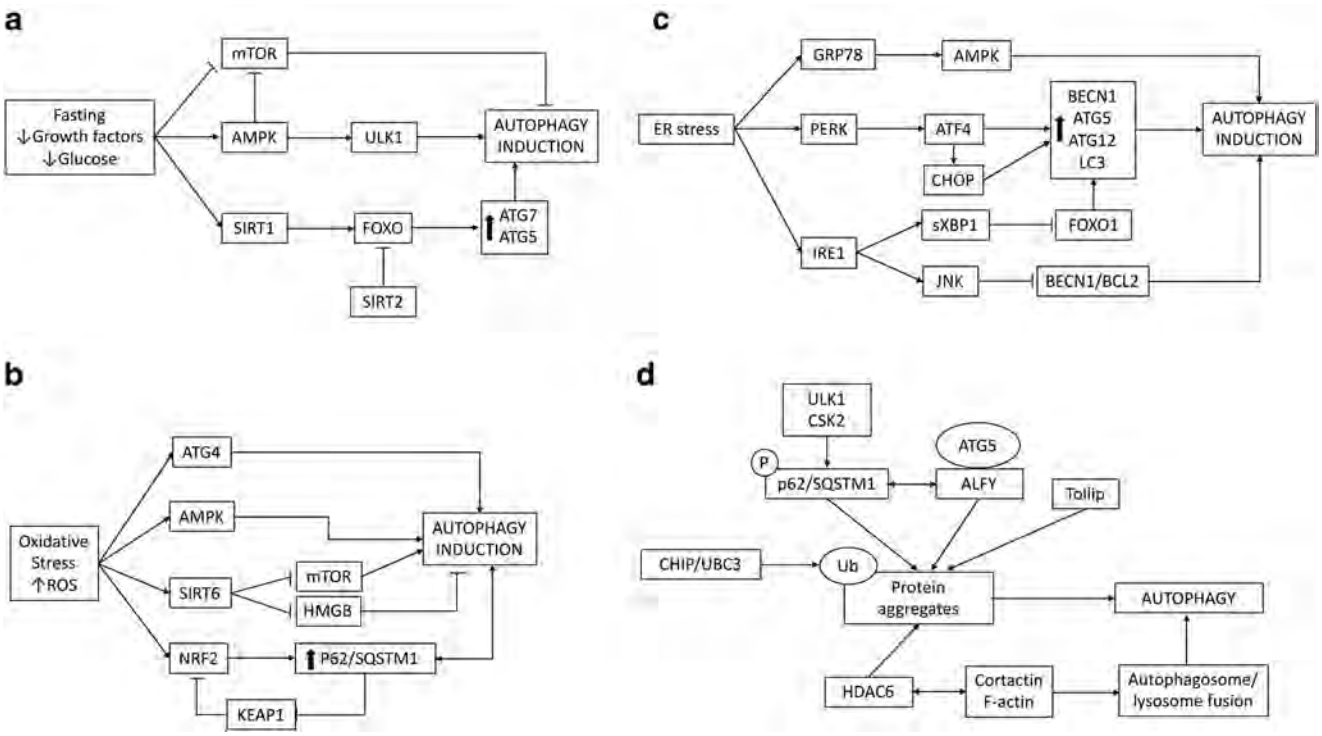

Fig. 2 Signal transduction pathways that regulate neuronal autophagy in response to **a** starvation and nutrient deprivation, **b** oxidative stress, **c** endoplasmic reticular stress, and **d** proteotoxic stress

protects against ischemia by activation of AMPK-dependent autophagy [57]. As mentioned before, autophagy plays an adaptive role in response to different types of stress; however, autophagy defects can compromise this adaptive response increasing the susceptibility to acute stress.

Manipulations that induce autophagy can elicit a hormetic effect increasing the resistance to several stressful conditions [28]. Autophagy induction during ischemic/hypoxic preconditioning exerts protection against a subsequent lethal hypoxic/ischemic insult. The mechanisms involved are not completely clear but some have been proposed. A recent study suggests that autophagy induction by hypoxic preconditioning (HPC) is mediated by the increased expression of HIF-1α and its downstream targets BECN1 and BNIP3, in SH-SY5Y cells exposed to oxygen and glucose deprivation exerting neuroprotection [58]. BNIP3 activates autophagy by mTOR inhibition and through the dissociation of BECN1 form Bcl-2 or Bcl-XL by competition with BECN1, favoring autophagosome formation [59]. Another recent study showed that HPC prevents neuronal damage in the hippocampus of rats exposed to transient global ischemia, through the restoration of the otherwise impaired autophagic flux. This effect involves the stimulation of autophagosome maturation by the activation of the small GTPase, Rab7, mediated by its interaction with UVRAG and Vps16, favoring the autophagosome-lysosome fusion [60].

On the other hand, autophagy activation by rapamycin increases the expression of p-PI3K, p-Akt1, and p-CREB, which correlates with decreased β-amyloid toxicity and improved cognitive decline in rats, suggesting that autophagy is part of a pro-survival response involving the activation of the pAkt1/CREB signaling pathway [61]. The molecular mechanisms involved in the activation of this survival pathway after autophagy induction have not been described. Additionally, rapamycin treatment prior to hypoxia-ischemia promotes neuroprotection through activation of either autophagy or Akt/CREB pathway [62].

Increased tolerance to lethal ischemic injury after ischemic preconditioning (IPC) has been shown to involve the increased expression of GRP78, an endoplasmic reticulum (ER) chaperone implicated in the unfolded protein response (UPR). GRP78 stimulates autophagy through the upregulation of AMPK in in vitro ischemia models, but the molecular mechanisms involved are still not clear [63, 64]. In addition, GRP78 can bind to p62/SQSTM1 to induce a conformational change which favors cargo degradation [65]. Conversely, autophagy activation during IPC upregulates GRP78, HSP60, and HSP70 and reduces the severity of ER stress triggered by lethal ischemia preventing ER-mediated apoptosis. Moreover, rapamycin administration before ischemia exerts similar effects, suggesting that protection elicited by IPC is mediated by the reduction of ER stress through autophagy activation [66]. From these studies, it can be concluded that moderate autophagy activation and mild ER stress induction are responsible at least in part of IPC protection against lethal ischemia.

Autophagy can be also regulated by Sirtuins, a family of NAD-dependent protein deacetylases that sense environmental stress. Sirt1 activity is necessary for the induction of autophagy by starvation, as it interacts and deacetylates autophagy-related proteins including ATG7, ATG5, and LC3 [67]. The lack of Sirt1 results in acetylated ATGs which associates with impaired autophagy, including the accumulation of p62/SQSTM1 and damaged organelles, disruption of energy homeostasis, and early death after birth [68]. Moreover, overexpression of Sirt1 is sufficient to stimulate autophagy even under nutrient-rich conditions. Increasing Sirt1 activity confers protection against axonopathy and neurodegeneration [69]. Furthermore, the sirtuin activator, resveratrol, rescues neuronal dysfunction induced by polyQ and β-amyloid toxicity through autophagy induction [70, 71]. Additionally, sirtuins can enhance the expression of autophagy proteins via deacetylation of FoxO, a well-known transcription factor regulating the expression of autophagy genes (Fig. 2a). Sirt1 promotes FoxO transcription activity, while Sirt2 prevents the interaction of acetylated FoxO with ATG7 preventing autophagy [67]. In addition, neurons lacking Sirt2 showed increased ATG5 acetylation and less recruitment of Parkin toward mitochondria resulting in mitophagy dysfunction [72], suggesting a crucial role of Sirt2 in mitochondrial homeostasis. In contrast, the overexpression of Sirt2 in cholinergic SN56 cells and neuroblastoma SH-SY5Y inhibits the autophagy flux leading to the accumulation of protein aggregates [73] by a mechanism that has not yet been elucidated.

Oxidative Stress and Autophagy

Due to its high metabolic energy requirements and rate of oxygen consumption, the brain is prone to reactive oxygen and nitrogen species (ROS/RNS) production and particularly vulnerable to oxidative stress. The antioxidant capacity of the brain to counteract ROS is limited compared to other organs. In addition, brain contains high levels of polyunsaturated fatty acids, which are targets for lipid peroxidation and act as pro-oxidants [74]. Oxidative stress has been implicated in the pathogenesis of neurodegenerative disorders, which are characterized by high levels of ROS [75]. Under these circumstances, autophagy reduces oxidative damage and ROS levels through the removal of pro-oxidant protein aggregates and damaged organelles [76].

ROS act as signaling molecules and modulate various pathways, including autophagy, through the redox regulation of proteins. Starvation triggers the accumulation of ROS, mainly H_2O_2, which leads to the inactivation of ATG4 ensuring the conjugation of LC3 with the autophagosome membrane, an essential step in autophagosome formation [77] (Fig. 2b). Given the role of ROS in autophagy induction, non-enzymatic and enzymatic antioxidants act as natural downregulators of this process.

Oxidative stress leads to autophagy activation and the accumulation of autophagosomes in different types of cells. Mitochondrial ROS, mainly $O_2^{\cdot-}$, induce autophagy mediated by AMPK activation during starvation [78, 79]. Likewise, in U87 glioblastoma cells, inhibitors of mitochondrial complexes I and II induce ROS-mediated autophagy, and SOD2 overexpression markedly reduces autophagosome formation [80]. Autophagy inhibition reduces the toxicity of mitochondrial electron transport chain inhibitors, suggesting that autophagy contributes to cell death. In normal mouse astrocytes, inhibition of mitochondrial complexes fails to produce ROS and to induce autophagy, possibly because of the lower energy requirements of this type of cells as compared to others such as cancer cells [80]. In contrast, in human neuroblastoma cells, SH-SY5Y rotenone (complex I inhibitor) treatment inhibits the autophagic flux and leads to cell death [81], while treatment with resveratrol, a well-known autophagy inducer, partially rescues SH-SY5Y cells from rotenone toxicity [82]. In the same cell line and in primary dopaminergic neurons, cell death induced by mitochondrial complex I inhibitor MPP+ is accompanied by the activation of autophagy mediated by the ERK/MAPK pathway. Under these circumstances, ablation of autophagy or inhibition of ERK signaling decreases MPP+ toxicity, suggesting the contribution of autophagy to cell death [83, 84]. However, manipulations that enhance autophagy and promote the autophagy flux, such as ischemic preconditioning or pharmacological pretreatments, protect against MPP+ toxicity [85–87], suggesting an adaptive role of autophagy under these circumstances.

On the other hand, oxidative stress caused by the direct exposure to H_2O_2 induces the accumulation of autophagosomes in primary cortical cultures and the genetic or pharmacological ablation of autophagy prevents neuronal death [88]. This result suggests that autophagy contributes to H_2O_2-induced oxidative stress and neuronal death. Furthermore, in SH-5YSY neuroblastoma cells, H_2O_2 exposure induces the activation of autophagy and the subsequent lysosome membrane permeabilization causing cell death [89, 90]. Inhibition of autophagy or prevention of lysosome membrane permeabilization protected cells against H_2O_2 damage. In contrast to H_2O_2 exposure, generation of $O_2^{\cdot-}$ by the xanthine + xanthine oxidase system causes neuronal death accompanied by autophagic features. Under these circumstances, ATG7 knockdown delays early cell death progression, suggesting the involvement of other cell death mechanisms in $O_2^{\cdot-}$-mediated oxidative stress damage [91].

Under acute stress such as traumatic brain injury, ischemia/reperfusion, and hypoxia, the excessive production of ROS leads to the loss of cellular homeostasis and autophagy induction [76]. Excessive production of ROS from NADPH oxidase and autophagy play an important role in neuronal death

INFORME DE LABORES 2019

induced by hypoxia-ischemia and ischemia/reperfusion in vitro and in vivo [92]. Treatment with the autophagy inhibitor 3-MA effectively reduces the abundance of autophagy markers and OGD-induced neuronal death. Moreover, inhibition of NADPH oxidase decreased autophagy in an OGD model, suggesting that oxidative stress-dependent autophagy, mediated by NADPH, contributes to brain injury [93]. On the other hand, during hypoxic conditions, autophagy can also be regulated by the hypoxia-inducible factor-1 (HIF1), a key player in the cellular response to hypoxia. HIF is stabilized by ROS and activates target genes such as BNIP3 and NIX [94]. In addition, BNIP3 and NIX are involved in mitophagy [95]. However, the direct activation of NIX-mediated mitophagy by ROS has not been explored.

The nuclear transcription factor NRF2 is considered as the master regulator of the antioxidant cell response [96]. NRF2 controls over 250 genes, including p62/SQSTM1, which in turn positively regulates NRF2. Under basal conditions, NRF2 is repressed by Keap1, which mediates its proteasomal degradation. However, ROS-induced autophagy leads to p62/SQSTM1 accumulation and sequestration of Keap1, leading to increased NRF2 signaling [97] (Fig. 2b).

Analysis of postmortem brain tissue from Alzheimer's patients supports the role of p62/SQSTM1 in NRF2 regulation during neurodegeneration. These samples show p62/SQSTM1 accumulation and co-localization with Keap1, suggesting that Keap1 is recruited to autophagosomes allowing NRF2 activity [98]. However, it is well known that autophagy is impaired in neurodegenerative diseases and thereby contributes to neuronal demise; thus, it is unknown to what extent autophagic degradation of Keap1 contributes to NRF2 transcriptional activity in Alzheimer's disease.

On the other hand, SIRT6, a NAD-dependent histone deacetylase, has been implicated in the regulation of metabolism, inflammation, and aging. SIRT6 deficiency leads to oxidative stress and mediates premature senescence-like phenotype, suggesting that disturbances in SIRT6 levels are involved in the aging process. Moreover, SIRT6 counteracts oxidative stress by transactivation of antioxidant genes like NRF2 [99]. SIRT6 stimulates the autophagy flux via attenuation of Akt/mTOR signaling under H_2O_2-induced oxidative stress (Fig. 2b). However, under these circumstances, inhibition of SIRT6 increases neuronal survival by suppressing autophagy [100].

On the other hand, SIRT6 can also modulate autophagy after cerebral ischemia. Reduced SIRT6 levels associate with the release of the high-mobility group box (HMGB1), a chromatin-associated nuclear protein that plays a pivotal function in inflammation and acts as autophagy effector [101]. HMGB1 interacts with BECN1 leading to its subsequent dissociation from Bcl-2 and autophagy activation under oxidative stress [102]. The mitochondrial inhibitor 3-nitropropionic acid (3-NP) induces oxidative stress, autophagy, and striatal neurodegeneration in vivo through HMGB1 activation. Pharmacological inhibition and shRNA targeting of HMGB1 reduces autophagy markers and striatal damage suggesting that HMGB1 is an important signaling molecule for autophagy in neurodegeneration induced by mitochondrial dysfunction [103]. During acute brain damage, HMGB1 is released from neurons and contributes to the inflammatory response. Particularly, after ischemia/reperfusion, HMGB1 mediates brain inflammatory injury and blocking HMGB1 function reverses the inflammatory response and brain damage [104]. Therefore, HMGB1 can be another mediator of oxidative stress-induced autophagy (Fig. 2b).

Altogether, the observations described above suggest that in response to ROS production and oxidative stress, autophagy plays a critical role in the maintenance of cellular homeostasis by degrading damaged proteins and organelles. Several molecules and proteins integrate ROS signals leading to autophagy activation. However, the correlation of autophagy markers with neuronal death under oxidative stress conditions suggests its contribution to neuronal damage, due to the impairment of this process, such as that resulting from the interruption of the autophagic flux. Therefore, genetic of pharmacologic ablation of autophagy confers protection against damage induced by oxidative stress. On the other hand, manipulations that enhance autophagy or stimulate the autophagy flux increase the resistance to oxidative stress conditions and promote cell survival.

ER Stress, UPR Activation, and Autophagy

The ER is an important organelle involved in cellular homeostasis and protein quality control. Several extracellular or intracellular stimuli can disturb ER homeostasis leading to ER stress. To counteract this condition, cells activate the UPR, which reestablishes ER function and ultimately cell homeostasis. Three ER transmembrane sensors, PERK (PKR-like ER kinase), IRE1 (Inositol-requiring enzyme 1), and ATF6 (activating transcription factor 6), orchestrate the UPR, which attenuates global protein translation, upregulates protein folding capacity, and executes programmed cell death. ER stress has been shown to induce autophagy through UPR signaling. Under these circumstances, autophagy functions as an adaptive response to alleviate ER stress.

The mechanisms involved in autophagy induction by activation of the UPR have not been completely elucidated but some reports have implicated GRP78/Bip. GRP78/Bip is an ER-resident chaperone that binds to and inhibits the three UPR sensors. Accumulation of unfolded proteins within the ER lumen recruits GRP78 releasing UPR sensors and allowing UPR activation. As mentioned above, GRP78 can regulate autophagy during ischemic preconditioning. Also, in primary cortical neurons, it has been reported that GRP78 can regulate autophagy. Exposure to cadmium produces ER stress,

which induces autophagy mediated by GRP78 upregulation. Conversely, GRP78 siRNA blocks the conversion of LC3-I to LC3-II and autophagosome formation. Furthermore, it is suggested that cadmium-induced GRP78 upregulation stimulates autophagy via AMPK activation [105] (Fig. 2c).

Under severe brain injury conditions such as hypoxia/ischemia, ER stress and UPR activation contribute to neuronal death [106]. In addition, the PERK and the IRE1 branches of the UPR can activate autophagy [107]. However, the role of autophagy in ischemic injury is still controversial. During ischemic preconditioning, mild ER stress induces autophagy and confers neuroprotection against the ischemic insult. Therefore, inhibition of ER stress and subsequent autophagy activation inhibits neuroprotection elicited by ischemic preconditioning [106]. Moreover, mild ER stress induced by tunicamycin triggers an autophagic response, which protects against 6-OHDA toxicity in mice [108]. On the other hand, it has been shown in in vitro and in vivo models of ischemia-reperfusion that autophagy is activated during the reperfusion phase contributing to the clearance of damaged mitochondria. In agreement, pharmacological or genetic inhibition of autophagy enhanced neuronal damage [109]. In accordance with these results, tunicamycin and thapsigargin administration during reperfusion confers protection against transient ischemia, enhancing autophagy, particularly mitophagy, through PERK-eIF2a-ATF4 signaling [110] (Fig. 2c).

ER stress and UPR dysfunction play an important role in the pathogenesis of neurodegenerative diseases and aging. In Huntington's disease models, upregulation of IRE1 kinase activity leads to impaired autophagic flux and thereby accumulation of mHTT, while reduction of IRE1 expression or inhibition of its kinase activity reduced the accumulation of mHTT [111]. However, how IRE1 inhibits the autophagy flux still remains to be elucidated.

IRE1 can induce autophagy by recruiting TRAF2/ASK and the activation of JNK, which phosphorylates Bcl-2, disrupting its interaction with BECN1, thereby activating autophagy [112] (Fig. 1c). This signaling depends on IRE1 kinase activity. In streptozotocin-induced diabetic mice, ER stress and UPR lead to cognitive decline. In this condition, autophagy activation through the JNK pathway counteracts ER stress-associated neuronal damage [113]. In addition, IRE1 RNAse activity can inhibit autophagy through the downregulation of FOXO1, a transcription factor that regulates autophagy through the upregulation of ATG5, LC3, and BECN1 transcription [114] (Fig. 2c). It has been shown in a transgenic mice model expressing mHTT that IRE1 RNAse activity leads to XBP-1 alternative splicing, which downregulates FOXO1 promoting its degradation by the proteasome. Thus, XBP1 deficiency enhances FOXO1 expression and autophagy reducing HD neurodegeneration [115]. These results suggest that IRE can induce opposite effects on autophagy activation through either its mRNAse or kinase activity.

The PERK branch of the UPR has been also implicated in autophagy. It has been reported that polyQ aggregates induce the activation of PERK/eIF2α-dependent autophagy, as defense mechanism against polyQ-induced cell death. PERK/eIF2α activates autophagy possibly through the upregulation of ATG12 mRNA and increased ATG5-dependent LC3 lipidation [116]. Furthermore, it is known that ATF4 and CHOP, the downstream transcription factors of the PERK pathway, induce the expression of autophagy genes such as ATG12, ATG5, LC3, and BECN1, connecting UPR signaling and autophagy (Fig. 2c) [117].

Proteotoxic Stress and Autophagy

Neurons are particularly vulnerable to the accumulation of misfolded proteins; due to their post-mitotic nature, protein aggregates cannot be dissipated by cell division. Additionally, the decline of degradation systems with advancing age further contributes to neuronal vulnerability. Approximately 30% of the newly synthetized proteins are misfolded and prone to form aggregates interfering with normal cellular function [118]. Therefore, quality control systems continuously operate to manage the flux of misfolded proteins and maintain proteostasis. This quality control machinery involves refolding (chaperones) and degradation (autophagy and ubiquitin proteasome system). The ubiquitin proteasome system (UPS) represents the first line of defense against misfolded proteins; however, aggregates or oligomeric forms of misfolded proteins are not efficiently degraded by the proteasome. Moreover, accumulation of protein aggregates leads to proteasome inhibition resulting in further accumulation of misfolded proteins [119]. Conversely, autophagy can target large protein complexes, aggregates, and organelles. Upon UPS inhibition, autophagy activity increases as a compensatory mechanism to alleviate subsequent proteotoxic stress [120]. Basal neuronal autophagy is critical to prevent the accumulation of ubiquitinated proteins and inclusion bodies, which can disrupt neuronal function [18, 19]. Thus, any genetic or pharmacologic manipulation that enhance autophagy results in the clearance of a variety of aggregate-prone disease proteins.

As we mentioned before, p62/SQSTM1 is the best-characterized autophagy receptor with a role in the clearance of ubiquitinated proteins, aggregates, and organelles [17]. Additionally, it has been identified as a common component of neuronal protein inclusions in several neurodegenerative diseases [121]. Phosphorylation of p62/SQSTM1 at serine 403 by casein kinase 2 (CSK2) increases the affinity of p62/SQSTM1 for polyubiquitinated proteins and the subsequent autophagy-mediated degradation. Overexpression of CSK2 reduces the formation of mutant huntingtin large inclusions [122]. Moreover, overexpression of mHTT induces the expression of p62/SQSTM1, suggesting that p62 plays an important role

in response to proteotoxicity [123]. Likewise, proteotoxic stress induced by proteasome inhibition or expression of polyQ-HTT causes ULK1-dependent phosphorylation of p62/SQSTM1 at S409. This phosphorylation increases binding affinity of p62 to ubiquitinated proteins. In contrast, phosphorylation of p62/SQSTM1 by ULK1 does not occur under amino acid or glucose deprivation, suggesting that ULK1-p62/SQSTM1 cascade is involved in the sensing of proteotoxic stress [124]. However, the upstream signaling pathway which activates ULK1-p62/SQSTM1 cascade remains unknown.

Another protein involved in the interplay between proteasome and autophagy is the histone deacetylase 6 (HDAC6), a microtubule-associated deacetylase that interacts with polyubiquitinated proteins. In Drosophila, HDAC6 activity is critical for autophagy in order to compensate UPS impairment. Furthermore, ectopic expression of HDAC6 is sufficient to prevent degeneration caused by proteasome inhibition and polyQ toxicity [125]. Additionally, HDAC6 controls the fusion of autophagosome with lysosomes in basal autophagy that targets protein aggregates. HDAC6 recruits and activates an actin-remodeling factor, cortactin, to the autophagy substrates and the subsequent assembly of F-actin network that facilitates the fusion of the autophagosome with the lysosome [126] (Fig. 2d). Interestingly, HDAC6 is not required for starvation-induced autophagy.

These two ubiquitin-binding proteins, p62/SQSTM1 and HDAC6, confer specificity to quality control by autophagy and distinguish aberrant protein aggregates and damaged organelles from normal ones. p62/SQSTM1 and HDAC6 bind preferentially lysine 63 (K63)-linked ubiquitinated proteins. Deletion of p62/SQSTM1 or HDAC6 induces a robust accumulation of K63-linked ubiquitin chains in mice brain and MEFs, respectively. This suggests that the specific type of ubiquitin chains added to misfolded proteins determines to which degradative pathway they are delivered [119]. On the other hand, CHIP, a chaperone-dependent ubiquitin E3 ligase, can form a complex with UBC3, which catalyzes the formation of ubiquitin chains in K63. Thus, this complex can direct the degradation of misfolded proteins via autophagy (Fig. 2d). In addition, CHIP colocalizes with α-synuclein and Hsp70 in Lewy bodies a hallmark of Parkinson disease, suggesting that CHIP plays a role in α-synuclein aggregation and degradation. Overexpression of CHIP promotes the degradation of α-synuclein by both proteasome- and autophagy-dependent mechanisms [127].

ALFY (autophagy-linked FYVE protein) has been shown to colocalize with ubiquitin and p62/SQSTM1-positive aggregates under stress conditions [128]. This protein acts as a scaffold which interacts with p62/SQSTM1 and ATG5 and recruits the autophagy machinery toward protein aggregates (Fig. 2d). ALFY is essential for selective autophagy under proteotoxic stress and its overexpression decreases the accumulation of polyQ-HTT and confers neuroprotection [129]. Conversely, ablation of ALFY in Drosophila results in the accelerated accumulation of ubiquitinated-positive inclusions and neuronal degeneration [130]. Tollip is another ubiquitin-binding protein with a role in the clearance of cytotoxic proteins such as polyQ-HTT. Tollip binds to polyubiquitinated proteins with high affinity compared to p62/SQSTM1 and may function cooperatively with p62/SQSTM1 in selective autophagy [131]. Interestingly, Tollip is downregulated in brain tissue samples from aged and Alzheimer's affected humans [132].

Besides protein aggregates, damaged organelles such as mitochondria are tagged with ubiquitin to trigger selective autophagy (mitophagy). Upon mitochondrial damage, the ubiquitin kinase PINK1 is translocated toward the outer membrane of mitochondria and phosphorylates ubiquitin. This activates the ubiquitin ligase Parkin, which builds ubiquitin chains to recruit autophagy receptors and subsequently the autophagy machinery. Under these conditions, PINK1 recruits the autophagy receptors NDP52 and optineurin but not p62/SQSTM1 [133]. Dysfunctional mitophagy is associated with degeneration in several neurodegenerative disorders (reviewed in [134, 135]).

Aging and Autophagy

Aging is associated with the loss of proteostasis, accumulation of altered macromolecules, and a decreased turnover of cellular components [136]. Reduced protein degradation can result from alterations in the autophagic/lysosomal system that finally contributes to the aging process [137]. In aged tissues, reduced expression of ATG proteins and other proteins required for autophagy induction has been reported. Particularly, in the human aged brain, key autophagy genes such as Atg5, Atg7, and BECN1 are downregulated, suggesting that normal aging is associated with decreased autophagy [138]. As previously mentioned, autophagy plays a protective role against neurodegenerative diseases; hence, its downregulation during aging might contribute to the predisposition to neurodegenerative diseases. Moreover, a decline in synaptic plasticity and deficient memory and cognitive function related to aging can be associated with the progressive transcriptional downregulation of autophagy genes [138, 139]. In addition, several autophagy proteins including ATG5-ATG12 and BECN1 complexes are highly reduced in old murine brains suggesting low levels of basal autophagy [140]. Furthermore, old brain tissue shows a significant increase in the protein level of mTOR, suggesting enhanced mTOR activity, which together with decreased autophagy machinery, may play an important role in the age-related impairment of autophagy [140].

A role of autophagy as an anti-aging mechanism has been suggested. Several interventions that modulate metabolism (augmenting ketone bodies), energy intake (caloric restriction), and energy expenditure (exercise) are shown to enhance

INFORME DE LABORES 2019

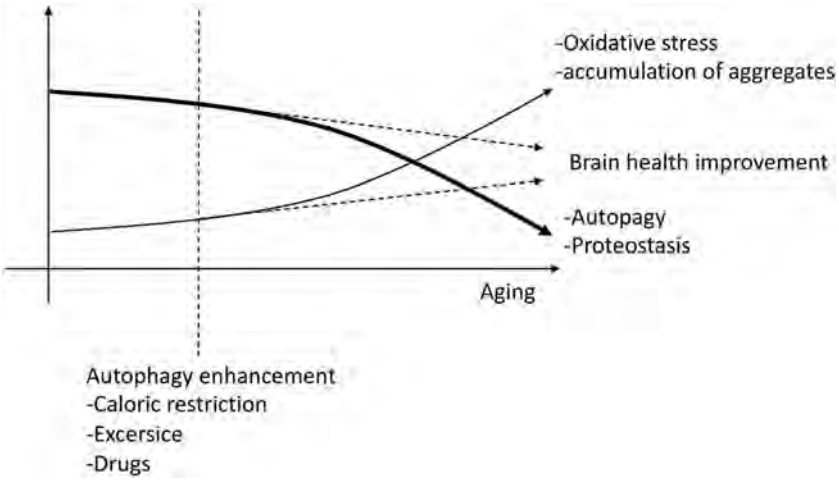

Fig. 3 Autophagy decreases with age leading to loss of proteostasis, accumulation of protein aggregates, and oxidative stress. Any intervention that enhances autophagy results in brain health improvement

autophagy and improve brain health. Inhibition of insulin-like growth factor promotes autophagy and shows an anti-aging effect extending the life span in some species such as the worm *C. elegans* [141]. Moreover, autophagy is required for dietary restriction to extend *C. elegans* life span [142]. Furthermore, caloric restriction delays the onset of age-associated pathologies including brain atrophy and extends life span in the rhesus monkey [143]. Likewise, in rodent models, caloric restriction extends the life span and reduces several age-associated process [144], although it is still not clear whether these effects are mediated by increased autophagy. Long-term exercise training ameliorates cognitive decline in aged rats and reduces oxidative stress. These effects are associated with the activation of autophagy in the hippocampus, which promotes mitochondrial recycling (mitophagy) [145]. Synaptic dysfunction is an early feature of aging that precedes neuronal loss and ultimately neurodegeneration. Therefore, restoration of synaptic homeostasis through the stimulation of autophagy has become a common strategy in order to help neurons to clear damaged proteins or aggregates [33]. Administration of spermidine increases the viability in an autophagy-dependent manner in several types of cells, including neurons [146]. Furthermore, this natural polyamine suppresses memory impairment by counteracting age-dependent synapse dysfunction in Drosophila. Conversely, memory improvement is impaired by deletion of Atg7 and Atg8 autophagy genes [147].

In addition to these findings, it has been observed that skeletal neuromuscular junctions of aged mice display a variety of alterations including axonal swelling and synaptic detachment, associated with autophagy impairment [148, 149]. Moreover, inhibition of autophagy exacerbates neuromuscular synaptic dysfunction and promotes the aging phenotype. Conversely, stimulation of autophagy by caloric restriction or exercise decreases pre- and post-synaptic abnormalities and reduces the loss of motor neurons in aged mice [148]. In agreement, it has been observed that metformin, an AMPK activator and a well-known autophagy inducer, mimics caloric restriction benefits in health. Long-term treatment with metformin counteracts oxidative stress augmenting the antioxidant defense and autophagy, suggesting that metformin promotes healthy aging in the brain [150]. Altogether, these observations lead to the suggestion that impaired autophagy contributes to brain aging and that pharmacologic or nutritional strategies to induce autophagy favor healthy brain aging (Fig. 3).

Conclusions

Autophagy is a major degradation system responsible for the turnover of cytoplasmic material in order to maintain cellular homeostasis. Particularly in neurons, autophagy plays a crucial role in the maintenance of protein and organelle

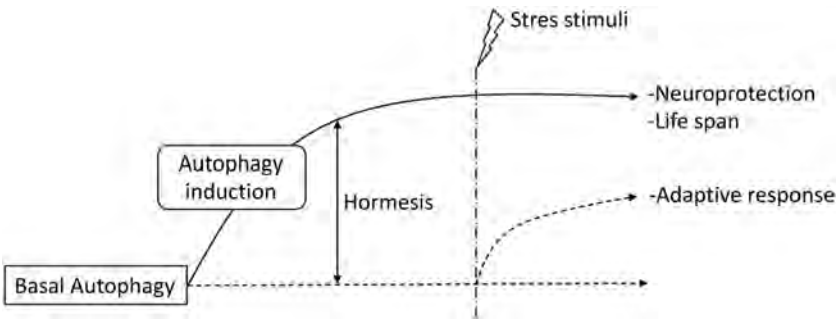

Fig. 4 Autophagy induction in the absence of stress stimuli leads to hormesis. Pharmacologic or nutritional manipulations that induce autophagy increase the resistance to stressful conditions resulting in neuroprotection or extended life span

homeostasis due to their post-mitotic nature. Besides its housekeeping role, autophagy is especially relevant as an adaptive mechanism in response to several stressful conditions to restore homeostasis and promote cell survival. However, autophagy has been implicated in neuronal damage, particularly that associated with acute injury, as autophagy markers correlate with cell death. Hence, ablation of autophagy elicits beneficial effects against brain injury. Nevertheless, in many reports, the lack of evidence to demonstrate whether the accumulation of autophagy markers (i.e., LC3-II, autophagosomes) results from the induction of autophagy or from the impairment of the autophagy flux has made it difficult to conclude about the role of autophagy. Therefore, in order to prove that autophagy is involved in cell death, it is essential to use both pharmacologic and genetic tools to inhibit autophagy components. On the other hand, under severe and prolonged stress insults, autophagy failure such as that induced by lysosome membrane permeabilization can trigger other cell death mechanisms, leading to the misconception that autophagy contributes to cell death. Finally, it is becoming clear that treatments that enhance autophagy (i.e., pharmacologic, nutritional, or preconditioning) or promote the autophagy flux increase resistance to acute stress and extend life span, supporting the idea of autophagy as an adaptive response (Fig. 4).

ABSTRACT: Traumatic brain injury (TBI) is becoming an increasing public health issue. With an annually estimated 1.7 million TBIs in the United States (U.S.) and nearly 70 million worldwide, the injury, isolated or compounded with others, is a major cause of short- and long-term disability and mortality. This, along with no specific treatment, has made exploration of TBI therapies a priority of the health system. Age and sex differences create a spectrum of vulnerability to TBI, with the highest prevalence among younger and older populations. Increased public interest in the long term effects and prevention of TBI have recently reached peaks, with media attention bringing heightened awareness to sport and war related head injuries. Along with short-term issues, TBI can increase the likelihood for development of long-term neurodegenerative disorders. A growing body of literature supports the use of glucagon-like peptide-1 (GLP-1), glucose-dependent insulinotropic peptide (GIP), and glucagon (Gcg) receptor (R) agonists, along with unimolecular combinations of these therapies, for their potent neurotrophic/neuroprotective activities across a variety of cellular and animal models of chronic neurodegenerative diseases (Alzheimer's and Parkinson's diseases) and acute cerebrovascular disorders (stroke). Mild or moderate TBI shares many of the hallmarks of these conditions; recent work provides evidence that use of these compounds is an effective strategy for its treatment. Safety and efficacy of many incretin-based therapies (GLP-1 and GIP) have been demonstrated in humans for the treatment of type 2 diabetes mellitus (T2DM), making these compounds ideal for rapid evaluation in clinical trials of mild and moderate TBI.

KEYWORDS: *TBI, incretins, GLP-1, GIP, Gcg, glucagon, exendin-4, neurodegeneration, microglia, brain trauma*

INTRODUCTION

Incretin Based Therapies: A Well Supported Approach to Traumatic Brain Injury Treatment. Traumatic brain injury (TBI) constitutes a significant public health issue worldwide, increasing disability and mortality rates among all age groups.[1] TBI ranges from mild (mTBI) to severe and presents diverse acute symptoms; the heterogeneity of the initial injury remains a barrier to the development of effective therapeutic interventions and clinical trials.[2] The randomness of events leading to human head injuries requires a range of models that produce trauma analogous to that seen in incidents ranging from falls and sports related injuries to a severe car crash or explosion in war.[3]

The primary injury of TBI involves damage to brain tissue from direct trauma, typically in combination with inertial forces, with a secondary injury later emerging and characterized by widespread degeneration of neurons and glial cells.[4] Secondary injury manifestations are delayed and suggest a possible therapeutic window.[5] Pharmacologic intervention to reduce progression and severity of the secondary injury presents the greatest promise for counteracting a patient's long-term morbidity and improving quality of life. Currently, there are no Food and Drug Administration (FDA) approved treatments for the secondary TBI injury;[6] instead there is

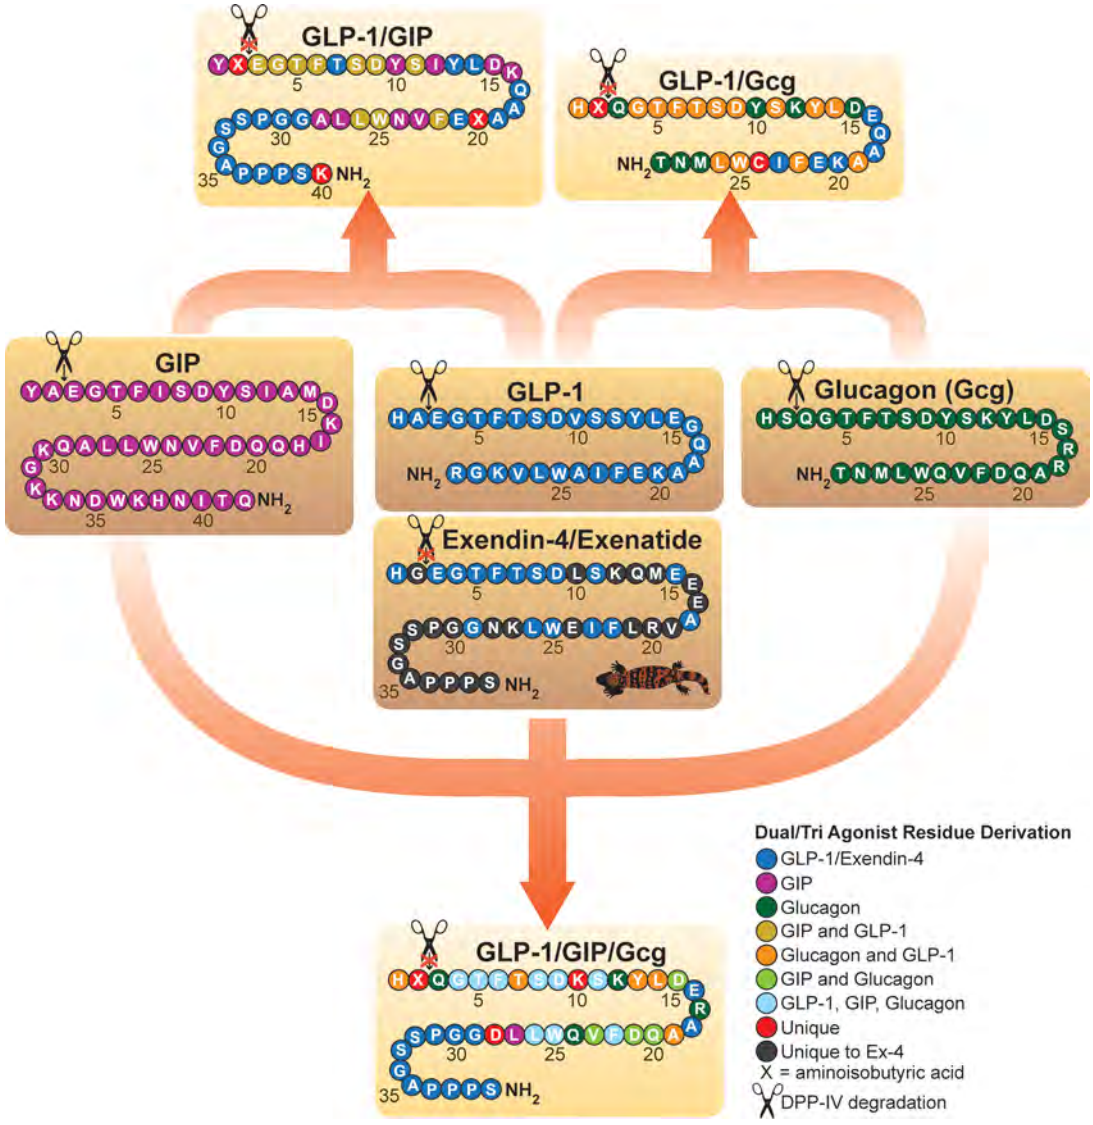

Figure 1. Amino acid sequences of incretins and glucagon and their mimetics. The discovery of the GLP-1 analogue exendin-4 (commercially known as Exenatide), in the saliva of the Gila monster has paved the way for DPP-IV resistant incretin mimetics. Residue derivations for the dual- and triagonist incretin-based therapies are highlighted as well as resistance to DPP-IV cleavage. All endogenous human peptides are susceptible to DPP-IV cleavage, while the mimetics display some form of resistance. For more detailed structures, see Tschöp et al. (2016) (ref 28).

much focus on symptomatic treatments of the condition, including those for headaches, sleep issues, fatigue, balance problems, and nausea.[7] Other common acute manifestations of TBI include cognitive deficits in attention, learning and memory, and higher-order executive functions. However, these consequences can remain long after the initial injury.[8,9] TBI can additionally lead to the development of chronic neurodegenerative disorders, including Alzheimer's disease (AD), Parkinson's disease (PD), frontotemporal dementia (FTD), and chronic traumatic encephalopathy (CTE).[10−12] As Masel and Dewitt (2010)[13] describe, TBI is "a disease process, not an event", referring to a common practice among insurance agencies to classify TBI as a singular injury. The long-term consequences of the injury need to be considered following initial treatment.

Understanding of the molecular mechanisms underpinning the secondary TBI injury are important for the development of effective therapies for the mitigation of long-term consequences. Pharmacological treatments focused on the secondary and long-term neurological effects of the condition are currently emerging.[14−20] Incretin mimetics are a particularly promising class of drugs for the treatment of mTBI and are based on the utilization of the endogenous incretin signaling system involving glucagon-like peptide 1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP), glucagon (Gcg), and their receptors (R). GLP-1 and GIP exert similar mechanisms of action,[21] and their long-acting drug analogues were originally developed for their insulinotropic and insulin-sensitizing actions for the treatment of type 2 diabetes mellitus (T2DM), characterized by insulin resistance[22,23] and blunted incretin effects.[24] Incretin effects account for up to 70% of insulin release and defects in this system are thought to be main contributors to the development of T2DM.[25] Endogenously, GLP-1 and GIP are chiefly produced in the small intestine and maintain low concentrations in the bloodstream[26] that are rapidly upregulated in response to food ingestion. Following upregulation, GLP-1 and GIP act in a glucose-dependent manner on pancreatic β-cells to stimulate

Table 1. Incretin-Based Therapies in Animal Models of TBI[a]

Action	Study and TBI Model Used	Treatment Effects	Treatment Evaluated
GLP-1R agonist	1) *Heile et al., 2009*[m]: Controlled Cortical Impact (CCI) 2) *Rachmany et al., 2013*[b]: Concussive weight drop model (mTBI) 3) *Eakin et al., 2013*[c]: Fluid Percussion Injury (FPI) model (mTBI) 4) *DellaValle et al., 2014*[d]: Cold lesion model (severe TBI) 5) *Li et al., 2015*[e]: Concussive weight drop - 30 gram (mTBI) 6) *Hakon et al., 2015*[f]: CCI 7) *Tweedie et al., 2016*[g]: Blast induced mTBI 8) *Rachmany et al., 2017*[h]: Blast induced mTBI 9) *Bader et al., 2018*[i]: Concussive weight drop model- 30 gram (mTBI)	1) Attenuated hippocampal neuron loss and other histopathology associated with TBI. 2) Ameliorated H_2O_2- induced oxidative stress and glutamate toxicity in cell culture and deficits in novel object recognition 7 and 30 days post trauma. 3) Reduced cognitive impairments (Morris Water Maze), protection from glutamate toxicity, decreased Caspase-3 activity. 4) Reduced reactive oxygen species, reduced lesion volume ~50%, CREB-regulated cytoprotective and anti-neurodegenerative proteins increased. 5) Increased cellular proliferation via CREB phosphorylation, protection from glutamate toxicity, reduction in pro-apoptotic signaling. 6) Preservation of BBB and improved sensorimotor function 48 hours post TBI. Lesion size and cortical neuron death was reduced. 7) Hippocampal and lateral neurodegeneration reduced (pre- and post-treatment effects), increased preference for novel object (Novel Object Recognition test), attenuated upregulation of neurodegenerative disorder related genes sets. 8) Maintained synaptophysin reactivity, prevented injury induced impairment in spatial working memory, and showed neurotrophic activity in vitro. 9) Improved cognitive impairments, neuroprotection, decreased glial activation, inhibition of TNF-a generation	1) Encapsulated mesenchymal stem cell transplant (native and GLP-1 overexpressing cells). 2) Steady-state Exendin-4 (Ex-4, ***Liraglutide***) (3.5 pM/kg/min) over 7 days starting 48 hr prior to or 1 hr post- TBI 3) Subcutaneuous (SC) Ex-4 administration via Alzet mini-osmotic pump (model 2001) (3.5 pM/kg/min) post- TBI. 4) SC Ex-4 administration via Alzet mini-osmotic pump (model 1007D) (3.5 pM/kg/min), pre- and post- TBI. 5) ***Liraglutide*** once daily injection for 7 days (246.7μg/kg/day) 6) ***Liraglutide*** twice daily at doses of 75μg /kg or 200 μg/kg or 200 μg/kg post-TBI. 7) SC Ex-4 administration via Alzet mini-osmotic pump (model 1007D) (3.5 pM/kg/min), 48 hrs pre and 2 hrs post- TBI. Favorable comparison to ***Byetta®*** (AstraZeneca) administration in humans. 8) SC Ex-4 administration via Alzet mini-osmotic pump (model 1007D) (3.5 pM/kg/min), 48 hrs pre- and post- TBI. Mimicked use of Exenatide LAR (***Bydureon®***; AstraZeneca) in humans. 9) A single SC injection of Slow Release (SR) Exenatide ***PT302*** (Peptron) (0.6, 0.12, and 0.024 mg/kg) was administered and plasma Exenatide concentrations were time- dependently measured over 3 weeks.
GIPR Agonist	1) *Yu et al., 2016*[j]: CCI (mTBI)	1) Ameliorated mTBI-induced memory impairments, poor balance, and sensorimotor deficits after initiation in the post-injury period. Mitigation of mTBI induced changes in GFAP, APP, and BMX observed.	1) SC GIP administration using ALZET micro-osmotic pump at a rate of 21.58 or 38.85μg/kg/day.
GCGR Agonist	1) *Fanne et al., 2011*[k]: Concussive weight drop model – 35 gram (mTBI) 2) *Armstead et al., 2011*[l]; FPI	1) Pre-treatment significantly reduced the neurological severity score (NSS) and TBI lesion size. Post-treatment reduced free glutamate in the CSF compared to saline controls. 2) Blocked NMDA receptor mediated vasoconstriction and restored vasodilation response (via reduction of tissue plasminogen activator (tPA)). Increased cAMP levels with pre- or post- treatment.	1) Mice were IP injected with 25ug Gcg 10 minutes prior to receiving head injury. For glutamate studies, IP injection given 10 minutes after injury. 2) Newborn pigs were pre- or post-treated with 25 ug/kg Gcg 30 minutes before or after FPI.
GIPR-GcgR Dual Agonists	None to date	———	———
GLP-1R/GcgR Dual Agonist	None to date	———	———
GLP-1R/GIPR Dual Agonist	1) *Tamargo et al., 2017*[m]: Weight drop model- 30 gram (mTBI)	1) Neurotrophic activity, neuroprotection from glutamate/oxidative stress, increased pCREB, and dose dependent elevation of cAMP levels SH-SY5Y cells; neuroprotection from 6OHDA in primary neurons; increased neurotrophic activity compared to single incretin mimetics (GIP and GLP-1); prevention of deficits in visual and spatial memory in mice 7 and 30 days post TBI.	1) SC daily injection of 50μg/kg dual GLP-1R/GIPR agonist ("Twincretin") for 7 days, with first injection administered 30 min after injury.
GLP-1R/GIPR/GcgR Triagonist	None to date	———	———
DPP-IV Inhibition	1) *DellaValle et al., 2016*[n]: Cold lesion model (severe TBI)	1) Significant results: reduction in lesion volume, increased activation of CREB system (neurotrophic), and increased manganese superoxide dismutase (MnSOD) transcription.	1) Sitagliptin (***Januvia®***; Merck and Co.) administrated once-daily 50 mg/kg of sitagliptin in a 0.1 mL Nutella® ball or Nutella® alone throughout the study, beginning 2 days before TBI.

[a]Incretin-based therapies have been studied across a variety of TBI models of and have demonstrated efficacy in preventing apoptosis, oxidative stress, and inflammation, while providing neurotrophic support. GLP-1R agonism has been the most widely explored incretin-based therapy for TBI, though others have shown promise as well. FDA approved drugs and drugs in clinical trials are shown in red and blue respectively. SC = subcutaneous injection. Sources: (a) ref 80; (b) ref 81; (c) ref 82; (d) ref 83; (e) ref 84; (f) ref 85; (g) ref 86; (h) ref 87; (i) ref 74; (j) ref 88; (k) ref 89; (l) ref 90; (m) ref 75; (n) ref 91.

the production and secretion of insulin and potentiate absorption of glucose by the body.

In contrast to the incretins, Gcg is most well-known for its action on the liver, stimulating the process of glycogenolysis, or the breakdown of glycogen into glucose. This lends itself to the effective treatment of severe hypoglycemia, or low blood sugar. GcgR antagonism has been explored as a way to effectively manage hyperglycemia. However, effects of GcgR agonism appear to play a pivotal role in satiety, metabolic homeostasis, and glucose metabolism.[27] Clinically balancing combinatory levels of GLP-1, GIP, and Gcg in unimolecular incretin mimetics counteracts monotherapeutic problems, such as hyperglycemic liabilities of Gcg. Minor changes in peptide analogue sequences allow for longer acting pharmacological effects on receptors of interest.[28] Endogenously, GLP-1, GIP, and Gcg are cleaved and inactivated by dipeptidyl peptidase-4 (DPP-IV) within two and 8 min of their release.[29,30] Resistance to this degradation is essential for incretin-based mimetics to effectively treat T2DM and other metabolic conditions (Figure 1).[28,31]

Incretin mimetics used in T2DM treatment are based upon the amino acid sequence of human GLP-1 and the naturally occurring analogue exendin-4 (Ex-4), which was originally isolated from the saliva of the Gila monster (*Heloderma suspectum*)[32] and is resistant to degradation from DPP-IV consequent to a substitution of alanine (A) to glycine (G) in the 2-position of Ex-4 (Figure 1). These drugs have received increasing attention for their extrapancreatic effects, especially within the central and peripheral nervous system, as they have been shown to confer neurotrophic[33] and neuroprotective actions in both *in vivo* and *in vitro* models of neurogenerative disorders.[34−37] The recognition of a synergistic GLP-1/GIP or GLP-1/Gcg effect has led to the development of dual GLP-1/GIP and GLP-1/Gcg receptor coagonists with the potential for enhanced efficacy than either mimetic alone.[38−41] Recently, unimolecular combinations of GIP, GLP-1, and Gcg, have been shown to be a more physiologically balanced and amenable incretin combination for the diverse needs of human patients[42] and show promise in several models of neurodegeneration.[43] GLP-1 based polypharmacologic approaches to the treatment of metabolic diseases, and possibly neurological disorders, seem to hold much promise, as single therapeutics often have limited effectiveness.[44] Although all commercially available GLP-1R agonists are effective for

Table 2. Incretin-Based Therapies Approved for Use or in Clinical Trials[a]

Mechanism of Action	Company	Drug Name		Administration	Uses	Other Notes
GLP-1R Agonist	AstraZeneca	Exenatide	*Bydureon®BCise™*	Once weekly SC	T2DM	Latest formulation of *Bydureon®*
			Bydureon®	Once weekly SC	T2DM	2 mg injection once each week, extended release formulation. Currently recruiting severely obese adolescents to participate in clinical trial (#NCT02496611). Phase 2 clinical trial (#NCT01971242) for PD patients completed (See a. *Athauda et al., 2017*)
			Byetta®	Twice daily SC	T2DM	Used any time within 1 hour before morning and evening meals (or before the two main meals of the day, approximately 6 hours or more apart). In clinical trial (#NCT02442791), neuroprotective effects of *Byetta®* administration following cardiac arrest showed no significant outcomes (See b. *Wiberg et al., 2016*). Phase 2 clinical trial (#NCT02838589) completed investigating effects on cerebral blood flow.
	Sanofi-Aventis	Lixisenatide	*Adlyxin®/ Lyxumia®*	Once daily SC	T2DM	10 mcg once daily injection for 14 days. On Day 15, dosage increased to 20 mcg once daily. Administered within one hour before the first meal of the day.
	Sanofi-Aventis/Hanmi Pharmaceuticals	Efpeglenatide	*HM 11260C*	Once weekly SC	T2DM	Currently recruiting patients for Phase 3 clinical trials (#NCT03353350, #NCT03496298)
	GlaxoSmithKline	Albiglutide	*Tanzeum®*	Once weekly SC	T2DM	Once weekly at any time of day, irrespective of meals. Dosage can be increased from 30 mg to 50 mg for those that need.
	Novo Nordisk	Liraglutide	*Victoza®*	Once daily SC	T2DM	Used at any time of day, independent of meals. Use 0.6 mg per day for one week then increase to 1.2 mg, which can be increased to 1.8 mg for additional glycemic control. Clinical trial in AD patients (#NCT01843933) completed in 2013 (See c. *Gejl et al., 2016*).
			Saxenda™	Once daily SC	Weight Loss	3 mg daily SC injection
		Semaglutide	*Ozempic®*	Once weekly SC	T2DM	0.25 mg (with or without meals). After 4 weeks, dose increased to 0.5 mg once weekly. Can be increased to 1 mg once weekly if needed.
			NASH	Daily SC	NASH/NAFLD	Currently in Phase 2 clinical trials (#NCT02970942). NASH measurements are primary outcome with NAFLD as secondary outcome measure.
		———	*NN9926, NN9927*	Oral	T2DM	Long acting, new molecular entities currently in development
	Eli Lilly	Dulaglutide	*Trulicity™*	Once weekly SC	T2DM	0.75 or 1.5 mg SC injection once weekly from single dose pen
	Peptron	Exenatide SR	*PT-302*	Biweekly SC	T2DM/ PD	Phase 2 clinical trials completed in South Korea for T2DM. Phase 1 clinical trial (#NCT00964262) completed for treatment of T2DM. Proprietary formulation allows for injection with smaller needle to reduce injection pain
	Intarcia	Exenatide	*ITCA 650*	Long term implant	T2DM	Implant with potential to offer 6 month exenatide delivery with 1 year delivery options in development. Phase 3 clinical trials have been completed with New Drug Application (NDA) submitted to the Food and Drug Administration (FDA) (pending approval)
	vTv Therapeutics	———	*TTP273*	Oral once or twice daily	T2DM	Non-peptide GLP-1R agonist. Has completed Phase 2 clinical trial (#NCT02653599).
	CSPC ZhongQi Pharmaceutical Technology Co., Ltd.	Recombinant Exenatide	*rExenatide-4*	SC twice daily	T2DM	Phase 3 Clinical trial (#NCT03239119) initiated, but not yet recruiting.
	Oramed	Exenatide Oral	*ORMD-0901*	Oral	T2DM	US FDA cleared Investigational New Drug (IND) application for trials in humans as of September 2018.
	Shanghai Biolaxy	Exenatide	*Nodaken*	Oral	T2DM	Nanoparticle oral delivery. Clinical trials ongoing in China.
	Jiangsu Hengrui Medicine Co. Ltd.	Loxenatide	*PEX168*	Once weekly SC	T2DM	Clinical trials in progress (#NCT02477969). This formulation is PEGylated.
	Neuraly Inc.	Exenatide	*NLY01*	Once weekly SC	PD/AD	Phase 1 clinical trial recruiting (#NCT03672604). This is a PEGylated formulation. See (d.) *Yun et al., 2018*
GIPR Agonist	———	GIP Peptide	———	———	T1DM	GIP peptide is currently recruiting for clinical trial (#NCT03556098) as a safeguard against hypoglycemia in patients with Type-1 diabetes mellitus (T1DM).
	Zealand Pharmaceuticals	———	*ZP4165*	Intra Venous (I.V.) or SC	T2DM	DPP-IV resistance and potentiates GLP-1 mediated weight loss and improved glycemic control in rats. See (e.) *Nørregaard et al., 2018*
GLP-1R/GcgR Dual Agonist	Hanmi Pharmaceuticals/ Janssen Research & Development, LLC	———	*HM12525A/ JNJ-64565111*	Once weekly SC	T2DM/Obesity	Currently recruiting for Phase 2 clinical trials (#NCT03586830).
	Zealand Pharmaceuticals/ Boehringer Ingelheim	———	*BI 456906*	Once weekly SC	Obesity	Long lasting analogue of amylin and partially builds on the effects of oxyntomodulin. Initiated Phase 1 clinical trial (#NCT03175211) in 2017 to assess safety, tolerability, and pharmacokinetics/pharmacodynamics. Phase 1 trials in Germany for obesity initiated.
	Astra Zeneca/ MedImmune	———	*MEDI0382*	Daily SC	T2DM	Completed Phase 2a clinical trials (see f. *Ambery et al., 2018*). Phase 2b clinical trials underway (#NCT03235050).
	Sanofi-Aventis	———	*SAR425899*	Daily SC	T2DM/Obesity	Clinical trials active (#NCT03414736). See (g.) *Gotfredi et al., 2018*
	Janssen Pharmaceuticals	———	*JNJ-54728518*	———	T2DM/Obesity	Phase I clinical trials initiated for obesity and T2DM in 2016. Pre-clinical trials for obesity also initiated in 2016.
	Novo Nordisk	———	*NNC9204-1177*	Once weekly SC	Obesity	Currently recruiting for Phase 1 clinical trial (#NCT03306721)
	Prolor/OPKO Biological	———	*OPK-88003*	Once weekly SC	T2DM	Currently recruiting for Phase 2 clinical trial (#NCT03406377)
	Spitfire Pharma	———	*SP-1373*	Once daily SC	NASH/T2DM/ Obesity	Clinical trial for T2DM and obesity planned for 2019.
	Boehringer Ingelheim	———	*BI 456906*	———	Obesity	Currently recruiting for Phase 1 clinical trials (#NCT03591718)
GLP-1R/GIPR Dual Agonist	Eli Lilly	———	*LY3298176*	Once weekly SC	T2DM	Completed Phase 2 clinical trials (#NCT03131687). See (h.) *Frias et al., 2018* for details.
	Novo Nordisk	———	*BG 7167/NNC0090-2746/ MAR709*	Once daily SC	T2DM	Completed Phase 2 clinical trial (#NCT02205528). See (i.) *Frias et al., 2017* for more details.
	Sanofi	———	*SAR438335*	Info not available	T2DM	Currently in Phase 1 clinical trials in France.
GLP-1R/GIPR/GcgR Triagonist	Novo Nordisk	———	*NNC9204-1706*	Once daily SC	Obesity	Current Phase I clinical trial (#NCT03661879) recruiting.
	Hanmi Pharmaceutical Co. Lmtd.	———	*HM15211*	SC	Obesity	Long acting formulation. Current Phase I clinical trial (#NCT03374241) recruiting. See (j.) *Kim et al., 2018* for latest research on compound
	Sanofi	———	*SAR441255*	SC	T2DM/Obesity/ NASH	Preclinical
DPP-IV Inhibition	Astra Zeneca	Saxagliptin	*Onglyza™*	Once daily oral	T2DM	2.5 or 5 mg regardless of meals
	Merck	Sitagliptin	*Januvia®*	Once daily oral	T2DM	25, 50, or 100 mg with or without food.
		Sitagliptin phosphate + metformin HCl	*Janumet®/ Janumet®XR*	Once daily oral (XR formula)/Twice daily	T2DM	Combination drug therapy with metformin. XR formulation is an extended release version. Max dosage 100 mg Sitagliptin and 2000 mg metformin.
		Omarigliptin	*Marizev®*	Oral once weekly	T2DM	Available in Japan. See (k.) *Goldenberg et al., 2017* for Phase 3 clinical trial information (#NCT01703221). Possible repositioning of drug for intranasal delivery for PD (l.) (*Ayoub et al., 2018*).
	Takeda	Trelagliptin	*Zafatek®*	Oral once weekly	T2DM	Approved for use in Japan. Phase 2 clinical trials abandoned in the USA because of costs.
		Alogliptin	*Nesina®*	Oral once daily	T2DM	25 mg with or without food
	Bristol-Myers Squib	Linagliptin	*Tradjenta®*	Oral once daily	T2DM	5 mg once daily
	Dong-A ST	Evogliptin	*Suganon®*	Oral once daily	T2DM	5 mg once daily. Approved for use in South Korea in 2015. Sold with extended release metformin.
	SatRx LLC	Gosogliptin	*Saxilin®*	Oral	T2DM	Approved for use in Russia. Completed Phase 3 clinical trial of safety alone or with metformin compared to Vildagliptin alone or with metformin (#NCT03088670.
	LG Life Sciences/ Sanofi	Gemigliptin	*Zemiglo™*	Oral once daily	T2DM	Long acting DPP-IV inhibitor. See (m.) *Kim et al., 2016* for characterization.
	Zealand Pharmaceuticals	Vildagliptin	*Galvus®*	Oral once daily	T2DM	50 mg in combination with metformin. See (n.) *Mathieu & Degronde, 2008*
	Mitsubishi Tanabe Pharma and Daiichi Sankyo	Teneligliptin	*Tenelia®*	Oral twice daily	T2DM	20 mg twice daily. See (o.) *Kishimoto, 2013*
	Zealand Pharmaceuticals	Anagliptin	*Suiny®*	Oral twice daily	T2DM	Approved for use in Japan, 200 mg daily. See (p.) *Nishio et al., 2015*

[a]There are currently a wide variety of incretin-based therapies approved for the treatment of metabolic diseases (shown in red and green if approved in the USA or elsewhere, respectively) and many more that are in clinical trials or development (shown in blue). Included in this table are the DPP-IV inhibitors which increase endogenous levels of GLP-1, GIP, and GCG. Formulations of incretin-based therapies in clinical trials focused on neurological diseases are highlighted in yellow. Bydureon and Victoza are the only FDA approved incretin analogues that have completed clinical trials for a neurological disease/disorder. There are currently no GIPR-GCGR antagonists under investigation. #: Clinical trials can be found at https://clinicaltrials.gov. NASH = nonalcoholic steatohepatitis; NAFLD = nonalcoholic fatty liver disease; SC = subcutaneous injection; T1DM = Type 1 Diabetes Mellitus. diabetes treatment, head to head comparisons of clinical trials of each drug reveal differential ratios of reduced blood glucose and weight loss and the amount of adverse events associated with intake.[45] No systematic comparisons of the effectiveness of T2DM treatment using dual and triagonists have yet been explored, although there are also likely differences in efficacy across these compounds as well. Understanding the residue contributions to the efficacy of these unimolecular combinations is difficult to assess, although the use of genetically modified mice with receptors of interest removed is an avenue to explore these questions.[25] As Capozzi et. al (2018)[25] point out, genetic deletion of these receptors has limitations and can potentially confound findings, as these mice may genetically compensate for these deletions and present atypical physiologic responses to the compounds.[46] This leaves potential gaps in understanding of which mimetics to use in future clinical trials, especially for neurologic disorders. The amino acid

Figure 2. Basic TBI diagnostic assessment in military and general clinical settings. Classifying the severity of a TBI is the first step in determining treatment options and trajectory. Basic diagnostic categorizations used in a military context are shown in panel A. With increasing use of blood-based biomarker surveillance, the use of brain imaging across each severity level will likely be highlighted less and perhaps deemed unnecessary for all cases. The Glasgow Coma Scale (GCS) (B) is a widely used diagnostic tool in assessing the severity of TBI, though the medical community is currently improving on less subjective readouts to better diagnose level of injury and needs of each patient. Panel A was adapted from Defense and Veterans Brain Injury Center (2015)[121] and panel B from Teasdale et al. (2014).[135]

sequences for GLP-1, GIP, Gcg, and their dual- or triagonist unimolecular combinations are shown in Figure 1.

Repurposing of the already well tested and tolerated incretin mimetics is promising for introduction to the general population for use in TBI treatment. Incretin mimetics have been shown to decrease neuroinflammation, excitotoxicity, oxidative stress, and apoptosis in animal models of a range of neurological maladies including autoimmune encephalomyelitis,[47] retinal neurodegeneration,[48,49] stroke,[50−53] AD,[54−57] PD,[58−63] and amyotrophic lateral sclerosis;[64] all of these processes are also implicated in the progression of secondary TBI injury.[65,66] Animal models of TBI have also demonstrated efficacy of incretin and Gcg based mechanisms; some of the treatments used in these studies are FDA approved or in clinical trials (Table 1). More promising, improved outcomes in human clinical trials for PD[67−70] and AD patients[71] following treatment with GLP-1 analogues provide additional evidence for the safe use of incretin mimetics for the treatment of neurodegenerative conditions. Only two of the FDA-approved incretin-based mimetics used for the treatment of metabolic diseases, *Bydureon* (AstraZeneca) and *Victoza* (Novo Nordisk), have entered into clinical trials for the treatment of a neurological disorder, although newer drugs are also currently being explored for similar trials (Table 2). Sustained release formulations of incretins are becoming available and have been used in human models of PD[67] and AD[71] and animal models of AD,[55] PD,[60,72,73] and TBI.[74] Recent studies of a unimolecular dual GLP-1/GIP receptor coagonist[41] have shown therapeutic promise in animal models of mTBI[75] (Table 1) and other neurodegenerative diseases.[39,40,76,77] The latest iterations of incretin-based analogues utilize unimolecular GLP-1/GIP/Gcg receptor triagonism[42] and have been shown to provide neuroprotection in models of AD.[78,79] These novel incretin mimetics likely provide similar neuroprotection and mitigation of neurodegeneration in models of TBI.

Traumatic Brain Injury: A Public Health Perspective.

The United States Center for Disease Control's (CDC) analysis of 2013 health care data finds that there were approximately 2.5 million TBI-related emergency department (ED) visits, 282 000 TBI related hospitalizations, and 56 000 TBI associated deaths,[104] all increases from previous estimates.[105] Although hospitalizations related to TBIs have remained consistent, TBI-related visits to the ED have escalated dramatically. Between 2007 and 2013 there was a 32% increase in overall TBI-related ED visits,[104] further corroborated by two other separate analyses showing significant upsurges in TBI related ED visits between 2006−2010[106] and 2007−2010.[107] The 2006−2010 analysis found a 56% rise in TBI-related hospitalizations, despite only a 3.6% increase in total ED visits. Increased public awareness of TBI, specifically of mild forms, has likely led to this rise in ED visits.[106] Increases in TBI-related ED visits include those associated with sports injuries, which saw a 65.9% rise in annual visits between 2006 and 2011 (65 516 to 105 384 annual visits).[108]

Epidemiological analyses of these trends is difficult to assess, although a similar conclusion can be made from them all: TBI remains a significant health issue for millions of people, both immediately following the injury and in the years and decades following. Estimates indicate approximately 3.2[109] to 5.3 million[110] Americans are currently living with a long-term disability associated with a TBI incident, albeit these estimates likely underestimate actual incidence due to underreporting from those sustaining a TBI and the lack of high quality monitoring data.[11,111] Long-term outcomes following a pediatric TBI are especially difficult to assess. Children, especially boys, are highly vulnerable to TBI.[112] Boys are less likely to wear head protection and are more likely to be injured deliberately causing much of the injury disparity compared to girls.[113] Whereas much of the general public's focus and interest in TBI stems from sports-related injuries, elderly individuals' falls are most associated with the increases in TBI-

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

related ED visits.[104] The elderly population has lower thresholds of injury severity that result in higher mortality and worse functional outcomes than younger individuals.[114,115] This, combined with higher medication use and comorbid conditions, exacerbate poor outcomes in the elderly.[104] Globally, TBIs result in over 10 million deaths per year. It is not currently known how many individuals are living with a disease/disability resulting from a previous TBI, but approximately 60 million individuals worldwide have previously been hospitalized for TBI-related injuries.[110]

Military personnel remain at high risk for TBI. The Global War on Terrorism in the Middle East and ongoing military operations in Iraq and Afghanistan have spanned 16 years and have involved more than 2.7 million U.S. and coalition personnel.[116] TBI is referred to as the "signature wound" of the ongoing military conflict due to the higher rates of these injuries than in prior conflicts. United States personnel TBI cases are in addition to many more cases in enemy combatants and the unfortunate innocent citizens of the countries in which the combat has occurred. Blast injury is the main cause of casualties and TBI, resulting from enemy combatants' increased use of improvised explosive devices (IEDs), rocket-propelled grenades, and landmines. Estimates range from approximately 15%[117] to 19.5−22.8% of all returning deployed US troops[118,119] having suffered a blast exposure TBI, with total cases of military related TBI injuries between the years 2000 and 2018 reaching greater than 383 947.[120] For this assessment, only the highest severity injury was recorded for individuals who sustained more than one TBI. On the basis of the updated 2015 version of the International Classification of Diseases[121] (Figure 2A), roughly 82% of all military related TBIs between 2000 and 2018 can be classified as mild.[120]

Diagnosis of blast induced TBI is often delayed. Military personnel are 8.4 times more likely to be diagnosed with a TBI within 4 weeks following return from deployment than before entering combat.[122] Chances of a TBI diagnosis remain heightened for over a year, with reasons ranging from a lack of recognition or underreporting of experiencing high-risk events by those injured during combat to riskier behaviors upon return home.[122,123] Long-term outlook for military personnel diagnosed with an mTBI have shown increased risks for developing PD[124] and dementia[125] years after initial injuries. Commonly referred to as "shell shock" or "post-concussion syndrome" during World Wars I and II, closed head injuries related with proximity to explosions resulted in symptoms including amnesia, concentration issues, headache, and dizziness. During these wars, debate on whether these symptoms were of psychological or physical manifestation were unclear;[126] however, scientists now understand clear physical connections between injuries from blast exposure and many of the symptoms observed.[127]

Increasing evidence suggests that both single and repetitive TBI injuries can lead to the development of neurodegenerative diseases with possible dose- and frequency-dependent correlations;[11,128] however, genetic predisposition and environmental factors likely play a key role in the threshold for clinical manifestation.[129−133] Moderate and severe TBIs require high levels of monitored care, although mild injuries can also result in long-term deleterious health effects. In addition, cognitive deficits and behavioral or emotional changes such as irritability, poor memory, attention, and depression may manifest.[134] Whereas many symptoms of mTBI may resolve rapidly, deficits can be evident years later, often unattributed to the initial injury.

Although much of the mystery surrounding the long-term effects of TBI remain today, advances in diagnostic metrics and severity assessments have the potential to change disease outlook and treatment options. Since the 1970s, diagnosis of TBI severity has relied on using the Glasgow Coma Scale (GCS), which scores patients' ability to open eyes, respond verbally, and perform a motor response[135] (Figure 2B). Scores range from 3 to 15, with lower scores associated with the most severe TBIs and higher scores with injuries considered moderate or mild. Even though it is an easy to use tool for TBI diagnosis and potential prognosis, the GCS does not provide objective readouts underlying patient specific pathophysiological sequalae that underpin such diverse outcomes,[2] especially with regard to severe trauma in elderly patients.[136,137] New technologies in brain imaging[134] and blood biomarker surveillance[138−140] are in rapid development and will likely be standardized in the near future. This will be particularly helpful for long-term diagnoses and potentially be used for early identification of secondary disease manifestations such as the that of CTE.[141] Use of blood biomarkers remains in its relative infancy, with the FDA approving the first blood test for TBI patients in 2018.[142,143] A quick turnaround is clearly essential for these tests to be effective, and once standardization is achieved, this will represent a shift to biological readouts to diagnose TBI, instead of or in combination with the commonly used, and still useful, GCS. Moreover, simple blood tests may potentially decrease the costs of healthcare by decreasing the needed number of procedures such as head scans for many mTBIs.

Mechanisms of TBI Damage. Despite the diversity of TBI cases and their outcomes, all CNS trauma pathology is determined by primary and secondary phases of injury. Immediately following a contusion; primary injury includes mechanical force damage to the brain that can rapidly cause neuronal cell necrosis (limited to the epicenter in mild cases), axonal injury, disruption of the blood brain barrier (BBB), reactive oxygen species (ROS) release, and spreading excitatory neurotransmitter release and depolarization[65,144] (Figure 3A). A hallmark of diffuse TBI is axonal damage, with visible degeneration of white matter tracts, as evidenced in CT and magnetic resonance imaging (MRI) brain imaging studies.[145,146] Stretching and shearing of cell membranes from TBI cause rapid sodium and calcium ion influx into neurons, resulting in cell membrane depolarization.[147] Shortly after the primary TBI injury, neutrophils arrive to contain the damage by removing cellular debris and damaged cells, although their action can also have pathogenic effects, especially in more severe TBIs.[148] In events such as TBI, damaged neurons undergoing nonapoptotic death release danger-associated molecular patterns (DAMPs), including S-100 proteins and other alarmins,[149,150] into the extracellular space where they can activate cytokine and pattern-recognition receptors (Figure 3B). Activation of these receptors, including purinergic and toll-like receptors (TLRs), especially on astrocytes and microglia, initiates an inflammatory response.[151]

Microglia are the resident macrophages of the brain and are endowed with highly motile processes that survey the brain for damage and maintain homeostasis.[152] DAMPs inform an immune reaction that causes a phenotypic shift in microglia from a resting or "surveying" state in to an "activated" pro- or anti-inflammatory state, traditionally referred to as M1 and

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

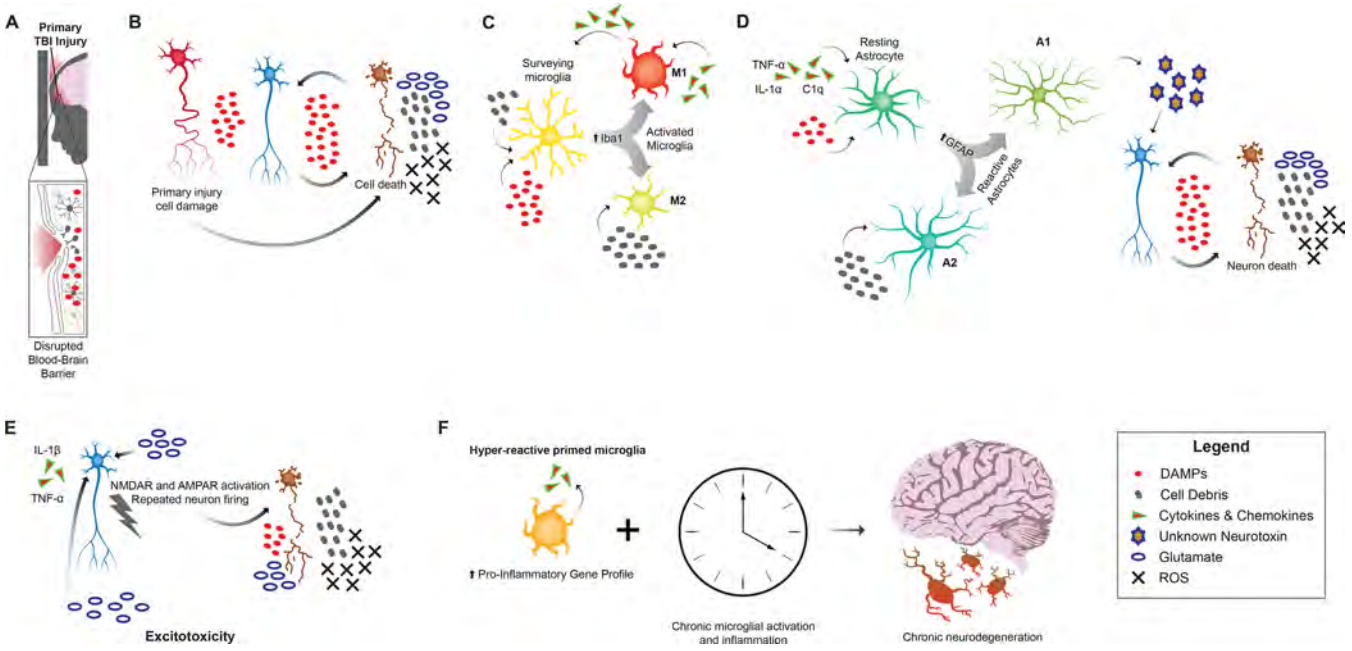

Figure 3. Mechanisms of TBI damage depend on severity. The primary TBI injury is scaled in the focal region and includes disruption of the blood-brain barrier (A) and direct injury to cells (B). This can result in cell death and release of intracellular contents including neurotransmitters, ROS, and other cell debris which act upon surrounding cells in a cascading fashion. Microglia phagocytize cell debris and detect damage signals that result in increased Iba1 expression, phenotypic shifts, and altering roles for microglia (C). M1 microglia act in a pro-inflammatory manner, releasing cytokines and chemokines that act in a paracrine and autocrine fashion alerting surrounding cells that damage has occurred. This initiates recruitment of other cells to respond. M2 microglia maintain a phagocytic role and continue to clear cell debris and release anti-inflammatory cytokines. DAMPs from damaged cells and cytokines released from M1 microglia, including Il-1α, C1q, and TNF-α, act upon resting astrocytes and initiate the formation of reactive astrocytes, most commonly characterized by increases in GFAP expression (D). A2 astrocytes are theorized to be reparative and maintain a phagocytic capability, clearing damage, while A1 astrocytes lose this ability and produce an unidentified neurotoxin that acts on surrounding neurons. Following TBI, astrocytes have decreased capability to transport free glutamate. This, compounded with cytokine, specifically TNF-α and IL-1β, initiated increases in glutamate production in neurons and the activation of glutamate receptors from excess interstitial glutamate, causes a classic excitotoxic response that damages healthy neurons and eventually can lead to cell death (E). Microglia affected during the TBI injury or secondary phase of the injury may become chronically activated with an overall increased pro-inflammatory profile (F). These cells are hyper-reactive to inflammatory stimuli (including subsequent TBIs) and have been implicated in the progression of long-term neurodegeneration and related diseases.

M2, respectively[153] (Figure 3C). However, this commonly used dichotomous nomenclature does not fully encompass the phenotypic diversity of microglia,[154] further supported by recent single cell RNA-sequencing of microglia throughout a mouse lifespan and following injury[155] as well as characterization of region-specific genetic diversity in mice[156] and rats.[157] Indeed, previous studies have shown varied activation states of microglia across a wide variety of models of TBI,[158] although a more thorough investigation of the diversity of microglia populations following this acute insult is needed. Markers of general microglia activation include antibodies to ionized calcium-binding adaptor molecule 1 (Iba-1) and/or some combination of others such as CD68 or CD11b.[159] A recent murine-based study found that following mTBI-induced disruption of the BBB, there is damage to the glial limitans—a barrier of astrocytic GFAP-positive endfeet tiling nearly all cerebrovascular basal lamina and that is central to the selective permeability of the BBB—resulting in a purinergic receptor-dependent recruitment of microglia to support or replace the damaged astrocytes. These microglia formed a phagocytic barrier, preventing further leakage into the brain parenchyma and provided neuroprotection early in the injury.[144] This is just one example of the many roles of microglia during a traumatic pathological event. Regardless of the current microglial heterogeneity debate, chronic activation of microglia is a hallmark of secondary TBI injury in humans. This has been demonstrated up to 17 years post-TBI *in vivo*[146] and in post-mortem tissues.[160] Inflammation can persist years after a single TBI event in humans,[160] and animal models of TBI show chronic microglial activation as a primary mechanism for TBI secondary injury and CNS deficits.[161,162] Chronic microglial activation in the thalamus, remote to the focal injury, is closely related to the amount of thalamocortical damage.[146] Preliminary evidence in human TBI patients indicates a correlation between increased chronic thalamic microglial activation and greater cognitive deficits.[146] Furthermore, diffusion tensor MRI studies in humans support the hypothesis that damage to thalamico-cortical fiber tracts is a key factor underpinning deficits in executive function following TBI.[163] Additional evidence comes from age-dependent upregulation of activated microglia in the thalamus in healthy individuals and in several cortical regions in humans with AD.[164]

Microglia in brains of people subjected to insult, injury, or disease, as well as microglia in aging, are often found to be in a "primed" state; that is, microglia that express a pro-inflammatory gene profile and exhibit a hyper-reactive inflammatory response to subsequent disturbances when compared to naïve cells.[165−167] Such priming of microglia is also thought to contribute to long-term effects of even a singular TBI event. Subsequent TBIs exacerbate the inflam-

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

mation response in these cells[166,168] (Figure 3F). In addition, chronically activated microglia interact with neurons, removing excess synapses,[169,170] and release higher basal levels of cytokines.[168,171] In animal models of brain injury and aging, Kim Green and colleagues have experimented with "resetting" the microglial phenotypic profile by pharmacologically (via colony-stimulating factor 1 receptor inhibition) ablating primed microglia and repopulating them via drug withdrawal. Microglia-depleted mice experience no behavioral deficits,[172] and when repopulated following injury or in aging models, microglia are morphologically naive. These animals experience decreased inflammation profiles, rescued behavioral outcomes, and increased dendritic spine numbers.[173] Aged mice with repopulated microglia show similar microglial densities, morphologies, and overall gene expression profiles as those of young adults, with increased neuronal function and reversal of impairments in long-term potentiation (LTP).[170] Though responses to inflammatory stimuli remain unchanged in the repopulated microglia, these improvements are notable. Importantly, this reveals links to long-term deleterious implications of primed microglia involvement in chronic neurodegeneration and the aging process. Another recent study corroborates Elmore et al. (2018)[170] with findings that microglial repopulation in aged mice reverts microglial phenotypes but does not change responses to subsequent inflammatory stimuli; deleterious environmental cues such as astrocyte activation remain after repopulation and contribute to hyper-reactivity of the new microglia.[174] Microglia depletion and repopulation therapies have been tested successfully across a wide range of animal models.[175] Only recently has this therapy been utilized in a TBI model, reducing both inflammation-related gene profiles and astrogliosis following injury.[176] Future research is needed to show cognitive effects of microglia replacement following TBI.

Shortly after TBI, cytokine and chemokine protein expression are upregulated.[177] This orchestra of proteins includes CCL2, CCL20, CCL21, Il-1α, IL-1β, IL-6, IL-10, TNF-α, IL-8, iNOS, MHCII, IL-12p40[177−179] and the complement cascade (including C1q and complement component 3 (C3)).[180−182] These proteins facilitate a panoply of both deleterious and restorative processes[179] and can act in a paracrine or autocrine fashion. Increased C3 active fragments are observed in human TBI patients.[181,182] In mouse models, pharmacological inhibition of C3 active fragment formation[183] and C3 knock out (KO) mice[184] provide neuroprotection following TBI. Release of Il-1α, TNF-α, and C1q by activated microglia is sufficient to induce the formation of neurotoxic A1 astrocytes that produce a neurotoxin capable of inducing rapid death of subsets of neurons and oligodendrocytes[185] (Figure 3D). This so-called "A1" astrocyte profile, characterized by high C3 protein expression (among others), is prevalent in normal aging[186] and chronic neurodegenerative diseases such as PD, AD, ALS, and HD.[185] Normally aged triple-KO mice (mice that do not produce Il-1α, TNF-α, and C1q) have significantly reduced A1 gene profiles,[186] highlighting a role for primed microglia in the development of this cell phenotype in normal aging. Microglia depletion therapy in mice prevented TBI-induced increases of IL-1α and C1q and downstream astrogliosis.[176] There is increasing interest in the role of C3 and the complement cascade in the exacerbation of secondary injury and chronic neuroinflammation following TBI.[180] Recent work shows that targeted inhibition of C3 activation in a controlled cortical impact (CCI) TBI model improves cognitive recovery and inhibits chronic neuroinflammation and neurodegeneration.[187] Furthermore, aged C3 deficient mice lack age-related neuronal functional deficits in the hippocampus,[188] and pharmacologic or genetic inhibition of the complement pathway following TBI in aged mice prevents cognitive deficits.[189] The acute inflammatory environment immediately following a TBI and the long-term elevation of TNF-α from primed microglia may, likewise, be implicated in impaired memory via altered astrocyte activity and signaling,[190] again highlighting the importance of understanding the crosstalk between multiple cells types following brain trauma. It is important to note that the inflammatory response is not wholly adverse. For example, inflammatory mediators such as TNF-α also induce CNS repair. In a TBI model using transgenic mice that did not produce TNF-α, wild type mice recovered motor function faster and experienced less cortical tissue loss from the injury.[191]

Astrocytes respond to pro- and anti-inflammatory cytokines in a "context-dependent" manner that allows for a diverse range of phenotypic subtypes.[192] These "reactive astrocytes" have traditionally been characterized by increased GFAP expression;[193] however, increased GFAP expression is not limited to the A1 variety[194] (Figure 3D). Indeed, GFAP is an important marker for TBI pathology, as upregulated levels of astrocyte-derived GFAP in the blood serum of TBI patients is recognized as an accurate indicator of TBI severity.[143] Though not fully understood, GFAP serum levels in older patients may not be as accurate an indicator of TBI as in younger patients.[195] Although the biological role of the "neurotoxic" A1 astrocytes is not well-defined, this cell population is clearly involved in the neurodegenerative process. Importantly, such a role is not exclusive among astrocytic involvement in TBI. Participation of other inflammation-induced subtypes of astrocytes, such as the "A2" variety,[194] appear to play crucial roles in mitigating TBI pathology by providing neuroprotection via a variety of mechanisms.[192,196] In synopsis, glial cells appear to take on many different activities during pathological events, and it is the balance between these that ultimately defines the final outcome.

Excitotoxicity is a common pathological feature of secondary TBI injury arising from excess extracellular glutamate, the prominent excitatory neurotransmitter[171,197] (Figure 3E). Regional microdialysis studies have reported elevations of glutamate immediately following TBI that appear to depend on both injury severity, with a prolonged elevation in severe traumas, and the number of physiological variables involved.[198−200] Astrocytes are largely responsible for the uptake of extracellular glutamate via glutamate transporters[201] and following TBI, decreased expression of these transporters in astrocytes has been demonstrated in animal models[202] and in humans.[203,204] Astrocytes[205,206] and microglia[207,208] responded to TNF-α by amplifying glutamate release. TNF-α, together with Il-1β, increases neuronal production and release of glutamate, further escalating extracellular levels of the neurotransmitter[209] (Figure 3E). Research describing the role of TNF-α in mediating excess interstitial glutamate is growing, and there is extensive interest in using drugs to reduce this cytokine's activity across a wide variety of CNS conditions and injuries.[210,211] Excess glutamate leads to overstimulation of postsynaptic glutamatergic receptors, specifically the *N*-methyl-D-aspartate receptors (NMDARs) and 2-amino-3-[3-hydroxy-5-methylisoxazol-4-yl] proprionate receptors (AMPARs), which allow calcium entry into cells and causes neuron

Table 3. Pharmacologic or Genetic Intervention of Cell Death Pathways in TBI[a]

Pharmacologic or Genetic Intervention	TBI Model/Outcome
Caspase-8 -/-	• *CCI*: Reduced injury size, apoptosis, reduced caspase-3 processing[a]
Caspase inhibitors	• *CCI* + secondary insult: Reduced contusion size, caspase-3 activity and DNA fragmentation but no functional benefit[b] • *FPI*: Improved motor and spatial learning[c] • *CCI*: Improved motor and cognitive function[d] • *CCI*: No improved functional or histological outcomes but reduced caspase-3 activity and cytochrome c expression[e]
Cyclin D1 -/-	• *CCI*: Reduced cell cycle activation, decreased lesion volume and microglial activation[f]
Cell Cycle inhibitors	• *FPI*: Decreased neuronal cell death, lesion size, glial activation, and improved cognitive recovery[g] • *FPI*: Decreased glial activation, oxidative stress, neuronal cell loss, and improvements in cognitive function[h]
p53 -/-	• Improved neuromotor function (cell loss not attenuated)[i]
p53 inhibitors	• *CCI*: Reduced lesion size and inhibition of NF-κB[j] • *CCI*: Decreased contusion volume, apoptosis, protection from glutamate excitotoxicity[k] • *CCI*: Improved motor deficits and memory and decreased apoptosis and apoptosis related gene expression[l] • *CCI*: Improved motor deficits and reduced oxidative damage, glial activation, inflammation, and apoptosis[m]
PARP -/-	• *CCI*: Improved motor and memory function but no effect on contusion volume[n]
PARP-1 inhibitor	• *FPI*: No effect on TUNEL-positive apoptotic cells but significantly reduced lesion size[o] • *CCI*: Decrease neuron death, microglial activation, and neurological deficits[p] • *CCI*: Reduced inflammation and glial cell activation[q]
AIF deficient (hq_{hom})	• *CCI*: Decreased neuronal cell death[r]
CypA -/-	• *CCI*: Reduced apoptotic cells and improved motor and cognitive recovery[s]
Bax Inhibitor-1 Tg	• *CCI*: Reduced brain lesion volumes and improved motor performance[t]
Bcl-2 Tg	• *CCI*: Reduced lesion volume in cortex and hippocampus with reduced glial cell activation[u] • *CCI*: Reduced lesion volume. No effect on composite motor scores or hippocampal death[v]
Bid -/-	• *CCI*: Decreased early cell death and tissue damage but no effect on functional outcome deficits[w]
Bax -/-	• *CCI*: Improved neurogenesis and increased neural progenitors[x]
TNFR -/-	• *CCI*: Reduced cortical lesion volume and improved BBB integrity[y]
MnSOD Tg	• *CCI*: Reduced cortical lesion volume and improved BBB integrity[y]

[a]Evidence for mechanisms of cell death in TBI are shown from pharmacologic (red) or genetic (green) disruption of these pathways. Included are transgenic (Tg) and knockout (−/−) animals of relevant cell death pathways. Effects of these interventions following TBI are shown on the right. Adapted from Schoch et al. (2012).[255] CCI = controlled cortical impact; FPI = fluid percussion injury; hq_{hom} = homozygous Harlequin mice. Sources: (a) 241; (b) 242; (c) 243; (d) 244; (e) 245; (f) 228; (g) 227; (h) 229; (i) 246; (j) 232; (k) 233; (l) 238; (m) 20; (n) 218; (o) 247; (p) 217; (q) 220; (r) 248; (s) 222; (t) 249; (u) 250; (v) 251; (w) 252; (x) 253; (y) 254.

depolarization and further glutamate release.[212] Overstimulation of these receptors leads to intracellular ionic imbalance, with excess calcium playing important roles initiating intracellular cascades and cell damage (Figure 3E). Altered calcium homeostasis can lead to calcium-dependent cysteine protease, or calpain, activation which amplifies pro-apoptotic signaling, including activation of BID, BAX, and p53, while decreasing antiapoptotic Bcl-2 protein. This leads to neuronal dysfunction and apoptosis,[213] and at very high levels of calpain activation, necrosis can result.[214]

In response to elevated levels of ROS and subsequent DNA damage during TBI, overactivation of poly(ADP-ribose) polymerase-1 (PARP-1) may result and is associated with depletion of cellular energy stores and necrosis.[215] PARP-1 inhibition shows improved outcomes in animal models of TBI[216−218] (Table 3) and increased expression of PARP-1 has been demonstrated following human TBI.[219] Along with its involvement in microglial activation,[217,220,221] PARP-1 promotes the mitochondrial release of apoptosis inducing factor (AIF) and its carrier protein cyclophilin A (CypA).[222,223] AIF is then translocated to the nucleus where it initiates chromatin condensation, DNA fragmentation, and ultimately cell death[223] (Table 3). Uniquely, this cell death pathway is caspase independent.[222] Additional cell death mechanisms can involve the initiation of cell-cycle activation (CSA). Neurons are postmitotic cells though CSA pathways may be reinitiated from oxidative stress and DNA damage induced from TBI or other insults.[224,225] This is supported by increased expression of the CSA markers cyclin D1, CDK4, E2F5, c-myc, and PCNA and downregulation of cell cycle inhibitors following TBI.[226] Genetic or pharmacologic inhibition of CSA in animal models of TBI show decreased cell death, glial activation, lesion size, and improved cognitive recovery[227−229] (Table 3).

Following even mild cases of TBI, apoptotic pathways rise acutely and are sustained in the long term.[230] Hyperactivity in neurons and decreased blood flow to the focal injury leads to increased metabolic stress and subsequent depletion of adenosine triphosphate (ATP) stores. This may cause high levels of ROS which can lead to cell death.[231] Within neurons, the transcription factor p53 is activated and results in delayed apoptotic cell death in the subacute period after TBI (as well as in response to oxidative stress, glutamate excitotoxicity, and other insults). In a CCI model of TBI in mice, p53 levels were found to be elevated in the brain as early as 15 min after the TBI procedure and time-dependently rose and was sustained over time.[232] At 5 h after TBI, a robust increase in p53-labeled

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

cells was evident within the site of maximal CCI injury in the brain.[233] Stable inhibitors of p53 (Table 3), pifithrin-α (PFT-α) and analogues,[234,235] have been shown to minimize apoptotic cell death by inhibiting p53 transcriptional activity and preventing p53-dependent activation of apoptotic pathways.[236,237] This is also purported in rodents challenged with CCI-induced moderate TBI[20,232,233,238] as well as weight drop-induced mild TBI,[18] resulting in substantial mitigation of ensuing neuronal loss and cognitive deficits with a therapeutic window of 5 to 7 h after injury. These studies clearly demonstrate that the secondary TBI phase of cell death involves apoptosis and that post-TBI inhibition of apoptotic mechanisms can mitigate the associated deficits. Whereas PFT-α and analogues are pharmacological tools to inactivate p53-dependent pathways; importantly, approved classes of drugs can likewise prevent neuronal p53-dependent apoptosis *without* the potential concerns of globally blocking p53 activity. In addition to transactivation of multiple apoptotic gene pathways within the nucleus, p53 also mediates apoptosis by binding and inactivating the antiapoptotic proteins Bcl-xL and Bcl-2 on the mitochondrial surface and directly activating the apoptotic proteins Bak and Bax. Mitochondrial p53 translocation induces mitochondrial outer membrane permeabilization (MOMP) via Bak and Bax, release of mitochondrial proapoptotic factors (e.g., cytochrome *c*, Smac/DIABLO, PUMA, and AIF) into the cytosol, and subsequent activation of caspase 3-dependent apoptosis.[234,236,237,239,240] A thorough summary of the effects of various genetic and pharmacologic disruptions of cell death pathways following TBI is shown in Table 3.

Animal Models of TBI. Significant heterogeneity across the spectrum of clinical TBI subtypes necessitates a wide range of models to mimic aspects of human injury. Although similar GCS scores may indicate similar levels of injury, the appearances of those injuries can vary widely, including the presence of hematomas, cerebral contusions, pneumocephaly, hemorrhaging, and subdural hydromas,[256] or none of these at all. A wide range of models of TBI are necessary to evaluate the random nature of the injury. Although larger animals have been used in modeling TBI,[257] their expense and ethical concerns have shifted the scientific community to primarily use rodents for these studies. Arguments for the use of larger animals in these studies cite differences in the size and structure of rodent brain compared to human (lissencephalic versus gyrencephallic), clinically relevant monitoring ability (intracranial pressure, brain tissue oxygen content, and cerebral blood flow), and possible differences in mechanisms of repair.[257,258] The body of work using rodent models continues to grow due to the low cost, standardized methodologies, especially regarding behavioral testing, and ease of manipulating complex molecular cascades via pharmacologic or genetic means[255,259] (see Table 3). A focus on animal models that resemble mild human head injury is essential, as a majority (>70%) of human TBI's are classified as mild.[260]

The most commonly used models include the weight drop (WD) method, controlled cortical impact (CCI), and fluid percussion injury (FPI), and more recently models of blast injury to understand the large number of TBI cases from military personnel (all reviewed extensively).[3,259] Although rodents are primarily used in these models, they are amenable to larger species.[3] The CCI and FPI models require removal of a piece of skull (craniectomy in CCI and craniotomy in FPI) in a region of interest and are defined by a controlled pressure pulse initiated by either the tip of a rod attached to the CCI device or a pendulum striking a piston attached to a reservoir of fluid for the FPI device. Albeit the direct impact onto the dura and method of injury makes these models not completely analogous to common head injuries seen in humans, they are particularly effective at consistent and graded injuries.[3] The WD and blast models of TBI both utilize closed head injuries whereby a weight is dropped through a cylindrical tube of a predetermined height (such as 80 cm) and onto the head of an anesthetized mouse or the anesthetized mouse is exposed to some variation of blast waves from a controlled open-field explosion of TNT.[3] Due to the limitations and danger of explosives, increased use of "shock tubes" that use compressed gas to deliver shock waves are expanding the research of blast TBI.[261] These injury models closely resemble common clinical cases of TBI incurred through falls, sports injuries, traffic accidents,[262] or on the battlefield.[261]

The use of standard behavioral assays in rodent models are valuable for understanding cognitive deficits in human TBI, often considered a silent symptom of the condition. WD, CCI, FPI, and blast TBI models all demonstrate cognitive deficits (cited in Table 4). This is manifested in a neurological severity score (NSS), which combines behavioral and motor function performance tests (see ref 263), or in some cases, more simplified behavioral assays of memory such as the novel object recognition (NOR) or Y-Maze spontaneous alteration tests.[3] Previous WD-based studies confirm the visual memory deficits demonstrated by the NOR test at 7 and 30 days post-TBI,[81,84,264−266] although memory deficits demonstrated via the Y-maze are often evident but not as consistent across these same studies. This highlights the heterogeneity across mTBI injury and potential inconsistency in delivery of the TBI, which is in line with the human condition in which no two TBI events are identical. Depressive effects of mTBI are evaluated by the forced swim test and have been observed 7 days (for the 70 g WD) and 30 days (50 and 70 g WD) post-TBI. This is notable, as depression is a common symptom in human TBI patients.[267]

In addition to assessing behavioral and motor outcomes, WD, CCI, FPI, and blast models of TBI demonstrate a wide variety of pathophysiological sequelae similar to human TBI including (a) neuroinflammation, epitomized by increased cytokine production and microglial (increased Iba1 expression) and astrocyte (increased GFAP expression) activation; (b) apoptotic signaling and cell death/neurodegeneration indicated by increased TUNEL and BID positive cell staining, decreased neuronal nuclei (NeuN) staining, and increased protein expression of proapoptotic AIF, BAX, and caspases; (c) decreased synaptic plasticity and function shown by deficits observed in long-term potentiation (LTP) in brain slice preparations and decreased synaptic protein expression, such as synaptophysin; (d) blood-brain barrier degradation as evidenced by Evans blue dye or other blood-originating tracers entering into brain tissue following TBI; (e) oxidative stress shown by increased production of antioxidants, ROS, or remnants of oxidation such as malondialdehyde using thiobarbituric acid reactive species (TBARS) assays in brain tissue; and finally (f) glutamate regulation dysfunction shown by decreases in glutamate transporters, RNA sequencing data, or increases in free extracellular glutamate. A summary of the many studies demonstrating the effects observed in WD, blast, FPI, and CCI TBI models is shown in Table 4. Work demonstrating glutamate toxicity is lacking across all models

[a]The weight drop (WD), blast, fluid percussion injury (FPI), and closed cortical impact models of TBI effectively model pathophysiological sequalae of TBI in humans. Differences in reproducibility and applicability to human injury should be assessed before using one model over another, as each model has its own positive features and caveats. BBB = blood-brain barrier.

and generally relies on indirect indicators of glutamate regulation issues. Although rodent models of TBI are extremely useful, development of standardized models of TBI in larger animals should facilitate transfer to clinical trials.[258]

Incretin-Based Signaling To Counteract TBI Damage Mechanisms. GLP-1 and GIP are gastrointestinal peptide hormones with well-studied functions in glucose-dependent insulin secretion. Gcg has an opposing physiological effect, increasing glucose concentrations in the blood. As members of the glucagon peptide family, GLP-1 and Gcg are derived from the same proglucagon gene, while GIP originates from the GIP gene.[335] All three peptides are susceptible to cleavage and neutralization by the enzyme DPP-IV (Figure 1), reducing active endogenous levels of each within minutes after production and release.[29,30] Three forms of endogenous GLP-1 have been studied for their insulinotropic effects: the full-length form of GLP-1 (1−37), the truncated form of GLP-1 (7−37), and the truncated amide form (7−36 amide). Only the truncated forms have been found to stimulate glucose-dependent insulin secretion, while the full-length form appears inactive.[336] Most of the truncated GLP-1 that is produced undergoes amidation on its c-terminal glycine to form GLP-1 (7−36) amide. The benefit from amidation is unknown; it is thought that the amide form is more stable in the circulation, considering that GLP-1 (7−36) amide constitutes 70% or more of circulating GLP-1.[337]

The receptors for GLP-1, GIP, and Gcg are class B G-protein coupled receptors (GPCRs). Although the receptors for GIP and GLP-1 are predominantly expressed in the pancreatic islet cells[21,22] and those of Gcg in the liver,[338] all three are present in the CNS.[339−341] GLP-1R, GIPR, and GcgR mRNA are chiefly expressed in neurons,[342] and differential GLP-1R protein expression has been observed throughout the brain.[343,344] Under pathological conditions, such as in PD or TBI, expression of GLP-1R mRNA in affected brain regions and cells types can change drastically.[345] Observations in a mouse model of PD demonstrate decreased expression in neurons and 2-fold increases in microglia.[93] Additionally, human PD cases show 10-fold increases in GLP-1R expression in the substantia nigra.[93] These receptors have seven α-helical transmembrane domains (TMDs), a classic signature of all GPCRs, and an N-terminal extracellular domain (ECD) typical of class B GPCRs. The TMDs bind the N-terminal portion of the truncated GLP-1 peptide and the ECD binds the C-terminal portion of the peptide,[346] with multiple binding sites biasing activated intracellular cascades.[347−349] Unlike class A GPCRs, the class B ECD acts as more than an affinity trap, as both the ECD and TMD are responsible for class B GPCR activation.[350] All three receptors' activation can lead to neuroprotection and neurotrophic effects through multiple pathways.

Activated receptors interact with Gαs and dissociate the trimeric G protein to activate adenylyl cyclase and subsequent conversion of ATP to cAMP[27,335,351] (Figure 4). Upon GLP-1 addition, cAMP concentrations reach a peak at the 15 min time-point in PC12 cells,[33,51] neuroblastoma SH-SY5Y cells,[352] and rat hippocampal cells,[35] leading to cAMP-dependent protein kinase A (PKA) and exchange protein activated by cAMP (Epac) activation.[353−355] PKA directly activates the cAMP-responsive element binding protein (CREB) by phosphorylating Serine 133 on the protein.[356] CREB is a transcription factor with a well-studied role in neuronal plasticity and neuronal survival; it is regulated by multiple

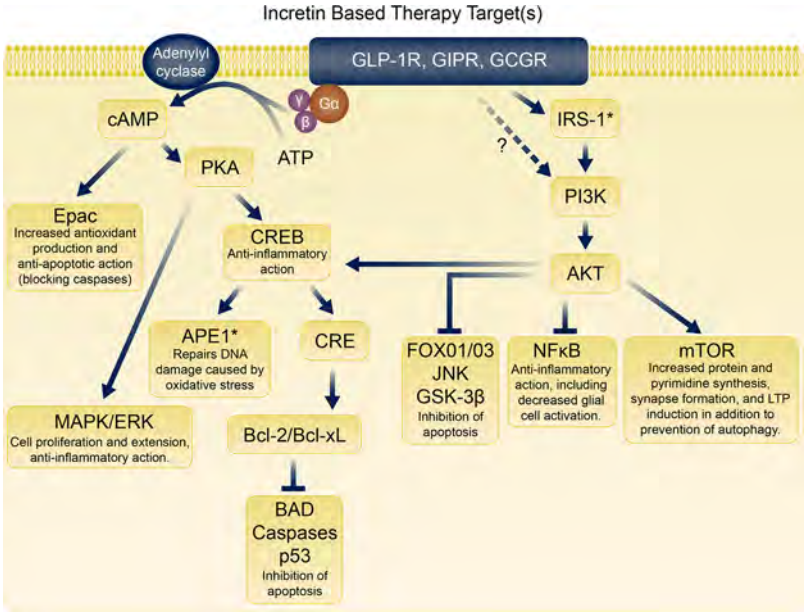

Figure 4. Incretin-based signaling to counteract TBI. Incretin based therapies target key cell signaling pathways that counteract TBI secondary phase injury. These include mechanisms to decrease apoptosis, inflammation, and oxidative stress, while also promoting repair. *Only demonstrated through GLP-1R agonism.

pathways in addition to the cAMP associated route, including the phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K)/AKT pathway.[357] Epac activation leads to similar downstream events.[354] Increasing circulation times of endogenous GLP-1, GIP, and Gcg via DPP-IV inhibition increases CREB activation.[91] Furthermore, Perry et al.[33] showed that activation of PKA nonessentially enhances GLP-1 mediated neuroplasticity in PC12 cells, and PI3K and ERK were found to play a role in neurite extension as a result of GLP-1R activation.[33]

The mechanism of GLP-1R/GIPR/GcgR activation of the PI3K pathway is unclear. However, GLP-1R appears to initiate this neurotrophic pathway near its beginning, as activation of the upstream protein, insulin receptor substrate-1 (IRS-1), was found to be markedly increased one hour after Ex-4 administration in hypothalamic neurons[358] (Figure 4). Downstream, the neuronal PI3K pathway branches to produce a variety of protective and neuroplastic effects. AKT, also known as Protein Kinase B (PKB), promotes cell survival by phosphorylating and thereby sequestering pro-apoptotic protein Bad, which normally heterodimerizes and neutralizes the mitochondria associated antiapoptotic protein, Bcl-2. In addition, AKT inhibits p53,[359] Forkhead box protein O1/03 (FOXO1/03), and subsequent production of pro-apoptotic proteins.[335,360] AKT also promotes the activation of mTOR which supports neuronal differentiation and growth by increasing protein synthesis, pyrimidine synthesis, and preventing autophagy.[360] Direct phosphorylation of CREB by AKT further promotes cell survival, possibly in part by inducing the expression of Bcl-2.[361] Numerous benefits of activation of CREB and downstream cAMP responsive element (CRE) by a GLP-1/GIP/Gcg receptor triagonist were recently described in a mouse model of AD.[79] Furthermore, in a secondary analysis of the recent successful 48-week Exenatide-PD trial,[67] researchers extracted neuronal derived exosomes from blood serum of human participants, and within these exosomes, found increased protein levels of IRS-1, AKT, and mTOR.[362] These findings present a clinical context for the positive outcomes of the Exenatide-PD trial, which noted improvements in motor scores for patients, and furthers understanding of GLP-1R agonism in the human CNS.

Following TBI, much of the oxidative stress, excitotoxicity and inflammation observed in the injured brain can be attenuated by incretin-based therapies. Such actions are a clear parallel to antiapoptotic effects provided by GLP-1 and analogues on pancreatic cells[21] and have been demonstrated in neuronal cell culture models[51] and recent mouse models of stroke and chronic cerebral hypofusion.[363,364] Pretreatment of β-cells with Ex-4 and subsequent induction of oxidative stress via hydrogen peroxide (H_2O_2) addition resulted in a 41.7% decrease in apoptosis. This was mediated by AKT inhibition of the c-Jun N-terminal kinase (JNK) and glycogen synthase kinase 3β (GSK3β)-mediated apoptosis pathway[365] (Figure 4). A GLP-1/GIP/Gcg triagonist was also shown to block activation of GSK3β and is thought to be a potential mechanism for rescue of neuronal plasticity deficits in a mouse model of AD.[79] Activation of caspase-9 and -3, two important mediators of apoptosis, was also reduced as a result of this pretreatment. Treatment with Ex-4 in similar H_2O_2-induced oxidative stress experiments resulted in Epac-dependent increases in β-cell production of prominent antioxidant enzymes, including catalase, glutathione peroxidase-1, and manganese superoxide dismutase (MnSOD).[353] Following oxidative stress, activation of PKA and induction of oxidative defense genes *HO-1* and *NQO1* via Ex-4 improved cell viability in human umbilical vein endothelial cells.[366] A recent report describes mitigation of oxidative DNA damage in a model of stroke through neuronal GLP-1R activation and subsequent enhancement of PI3K-AKT-induced expression of apurinic/apyrimidinic endonuclease 1 (APE1),[367] a protein key to amplifying base excision repair of oxidative DNA damage[368,369] (Figure 4). Further evidence for the antioxidant effects of incretin-based therapies comes from the use of the DPP-IV

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

inhibitor sitagliptin in a mouse model of TBI, which resulted in increased MnSOD production and overall improved outcomes[91] (Table 1). In a model of stroke, GLP-1 analogues induced similar increases in MnSOD production.[363]

Another important neuroprotective effect of incretin-based therapies includes a strong anti-inflammatory component, namely the reduction of glial cell activation and related cytokine production. In a model of PD, the GLP-1 analogue NYLO1 (Table 2) blocked the formation of A1 astrocytes, indicated by decreased C3 immunoreactivity. Significant reduction in the number of activated microglia and subsequent production and release of Il-1α, TNF-α, and C1q was also observed.[93] In this model, blocking the formation of A1 astrocytes proved to be a major mechanism preventing neuronal loss, attributable to the attenuated microglial activation. Yun et al.[93] and Athauda and Foltynie[360] point out that reduction in microglial activation or activity by GLP-1R agonists may be the primary mechanism for neuroprotection in models of stroke,[53,58,370,371] PD,[372] ALS,[64] and other conditions.[49,373] GLP-1R agonism in microglia promotes an M2 phenotype induction[58,374] possibly via alternative CREB mediated pathways,[375] increasing the anti-inflammatory and reparative functions of these cells. In models of TBI and related *in vitro* studies, incretin-based therapies have shown efficacy in increasing CREB signaling[75,83,84,91] and anti-inflammatory effects, including reduced glial cell activation and cytokine production using independent administration of GIP[88] and the GLP-1 analogue PT-302[74] (Table 1). PARP-1 is involved in microglial activation[221] and its inhibited expression by GLP-1 and analogues, shown in models of stroke and chronic cerebral hypofusion,[363,364] may provide an additional anti-inflammatory mechanism for GLP-1 based therapies. Finally, inhibition of NF-κB downstream of PI3K and AKT is yet another possible mechanism of GLP-1R agonism for the mitigation of inflammation-related sequalae.[360] NF-κB inhibition is neuroprotective in models of PD[376] and TBI,[232] with DPP-IV inhibitors and GLP-1 analogues significantly suppressing the transcription factor and potentially increasing endogenous inhibitors.[93,360] Though NF-κB induction is neuroprotective when activated in neurons, blockage of glial cell NF-κB induction supersedes this potential benefit through mitigation of the release of inflammatory mediators and other neurotoxic proteins.[377]

In synopsis, incretin-based therapies present a multitude of beneficial signaling end points that can readily be applied to TBI pathophysiological sequalae (Table 4). Considering the strong neurotrophic/neuroprotective, antioxidant, and anti-inflammatory components that underlie the actions of incretin-based therapies, all of which are beneficial for TBI pathophysiological effects, these compounds appear to be ideally suited for introduction into clinical trials for TBI.

Targeting Specific Intracellular Pathways. As shown above, incretin-based mimetics affect a wide variety of intracellular pathways. Interest in the many signaling profiles of GPCRs is growing, including that of incretin receptors, and investigation of how these diverse pathways are activated is an increasingly important area of research for the development of more effective, disease-specific therapies.[378] Evidence of various biased activation sites of incretin receptors, specifically GLP-1R, adds an additional layer of complexity to their known pleiotropic signaling and provides possible opportunities for optimization of signaling pathways to best treat TBI or other neurological disorders with reduced side effects. Recent work has described specific binding sites of the GLP-1R receptor that preferentially activate intracellular calcium recruitment and cAMP and pERK1/2 signaling in insulinoma cells.[349] Adding to this knowledge, replacing the α-amino acids of the endogenous GLP-1 backbone with β-amino acids has helped characterize further nuances in these signaling paradigms.[379] Biased agonism is not exclusively a function of receptor binding sites and ligand structure, but can also depend on effector molecules and adapter proteins recruited to or allosteric modulation of the GPCR.[380] β-arrestin proteins are regulators of GPCR activity, including receptor desensitization.[381] Varying the amino acid backbone of GLP-1R agonists differentially promotes characteristic G-protein signaling (cAMP, etc.) and β-arrestin recruitment,[382] with the impacts of effector molecules or adapter proteins on downstream signaling and phenotypic responses varying.[383] In pancreatic β-cells, for example, β-arrestin 1, recruitment has been shown to help facilitate the antiapoptotic effects of GLP-1 through the phosphorylation of the pro-apoptotic protein, Bad.[384]

As yet, little to no information is available elucidating the occurrence of GLP-1R biased agonism in nervous system tissue or in relation to contributions of GIP or glucagon,[383] but this clearly appears to be a potentially fruitful avenue to evaluate. Furthermore, the differential expression patterns of incretin receptors in neurons or microglia also may add another level of intricacy to understanding the diverse pathways initiated by both endogenous and designer agonists. Interest in nonpeptide GLP-1R agonists is substantial and an example is the experimental diabetes drug TTP273 (Table 2). TTP273 appears to be a functionally biased ligand with a favorable tolerability and low incidence nausea and vomiting.[385] Interestingly, TTP273 lacks any β-arrestin 2 recruitment typical of endogenous GLP-1R agonists,[385] which promotes stereotypic GPCR signaling cascades.[386] β-arrestin 2 recruitment, however, can attenuate this normal signaling pattern, with the GLP-1R/β-arrestin 2 complex increasing the receptor's affinity for glucagon and internalization of the receptor.[386] The route of administration (e.g., oral, subcutaneous injection, or transdermal) can also impact a drug's time-dependent pharmacological actions as well as compliance.[387] Preliminary evidence shows that TTP273 has differential effects on food intake depending on its route of administration.[385] Delivery to target sites is also paramount to initial drug design and, for the treatment of neurological disorders a reasonable BBB penetration is vital to support therapeutic levels being achieved in brain. In the case of TTP273 that was designed for T2DM and likely not intended for neurological disorders, BBB permeability was probably not a key concern during the agent's initial design, with preliminary evidence showing that brain drug concentrations are only 2 to 3% of that of plasma's,[388] similar to Ex-4.[67,74] With these many considerations, understanding the mechanisms of biased agonist signaling may allow for the development of disease tailored drugs, particularly in relation to incretin receptor agonists.

CONCLUSION

In the present review, we have provided an overview of the current literature supporting the use of incretin-based therapies across a wide variety of nervous system disease and injury models, including TBI. The safety, availability, and demonstrated efficacy of incretin-based therapies make them ideal for rapid introduction into clinical trials to evaluate alternative

DOI: 10.1021/acsptsci.9b00003
ACS Pharmacol. Transl. Sci. 2019, 2, 66−91

uses to their already prescribed treatment of metabolic diseases. There is a great and immediate need for an effective drug therapy for treatment of secondary injury related to TBI, especially considering the long-term consequences of even a single TBI injury, including the development of conditions such as PD and AD that can be triggered by TBI. Considering the dangers of even just one TBI, it is encouraging that the general public is heeding current science and increasingly seeking medical attention for head injuries. Unfortunately, there are no treatments for secondary injuries associated with TBI. Incretin-based therapies can fill this pharmacological void, and there is sound and increasing scientific evidence of using translationally relevant doses across both cellular and animal models of brain injury to support trials of evaluating incretin-based mimetics in human TBI. Biased, designer incretin-receptor agonists are currently in development and further work needs to be done to tailor these compounds to neurological disorders. The next questions to consider are as follows: (a) Which of the available agents should be first appraised? (b) Which TBI subjects (mild, moderate or severe) should be evaluated in clinical trials? (c) When should treatment start and how should it be initiated to rapidly achieve and maintain therapeutic brain levels? (d) How long should treatment continue? (e) What biochemical and clinical outcome measures should be evaluated to define target engagement and response? With the use of the dose and route of administration approved and found effective for the treatment of T2DM, it is encouraging that several FDA approved incretin-based therapies and other emerging analogues are making their way into clinical trials for neurological diseases. A concerted effort is needed to effectively apply these safe and efficacious drugs to trials for TBI treatment.

ABSTRACT

Mammea-type coumarins are a particular type of secondary metabolites biosynthesized by the tropical rainforest tree *Calophyllum Brasiliense*, which is distributed from South America to Mexico. Particularly, mammea A/BA and A/BB (alone or as a mixture) possess biological properties such as cytotoxic and antitumoral activities, however, most of its molecular targets remain unknown. In this context, novel bioinformatic approaches, such as network pharmacology analysis, have been successfully used in herbal medicine to accelerate research in this field, and the support of experimental validations has been shown to be quite robust. In the present study, we performed a network pharmacology analysis to assess the possible molecular biological networks that interact with mammea A/BA and A/BB. Moreover, we validated the most relevant networks experimentally *in vitro* on K562 cancer cells. The results of the network pharmacology analysis indicate that mammea A/BA and A/BB interacts with cell death, PI3K/AKT, MAPK, Ras, and cancer pathways. The *in vitro* model shows that mammea A/BA and A/BB induce apoptosis through the overexpression of the proapoptotic proteins Bax and Bak, disrupt the autophagic flux as seen by the cytosolic accumulation of LC3-II and p62, disrupting the mitochondria ultrastructure and concomitantly increase the intracellular calcium concentration. Additionally, docking analysis predicted a possible interaction with a rapamycin-binding domain of mTOR. In conclusion, we validated network pharmacology analysis and report, for the first time, that mammea A/BA and A/BB coumarins induce apoptosis through the inhibition of the autophagic flux, possibly interacting with mTOR.

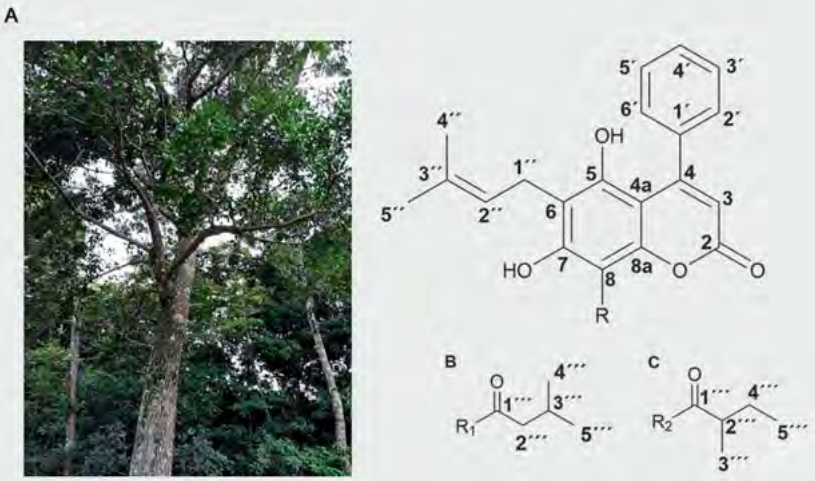
Introduction

Coumarins comprise a large class of secondary metabolites with phenolic structures, composed of fused benzene and α-pyrone rings, biosynthesized by several species of plants, fungi, and bacteria. Several studies have shown a wide range of pharmacological properties for these compounds, including anticoagulant, anti-inflammatory, antiparasitic, antibacterial, antiviral, and anticancer. These heterocyclic compounds represent the core structure for several molecules with pharmaceutical relevance already used in therapeutics, e.g., warfarin, coumermycin, and novobiocin, among others [1]. In this context, mammea-type coumarins, which are biosynthesized by plant species from *Mammea, Mesua*, and *Calophyllum* genera of the Calophyllaceae family, possess a 5,7-dihydroxycoumarin skeleton (▶ **Fig. 1**) and have different names, such as A/BA, A/BB, B/BB, A/AA, etc., according, to the type of substituent on C-4, C-6 and C-8 of the main chemical skeleton. In general, these compounds possess biological effects, such as antiparasitic [2, 3], anti-fimic [4], and cytotoxic [5]. For instance, mammea A/AA induces the release of the apoptotic-inducing factor to the cytoplasm in the HeLa cell line [6], and mammea E/BB plays an anionic protonophore [7] role that uncouples the mitochondrial electron transport in the cancer cell lines T47C and PC-3 [8]. On the other hand, mammeasin A, mammea A/AD, and kayeassamin G have shown an inhibitory effect on iNOS and, consequently, on the production of NO in lipopolysaccharide-activated RAW264.7 cells by an nuclear factor-kappa B-independent mechanism [9]. Particularly MABB (▶ **Fig. 1**), alone or as a mixture, displays antiparasitic effects against *Trypanosoma cruzi* [2] and *Leishmania amazonesis* [10], as well as cytotoxicity and antitumor properties *in vivo* [11]. These compounds have also been shown to be active against clinical isolates of *Mycobacterium tuberculosis*. Moreover, in a toxicogenomic analysis *in vivo* performed by our group, we describe that these compounds were not toxic over non-tumoral tissues from CD-1 mice [12]. Interestingly, in 2004, Reyes-Chilpa et al. [5] reported that mammea A/BA possess low cytotoxicity *in vitro* to normal human lymphocytes with an LC_{100} of 126.45 mg/mL.

NPr is a novel, exciting approach in herbal medicine and drug development that describes a field in systems biology to understand the role of how drugs interact with different targets, signaling pathways, organs, and diseases from a network point of view. This approach is used to discover novel mechanisms of actions and possible adverse effects of drugs through network analyses of multiple levels of biological complexity [13]. Altogether, these approaches combined with other chemoinformatic methods synergize the drug discovery process and help to rediscover the potential of already known compounds [13]. In recent years, several groups have used network pharmacology approaches to explore bioactive compounds, novel targets, and molecular mechanisms from different plants and fungi with known ethnobotanical uses [14–16], contained in different herbal preparations [17, 18], and to repurpose compounds in herbal remedies [19]. Therefore, in the present study, we used NPr to discover targets and pathways that could interact with MABB and performed an experimental *in vitro* validation of such paths on the K562 cancer cell line.



Results

We performed NPr on several databases. ▶ **Table 1** indicates the most enriched pathways, GO-Terms and diseases that interact with MABB (a set of the targets is shown in **Table 1S**, Supporting Information). Additionally, we performed the network construction for the first 50 targets to determine its potential relationships among them and its relation with pathways (▶ **Fig. 2**). Since the apoptotic process was the main enriched pathway, we evaluated the presence of the main proteins involved in such pathways as well as the mitochondrial ultrastructure morphology and intracellular calcium homeostasis ($[Ca2+]_i$).

As depicted in ▶ **Fig. 3**, MABB treatment increases the fluorescence of the proapoptotic proteins Bax (▶ **Fig. 3 A a, b**) and Bak (▶ **Fig. 3 B c, d**) in comparison to the vehicle (DMSO). Moreover, MABB treatment significantly decreases the fluorescence corresponding to Bcl-2 (▶ **Fig. 3 C e, f**), an antiapoptotic protein. These results suggest that MABB induces apoptosis through the overexpression of the proapoptotic proteins Bax and Bak, which are involved in the activation of the mitochondrial intrinsic apoptotic pathway in K562 cells.

We evaluated whether these compounds alter the $[Ca^{2+}]_i$. Interestingly, as seen in ▶ **Fig. 4 A–C**, MABB induces a slow rise in the $[Ca^{2+}]_i$, which reaches 600 nM. A plateau followed this increase a few minutes after MABB administration, however, the last seconds of the recording showed a burst in the $[Ca^{2+}]_i$, reaching 900 nM. These results suggest the possible activation of calcium-dependent pathways, since the $[Ca^{2+}]_i$ abruptly decreased once MABB was removed. Moreover, the $[Ca^{2+}]_i$ disruption, induced by MABB treatment, is accompanied by modifications in the ultrastructure of mitochondria of K562 cells. As seen in ▶ **Fig. 4 C**, MABB treatment induces mitochondria swelling. This morphology is typical in damaged mitochondria as depicted in the positive control, which was treated with rotenone, a specific inhibitor of the mitochondrial complex I (▶ **Fig. 4 C**). Interestingly, MABB in-

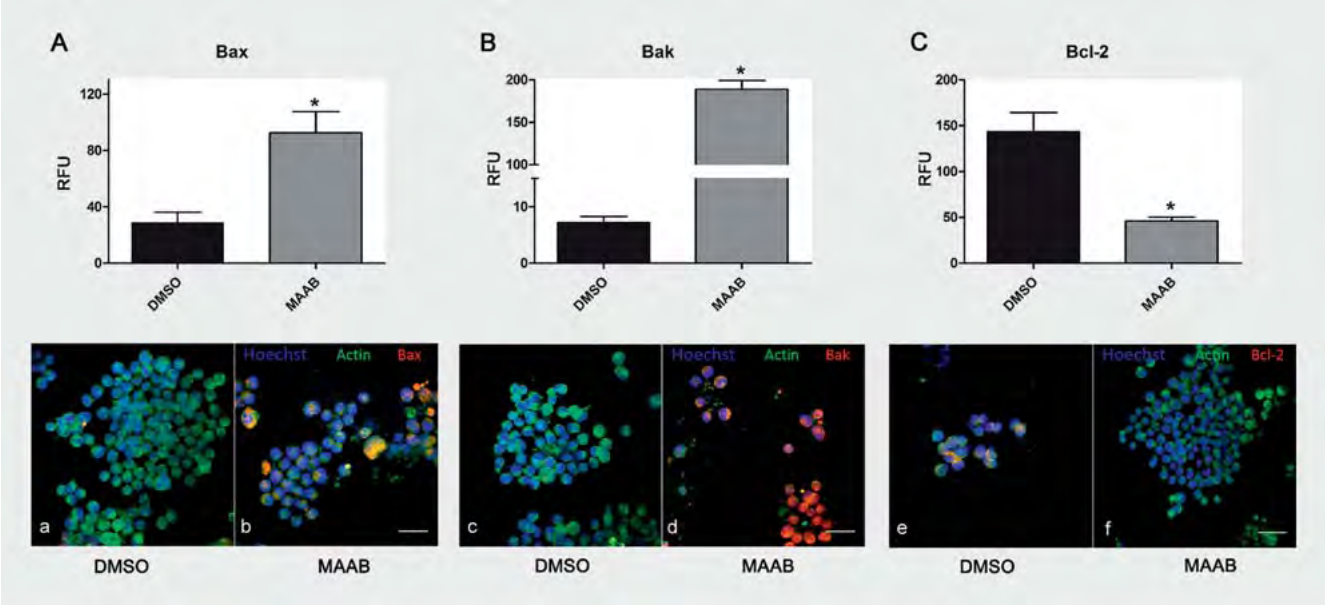
Red lines show physical interactions, yellow lines show predicted interactions, and blue lines show interactions shared by common signaling pathways.



duces cytoplasmic vesicles that surround the damaged mitochondria. This result is contrary to the negative control (DMSO) in which the cells showed mitochondrial ridges.

According to the NPr, PI3K-AKT and macromolecule metabolism were among the enriched pathways that correlate with the autophagy process. Therefore, we validated autophagy by the acidic vesicle formation and the quantification of autophagic markers, including the lipidated form of the microtubule-associated protein light chain 3 (LC3-II) and its receptor SQSTM1/p62 (p62). Finally, we evaluated the possible interaction between mTOR and MABB by a docking assay.

Autophagy induces the acidic vesicle aggregation, the decrease of LC3-I and p-62, and the increase of LC3-II [20]. As observed in ▶ **Fig. 5A**, MABB treatment induces acidic vesicle aggregation similar to that of the positive control CP (▶ **Fig. 5A** panels e and n, respectively). CQ prevented this effect, since the size of the vesicles is more significant than in MABB (▶ **Fig. 5A** panel k). Moreover, to evaluate the effect of MABB treatment on the autophagic flux, we determined the content of LC3-II and p62. Our results showed that MABB treatment increases the LC3-II protein content over 12 times (▶ **Fig. 5B**) in contrast to the vehicle (DMSO). However, MAAB treatment did not alter the content of p62 (▶ **Fig. 5C**), suggesting a disruption in the autophagic flux.

To predict whether coumarins may interact with mTOR, we performed an *in silico* study (docking), including binding sites, the ATP-binding domain, and the allosteric domain in the mTOR complex (▶ **Fig. 6**). We conducted a re-docking analysis of the co-crystallized ligands to validate our protocol. The docking of 17 G (PDB 4JSX) resulted in a similar conformation than the crystallized pose with an RMSD of 0.5789 and a docking score of

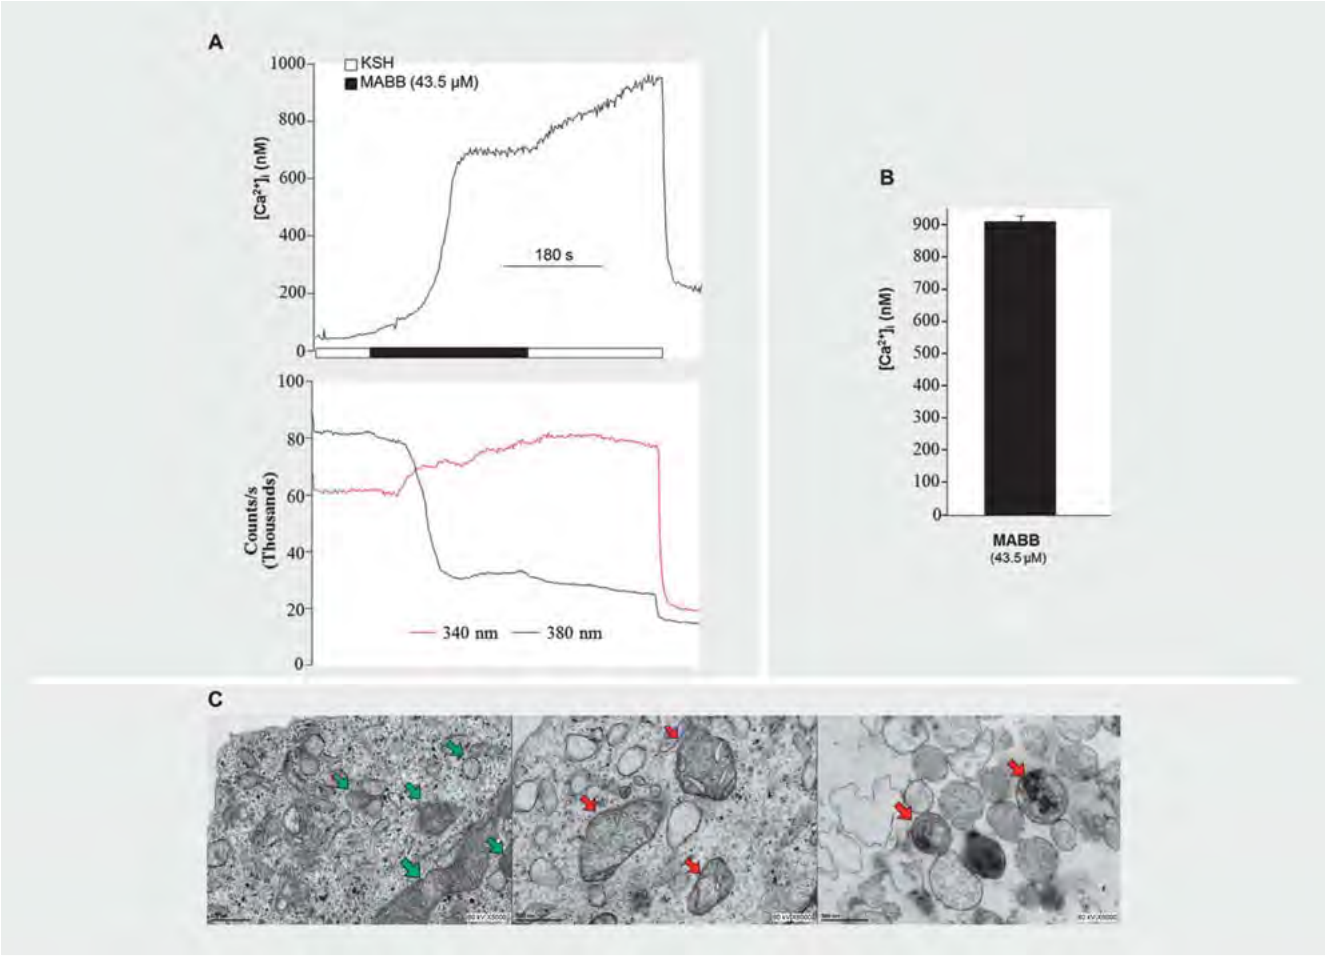
▶ **Fig. 3** MABB induce apoptosis in K562 cells. Immunofluorescence analysis and representative confocal images of triple immunofluorescence staining, showing the content, in red fluorescence, of Bax (**A**), Bak (**B**), and Bcl-2 (**C**) in K562 cells incubated with the vehicle (DMSO) (**a, c** and **e**) or with MABB (43.5 µM during 18 h) (**b, d** and **f**), respectively. Hoechst labeled nuclei in blue and phalloidin 488 labeled cytoskeleton in green. Bars represent the mean ± S. E. M. of the relative fluorescence units (RFU) from the red channel of five images from three independent experiments. Data were analyzed by Student's t-test followed by the Mann-Whitney test; $^{*}p \leq 0.05$ vs. vehicle. Scale bar: 50 nm.

− 33.07 kcal/mol. For the inhibitor ARD (PDB 3FAP), the RMSD was 2.0191 with a docking score of − 26.30 kcal/mol (**Fig. 3S A, B**, Supporting Information). These results suggest that the algorithm implemented in ICM Molsoft provides enough reproducibility and accuracy for the study. Based on the scoring function, the docking predicts that both coumarins may interact in the rapalogue-binding pocket (allosteric FRB domain), since docking scores for mammea A/BA were − 31.85 kcal/mol and − 21.13 kcal/mol for allosteric and ATP-binding domains, respectively. For mammea A/BB, the docking scores were − 31.98 kcal/mol and − 24.11 kcal/mol for allosteric and ATP-binding domains, respectively (**Table 2S**, Supporting Information). In the case of mammea A/BA, it's predicted to be stabilized by several hydrophobic interactions (Tyr26, Phe46, Glu54, Val55, Trp59) and a hydrogen bond with Ile56 of the FRB domain. According to the model, our results suggested hydrophobic interactions with the KD-N lobe, (Ser2036 and Phe2039) and a possible hydrogen bond with Tyr2105 for this analysis. In the same way, mammea A/BB appears to interact in a similar binding site as mammea A/BA, stacked in the pocket through hydrophobic interactions with Trp2101, Asp2102, Tyr2105, and Phe2039 of the KD-N lobe, and Phe36, Val55, and Ile91 of the FRB domain. Additionally, we predicted two hydrogen bonds with Ile56 and Tyr82 (FRB domain).



Discussion

As previously mentioned, MABB coumarins may be considered drug candidates since they present versatile pharmacological properties and have been shown to be safe [12]. Network pharmacology approaches have been used from two points of view: 1) to identify novel targets and 2) to determine which unknown signaling pathways interact with compounds [17, 21]. In this context, our data showed that MABB interacts with an apoptotic process and PI3K/AKT, MAPK, Ras, and Erb pathways. Interestingly, most of them possess tyrosine kinase properties [22] in this context, and the PI3K/AKT pathway is associated with the autophagy process [23]. Disease enrichment analysis indicates that MABB might be related with cancer pathways in general, suggesting its potential as an antitumoral compound.

First, we evaluated the effect of MABB in apoptosis through the fluorescence analysis of Bcl-2, Bax, and Bak proteins in K562 cells. Bax and Bak are two nuclear-encoded proteins that can pierce the mitochondrial outer membrane to mediate cell death by apoptosis, promoting permeabilization and the release of cytochrome C. Bcl-2 antiapoptotic protein also regulates this mitochondrial pathway. Our analyses showed that MABB treatment induces the overexpression of Bax and Bak. Meanwhile, the Bcl-2 signal was absent, suggesting that treatment induces apoptosis through the intrinsic mitochondrial pathway. These results are in concordance with another type of mammea coumarin that induces this type of cell death in another leukemia cell line [10].

Since we observed that MABB induces apoptosis through a previously mentioned pathway, we evaluated whether MABB could produce mitochondrial damage concomitantly. Transmission electron microscopy (TEM) images indicated the presence of mitochondrial damage, characterized by swelling and loss of the mitochondrial ridges, as well as cytoplasmic vacuolization surrounding damage. These results are consistent with previous studies in which similar coumarins induced mitochondrial uncoupling [6, 8]. Moreover, Brenzan et al. [10] demonstrated that

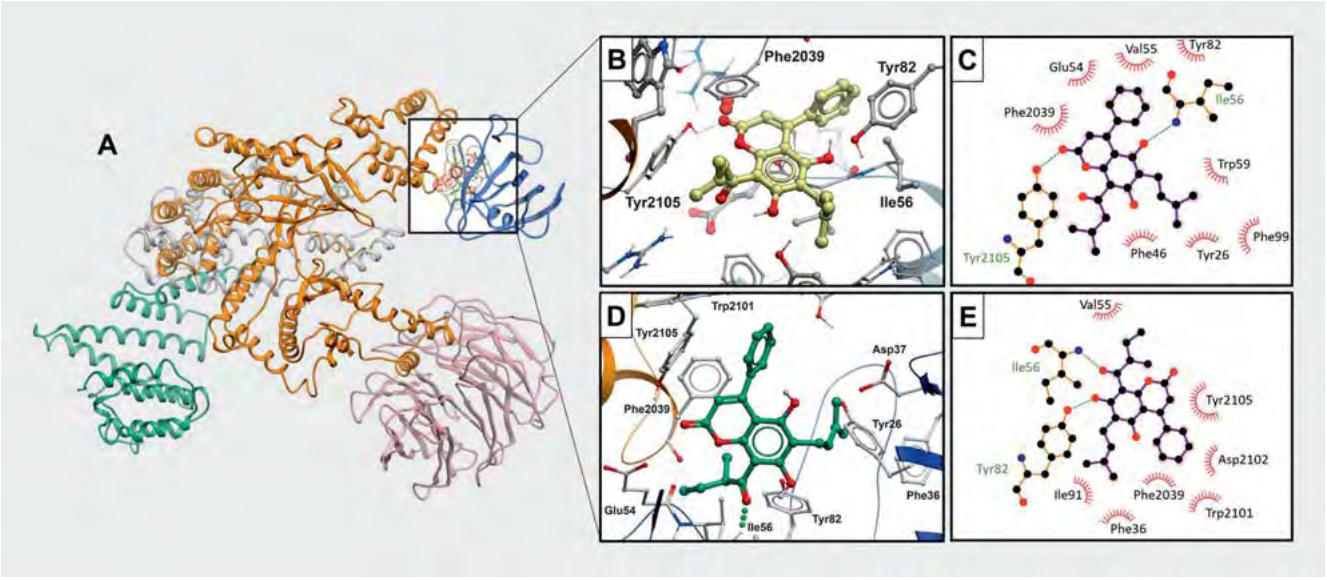
▶ **Fig. 4** MABB treatment induces $[Ca^{2+}]_i$ disruption and alters the mitochondria ultrastructure on K562 cells. **A** Representative recordings of the $[Ca^{2+}]_i$ measurements in cells treated with MABB (43.5 µM). Representative recording of Fura-2AM excitation at 340 nm and 380 nm. **B** The bar represents the $[Ca^{2+}]_i$ in MABB-treated cells (907 ± 14.71 nM, n = 5). **C** Representative images from TEM, respectively: negative control (DMSO), MABB (43.5 µM, 6 h), positive control (Rotenone, 13 µM, 6 h). Green arrows indicate normal mitochondrion and red arrows indicate damaged mitochondrion. Scale bar: 500 nm. Images represent three independent experiments.

mammea A/BB induces atypical cytoplasmic vacuolization and mitochondrial swelling in *Leishmani amazonensis*. Furthermore, our recordings indicate that 3 min after MABB administration, the $[Ca2+]_i$ rises to 900 nM, followed by an abrupt decrease, which suggests cell death. These results might explain the mitochondrial damage, the presence of acidic vesicles, and the eventual release of proapoptotic proteins that lead to cell death. Mitochondrion are active players in $[Ca^{2+}]_i$ homeostasis (chemiosmotic theory) and, as previously mentioned, the $[Ca^{2+}]_i$ overload induces the activation of several kinase-dependent proteins, such as PKC and ASK1, leading to apoptosis and mitochondrial damage [24, 25]. Our results are in accordance with other coumarins where the same effect was observed [26].



The second potential interaction, according to NPr, was PI3K/Akt, MAPK, and Ras pathways associated with autophagy. To validate this, we quantified the LC3-II and p62 protein content and the acidic vesicle aggregation, which are characteristics of such a process. Our results demonstrated that MABB treatment induces apoptosis through the disruption of the autophagic flux, since we observed acidic vesicle aggregation and autophagosome accumulation by LC3-II and p62. These results are in agreement with previous studies reporting that silver nanoparticles induce apoptosis through the cytoplasmic accumulation of LC3-II and p62 in NIH 3 T3 and HCT116 cells [27] and with those of spicatoside A, a steroidal saponin isolated from *Liriope platyphylla* that exerts antitumor activity through the modulation of both autophagy and apoptosis [28].

Finally, according to the literature, several synthetic coumarins have been found to possess potent anticancer properties through the inhibition of the PI3K-AKT-mTOR pathway [29] or as inhibitors of mTOR, a hub protein in this signaling pathway [30]. Moreover, some of these compounds are currently patented, such as CN103254203A. Hence, we decided to explore *in silico* whether MABB may interact with mTOR (since these types of approaches are a valuable low-cost tool). As reported in the literature, small molecules could inhibit the mTOR complex in two different ways [31]: 1) as competitive ligands in the ATP-binding pocket [32] or 2) as allosteric inhibitors interacting in the FRB domain [33]. The scoring function implemented in ICM software predicts that the coumarins interact in the allosteric binding site associated with

the analogs of rapamycin (rapalogues), which in turn could inhibit its activity. In both cases, the stabilization seems to be mainly by hydrophobic contacts, as expected for ligands that bind to the allosteric site [33]. According to a model proposed by Choi et al.

Downloaded by: Universidad de Barcelona. Copyrighted material.

[34], most of the interactions calculated for rapamycin and the FKBP12 domain (KD-N lobe) agree with the predicted ones for the MABB. These results predict that, as in the case of rapamycin, MABB may act as an inhibitor of the mTOR phosphorylation mechanism. Additionally, the prediction suggests that MABB may act as specific inhibitors of the complex, reducing the probability of side effects (by inhibiting other kinases).

In conclusion, NPr indicated that MABB is suitable for drug development of novel anticancer compounds since they interact with several targets related to cancer and induce apoptosis through the inhibition of the autophagic flux, possibly via an mTOR interaction. However, further experiments must be performed to experimentally validate the mTOR interaction with MABB to avoid false positives on the docking assay. Additionally, other possible targets and signaling pathways should be tested and experimentally confirmed since our results open possible novel applications and research for this type of compound.

Materials and Methods

Isolation and identification of mammea A/BA and A/BB

A mixture of coumarins, MABB, was isolated from *Calophyllum brasiliense* leaves (voucher 1523A-Instituto Mexicano del Seguro Social-Medicinal Herbarium), as previously described by [35], and identified by ^{1}H and ^{13}C NMR in comparison with previous reports [5]. For biological studies, we used a mixture of coumarins A/BA and A/BB, 75 to 25% (3:1) MABB. The content of each compound of the mixture was determined by ^{1}H NMR, assuming 100% for both compounds and using an integration of OH-7.

Network pharmacology

To identify if MABB could be repurposed or considered for treatment of other diseases, an NPr *in silico* approach was performed to identify novel target proteins and pathways that could interact with them. Predictive models were used, including DRAR-CPI [36], SEA [37], SwissTarget [38], and STITCH [39].

Enrichment analysis for targets

An analysis of network interactions related to the first 50 targets that interacted with each compound was performed using the CTD [40] and the GSEAPY package from Python. The main BP (GO:0008150), MF (GO:0003674), and CC (GO:0005575) were determined, as well as the main KEGG and Panther pathways along with OMIM-related diseases. The most significantly enriched terms in the BP, MF, and CC categories, KEGG, Panther, and OMIM ($p < 0.05$; p values were corrected using the Benjamini-Hochberg procedure) are listed in ▶ **Table 1** and separated accordingly with Pathways and Go-Terms and Diseases Related with Targets. We constructed the network of functional association of the targets with GeneMania (▶ **Fig. 2**) [41].

Cell culture

K562 cells were obtained from ATCC and cultured in RPMI (GIBCO) with 10% FBS (Mayimex) and 10000 IU/mL penicillin/streptomycin in humidified air at 37 °C with 5% CO_2. Cells used for confocal microscopy were cultured in 12-well plates, over rounded coverslips at 1×10^3 cells per well. For protein isolation, cells were cultured at 1×10^6 cells in 100 mm culture plates. The cultured cells were treated with MABB at 43.5 µM, CQ (20 µM, purity 98%; Sigma-Aldrich), CP (20 µM, purity 95%; Lemery Labs), or rotenone (13 µM, purity 95%; Sigma-Aldrich), as previously reported in [35]. DMSO (JT Baker) at a final concentration of 0.04% was used to dissolve the MABB, CQ, and rotenone compounds. CP was diluted in PBS 1X.

Immunofluorescence of BAK, BCL-2, and BAX

We performed the immunocytochemistry for all treatments according to the methodology of [42]. Briefly, K562 cells were cultured in round, glass coverslips and treated with MABB for 18 h and incubated with polyclonal antibodies of anti-Bax (1:100), anti-Bak (1:100), and anti-Bcl-2 (1:100) (Santa Cruz Biotechnology) overnight at 4 °C. Afterwards, cells were incubated with an anti-rabbit or anti-mouse secondary antibody conjugated with Alexa-Fluor 568 (1:500; Invitrogen). We used Alexa-Fluor 488 conjugated phalloidin (165 nM; Thermo Fisher Scientific) for cytoskeleton labeling and Hoechst 33342 (12 µg/mL; Thermo Fisher Scientific) for nucleus labeling. Confocal images were taken with an Olympus FV1000 microscope using a 60 x oil immersion objective and diode lasers (473 nm) at the USAII-Facultad de Química, UNAM, México. The fluorescence of Bax, Bak, and Bcl-2 was analyzed from five sections of three independent experiments using Image J software as previously described [43].

Transmission electron microscopy

K562 cells were treated with MABB at 43.5 µM for 6 h. DMSO 4% was used as a negative control (v/v) and rotenone (13 µM during 6 h) as a positive control. After 6 h of treatment, cells were fixed with 2.5% glutaraldehyde and postfixed in 1% OsO_4 and 0.8% $K_4Fe(CN)_6 \cdot 3H_2O$, and 5 mM calcium. Postfixed cells were dehydrated in acetone and embedded in Epon. Ultrathin sections were stained with uranyl acetate and lead citrate and examined under a JEOL JEM 12000 EII transmission electron microscope at the Unidad de Imagenología at the Instituto de Fisiología Celular (IFC) from UNAM, Mexico City, Mexico.

Microfluorometric Ca^{2+} measurements in K562 cells

K562 cells were plated at a density of 2×10^4 cells/cm^2 in round, 12 mm diameter coverslips and cultured for 24 h with supplemented DMEM. Cells were loaded with 2.5 Mm Fura 2-AM in low Ca^{2+} (0.1 mM) at room temperature and then treated according to [42]. Cells were stimulated with MABB (43.5 µM) for 3 min to determine the calcium response from 1 min to 1 h. Differences in the $[Ca^{2+}]$ response were evaluated through paired Student's t-test. Results presented as the mean ± SEM.

Lysosome membrane integrity assay

AO staining was performed as reported by [44]. Confocal images were taken with a Leica TCS SP5 using 63X water immersion objectives Arg 458/650 nm (red; acidic vacuoles) and Arg 488/525 nm (green; nuclei). Additionally, we used CP 20 µM for 18 h as a positive control for acidic vesicle formation since it is a well-known autophagy inductor, and CQ 20 µM for 12 h to disrupt the

Downloaded by: Universidad de Barcelona. Copyrighted material.

function of lysosomes and inhibit autophagy at the late stage due to its alkaline properties [45].

Western Blot

After cells were treated with MABB (43.5 µM for 18 h), we performed Western blot according to [42] with a few modifications as follows: Proteins were separated in 10 % (p62) or 18 % (LC3 and actin) SDS-PAGE and subsequently transferred to PVDF membranes. Membranes were incubated with anti-LC3 (1 : 1000; MBL international) and SQSTM1/p62 (1 : 1500; Cell Signaling Technology) overnight at 4 °C. The signal was detected by chemiluminescence using Immobilon Western Chemiluminescent HRP substrate (Millipore) with a blot scanner (LI-COR). We used Image Studio 3.1 to perform densitometry analysis. LC3-II and p62 contents were normalized against actin (1 : 7000; Millipore).

mTOR docking

Docking studies were performed using the Internal Coordinate System, ICM molecular modeling software (Molsoft). The crystal structures of the mTOR complex with an ATP-competitive inhibitor (PDB 4JSX) and an allosteric inhibitor (PDB 3FAP) were both retrieved from the PDB. We performed a validation protocol for the docking studies with the co-crystallized ligands in the original protein [9-(6-aminopyridine-3-yl)-1-[3-(trifluoromethyl)phenyl] benzo[*h*][1,6]naphthyridin-2(1*H*)-one, 17 G and C15-(*R*)-methylthienyl rapamycin for PDB 4JSX and 3FAP, respectively] structures removed, placed randomly outside the protein, and re-docked. The best poses were selected, according to the docking score, and the structural conformation was compared to that of the original pose in the crystal structure through their RMSD. Next, to determine the probable binding pocket of MABB coumarins, a 3D alignment of the protein structures was performed using the superimpose tool implemented in the ICM software, based on the KD-N lobe of the mTOR-mLST8 complex (**Fig. 3S**, Supporting Information). The receptor maps were calculated according to the pocket defined by the co-crystallized ligands (17 G and ARD). The grid box was built to cover both ATP and allosteric binding pockets entirely. The ICM software generates an internal docking score based on several energetic parameters, which include weighted van der Waals interactions, internal force field energy of the ligand, free energy of the conformational energy loss, solvation electrostatic energy upon ligand binding, hydrogen bonding, hydrogen donor, acceptor desolvation energy, hydrophobic free energy gain, and correction on the number of ligands. We built structures of MABB with Spartan v.10 software (Wavefunction) and the Monte Carlo protocol for energy minimization (MMFF98 force field) and conformer distribution. The structures of minimum energy were then geometrically optimized using density functional theory at the B3LYP/DGDZVP level of theory using Gaussian 09 software (Gaussian). The docking poses were analyzed and visualized in the ICM Molsoft software.

Statistical analysis

GraphPad Prism Software version 5.0 was used to process all statistic data. The Student's t-test analysis was used to examine the statistical difference between experimental data between groups. Significance was defined as $p < 0.05$.

Supporting information

A detailed scheme of NPr methodology (**Fig. 1S**), complete image for the Western blot of LC3 and P62 proteins (**Fig. 2S**), a complete list of the potential targets of MABB obtained by the NPr analysis (**Table 1S**), and the results for the validation of the docking protocol, which include resulting conformations of the validation protocol images (**Fig. 3S A, B**) and docking scores for MABB and ligands of co-crystallization for each mTOR studied (**Table 2S**), are available as Supporting Information.

Acknowledgements

This research was supported by grant IN210016 from DGAPA-PAPIIT, UNAM. The authors thank Lourdes Massieu, Ph.D. and Biol. Teresa Montiel from Instituto de Fisiología Celular, UNAM, for bringing the LC3 and p62 antibodies and for technical assistance during the Western blot. We also thank Karina Jiménez Duarte, Ph.D., for her technical support during the confocal sessions at Unidad de Servicio y Apoyo a la Industria e Investigación (USAII)-Facultad de Química, UNAM. The authors wish to thank Heidy Martínez-Pacheco for support with the docking assay.

Conflict of Interest

The authors declare no conflict of interest.

ABSTRACT

Parkin (PRKN) is a ubiquitin E3 ligase that catalyzes the ubiquitination of several proteins. Mutations in the human Parkin gene, *PRKN,* leads to degeneration of dopaminergic (DA) neurons, resulting in autosomal recessive early-onset parkinsonism and the loss of PRKN function is linked to sporadic Parkinson's disease (PD). Additionally, several *in vitro* studies have shown that overexpression of exogenous PRKN protects against the neurotoxic effects induced by a wide range of cellular stressors, emphasizing the need to study the mechanism(s) governing PRKN expression and induction. Here, *Prkn* was identified as a novel target gene of the aryl hydrocarbon receptor (AhR), a ligand-activated transcription factor and member of the bHLH/PAS (basic helix-loop-helix/Per-Arnt-Sim) superfamily. AhR binds and transactivates the *Prkn* gene promoter. We also demonstrated that AhR is expressed in DA neurons and that its activation upregulates *Prkn* mRNA and protein levels in the mouse ventral midbrain. Additionally, the AhR-dependent increase in PRKN levels is associated with a decrease in the protein levels of its target substrate, α-synuclein, in an AhR-dependent manner, because this effect is not observed in *Ahr*-null mice. These results suggest that treatments designed to induce PRKN expression through the use of nontoxic AhR agonist ligands may be novel strategies to prevent and delay PD.

1. Introduction

Parkinson's disease (PD) is the second most common neurodegenerative disease and is clinically characterized by bradykinesia, resting tremor, and postural imbalance induced by the progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNc). Histopathologically, it is characterized by the presence of intracytoplasmic inclusions of α-synuclein called Lewy bodies [1].

Several reports support the role of Parkin (PRKN) in the development of PD. Parkin is ubiquitously expressed but predominantly in the brain and is an E3 ligase that catalyzes the ubiquitination of several proteins, including Pael-R, α-synuclein, synphilin-1, and Cdc-Rel. Parkin confers protection against several insults to neurons, and impairments in ubiquitination of some of its targets have been linked to the degeneration of dopamine (DA) neurons [2,3]. The neuroprotective effect of Parkin is also mediated by promoting the removal of damaged mitochondria via mitophagy [4] and by regulating the function and stability of excitatory glutamatergic synapses [5].

Mutations in the *PRKN* in humans are the most common cause of autosomal-recessive early-onset parkinsonism, and reduced Parkin expression has been linked to late-onset PD [6]. Moreover, *PRKN* haploinsufficiency is associated with an increased risk of developing the sporadic form of PD [7]. In addition to genetic factors, other conditions may alter Parkin function. Several cell stressors, such as hydrogen peroxide, S-nitrosylation, 1-methyl-4-phenylpyridine (MPP^+), 6-hydroxydopamine (6-OHDA), paraquat, and rotenone, induce Parkin aggregation [8], while the native structure of PRKN in the brain is modified with age [9]. Therefore, any condition leading to reduced Parkin levels or function compromises neuronal survival.

In agreement with these findings, the overexpression of exogenous

INFORME DE LABORES 2019

Parkin confers protection against the neurotoxic effects induced by a wide range of cellular stressors [10–13], emphasizing the need to study the mechanism(s) governing *PRKN* gene expression and regulation. However, there is a lack of information regarding the transcription factors involved in *Prkn* gene regulation.

The aryl hydrocarbon receptor (AhR) mediates the expression of several genes encoding ubiquitin proteasome system proteins [14–16], in particular *Ubch7* (also known as *UBE2l3* in humans and *UbcM4* in mice), an E2 ubiquitin enzyme partner of PRKN. AhR is a ligand-activated transcription factor that mediates the toxicity of environmental pollutants, and its highest-affinity ligand is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Upon binding TCDD, AhR translocates to the nucleus, binds to xenobiotic-responsive elements (XREs), and upregulates the expression of a battery of genes that encode xenobiotic-metabolizing enzymes, including its canonical gene target, *Cyp1a1* [17].

On the other hand, it was reported that the promoter of the *D. melanogaster* homolog of human *PRKN* has a binding site for AhR [18], suggesting that AhR may be involved in the regulation of *Prkn* expression. Therefore, we initiated a study to determine whether AhR regulates *Prkn* expression in the mouse ventral midbrain and its effects on the protein levels of Parkin substrates, in particular α-synuclein (SNCA).

Our data showed that AhR is expressed in mouse DA neurons, and its activation by oral treatment with TCDD induces Parkin expression in the ventral midbrain and decreases the PRKN substrate α-synuclein.

2. Materials and methods

2.1. Materials

SH-SY5Y cells were obtained from the American Type Culture Collection (Manassas, VA, USA). 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) was purchased from AccuStandard (New Haven, CT, USA). Phenylmethanesulfonyl fluoride (PMSF) and dimethyl sulfoxide (DMSO) were acquired from Sigma (St. Louis, MO, USA).

2.2. Animals and treatments

The development of *Ahr*-null mice was described previously [19]. Wild-type (WT) littermates on a C57BL/6J background were used as controls. The animals were housed in a pathogen-free facility and fed with autoclaved Purina rodent chow (St. Louis, MO, USA) with water available *ad libitum*. All animal procedures were performed according to the Guide for the Care and Use of Laboratory Animals, as adopted and enforced by the U.S. National Institutes of Health and the Mexican Regulation of Animal Care and Maintenance (NOM-062-ZOO-1999, 2001). The mice were distributed randomly into TCDD and vehicle treatment groups (N = 3, for each of the assay performed), and the treatments were carried out as described previously [20]. TCDD was dissolved in corn oil, and a single dose of TCDD (250 μg/kg) or corn oil alone (vehicle) was administered by gavage to 8- to 9-week-old male C57BL/6J wild-type (WT) and *Ahr*-null mice. Seven days later, the mice were anesthetized with pentobarbital and euthanized by decapitation. The brains were rapidly removed, and the ventral midbrain was dissected out as follow: the brain was removed, and the dorsal side was placed up. Using a thin blade, a coronal rostral cut was made at the level of the pineal recess, the junction between the caudal part of the interhemispheric scissure and the medial occipital lobe border. Next, a caudal coronal cut in the intercollicular sulcus was made. The midbrain was dissected, and the ventral midbrain section obtained.

Liver sections were also extracted. Brain and liver samples were snap frozen and stored at −70 °C.

2.3. Real-time quantitative polymerase chain reaction (qPCR)

Total RNA was prepared from mouse liver and ventral midbrain using TRIzol reagent according to the manufacturer's instructions (Invitrogen, Camarillo, CA, USA). RNA was quantified spectrophotometrically at an optical density of 260 nm. RNA integrity was evaluated by electrophoresis on 1% agarose gels. cDNA was prepared for quantitative PCR from 2 μg of total RNA using the SuperScript First-Strand Synthesis kit (Invitrogen, Camarillo, CA, USA) and oligo dTs. PCR was performed on a StepOne Real-Time PCR System (Applied Biosystems, Branchburg, NJ, USA), and the results were analyzed using the comparative threshold cycle (C_T) method. mRNAs encoding *Ahr, Cyp1a1 Prkn,* and 18S ribosomal RNA (rRNA, endogenous), were amplified in a single PCR to allow for the normalization of the mRNA data. The PCR mixture contained 2 μl of cDNA, 1x TaqMan Universal PCR Master Mix (Applied Biosystems, Branchburg, NJ, USA) and 0.9 and 0.25 μM primers and probes, respectively. The primer and probe sequences used for *Prkn* were 5′-CAAACAAGCAACCCTCACCTT-3′ (forward), 5′-ATCCGGTTTGGAATTAAGACATCGT-3′ (reverse), and CCCA GGGCCCATCTT (probe, FAM). The probes used for *Ahr*, *Cyp1a1* and 18S rRNA were obtained from Applied Biosystems (Branchburg, NJ, USA) with identification numbers Mm01291777_m1, Mm00487218_m1, and Mm00507222_s1, respectively.

2.4. Immunofluorescence

The localization of the AhR protein in the SNc of adult mouse brains was determined by immunofluorescence, and tyrosine hydroxylase (TH) was used to identify DA neurons. Mice were injected with an overdose of pentobarbital (80 mg/kg) and perfused intracardially with saline. Subsequently, the brains were fixed with 4% paraformaldehyde in phosphate-buffered saline (PBS), postfixed in the same solution for 48 h and then incubated in 20% sucrose in PBS. Coronal sections (30-μm-thick) were cut with a cryostat and used for immunohistochemical assays. Briefly, free-floating sections were incubated at room temperature for 1 h in 0.25% Triton X-100/PBS buffer and subsequently in 5% BSA and 0.25% Triton X-100/PBS buffer for 3 h. Then, the sections were incubated in 3% BSA and 0.25% Triton X-100/PBS solution containing AhR (1:500) and TH (1:1000) antibodies (Abcam, Cat. ab2770, CA, USA and Cell Signaling Technologies, Cat. 2792, MA, USA, respectively). After 48 h of incubation, the sections were incubated with secondary antibodies (1:400) (Alexa 594 anti-mouse IgG, Cat. A-21203 and Alexa 488 anti-rabbit, Cat. A-11008; Thermo Fisher Scientific, MA, USA) diluted in PBS with 0.25% Triton X-100. The sections were counterstained with DAPI to reveal the nuclei and observed by confocal microscopy. Triple-labeled images were obtained using a confocal laser-scanning microscope (Leica TCS-SPE, Wetzlar, Germany) in the XYZ (Z-stacks) mode using a 40x objective. The Z-stacks (3–4 optical slices) were then converted into three-dimensional projection images using the Leica LAS AF lite software.

2.5. Western blotting

Ventral midbrain sections were homogenized in buffer containing 20 mM HEPES, 350 mM NaCl, 1 mM $MgCl_2$, 0.5 mM EDTA, 0.1 mM EGTA, 1% Nonidet P40, 0.5 mM DTT, 0.1% PMSF and Mini cOmplete protease inhibitor cocktail (1 tablet/10 mL, Roche, Mannheim, Germany). The protein suspension was homogenized completely by sonication for 30 s. Protein concentrations were determined using the Bradford assay (Bio-Rad, Hercules, CA, USA). Aliquots (40 μg) were solubilized in sample buffer (60 mM Tris–HCl, pH 6.8, 2% sodium dodecyl sulfate (SDS), 20% glycerol, 2% mercaptoethanol, and 0.001% bromophenol blue) and subjected to 12% SDS polyacrylamide gel electrophoresis. The protein extracts were transferred to a nitrocellulose membrane using a mini trans-blot system (Bio-Rad, Hercules, CA, USA). The transfer was performed at a constant voltage of 80 V for 2 h in transfer buffer (48 mM Tris–HCl, 39 mM glycine, pH 8.3, and 20% methanol). Following the transfer, the membranes were blocked overnight at 4 °C in the presence of 2% nonfat dry milk and

INFORME DE LABORES 2019

0.5% bovine serum albumin (BSA) in blocking buffer (25 mM Tris–HCl, pH 7.5, and 150 mM NaCl) and subsequently incubated at 4 °C for 3 h with mouse monoclonal anti-Parkin (1:500; Thermo Fisher, Cat. 39-0900, Meridian Rock, IL, USA), rabbit polyclonal anti-Cyp1a1 (1:100, Santa Cruz Biotechnology, Cat. sc-20772, Visalia, CA, USA), and goat anti-β-actin (1:1000; Santa Cruz, Biotechnology, Cat. sc-1616, Visalia, CA, USA), and for 16 h at 4 °C for mouse monoclonal anti-α-synuclein (1:4000; Santa Cruz Biotechnology, Cat. Sc-12767, Visalia, CA, USA). The antibodies were diluted in buffer (25 mM Tris–HCl, pH 7.5, 150 mM NaCl, 0.1% Tween 20, 0.05% nonfat dry milk, and 0.05% BSA). After washing, the membranes were incubated with the relevant horseradish peroxidase (HRP)-conjugated goat anti-mouse IgG (Thermo Fisher, Cat. 62-6520, Meridian Rock, IL, USA), horse anti-mouse IgG (Vector laboratories, Cat. PI-2000, Burlingame, CA, USA), goat anti-rabbit IgG (Cell Signaling, Cat. 7074, Danvers, USA), and rabbit anti-goat IgG (Thermo Fisher, Cat. 31402, Meridian Rock, IL, USA) secondary antibodies for 2 h at 4 °C. The membranes were washed, and the immunoreactive proteins were detected using an ECL western blotting detection kit (Amersham, Arlington Heights, IL, USA). The integrated optical density of the bands was quantified using scanning densitometry (GS-800 Calibrated Densitometer, Bio-Rad, Hercules, CA, USA).

2.6. In silico analysis

The mouse *Prkn* promoter was analyzed using the web-based bioinformatics tool EPD (https://epd.epfl.ch//index.php). $P < 0.01$ was considered significant.

2.7. Chromatin immunoprecipitation (ChIP)

ChIP assays were performed according to the kit protocol (Santa Cruz Biotechnology, Visalia, CA, USA) with an anti-AhR antibody (Thermo Fisher Scientific, Cat. MA1-514, Rockland, IL, USA). The PCR product corresponding to the *Prkn* proximal gene promoter was generated from an aliquot of immunoprecipitated material. Brain homogenates from WT mice treated with a single oral dose of TCDD or vehicle (corn oil) were washed with PBS buffer and crosslinked with 1% formaldehyde. After chromatin isolation, the DNA was fragmented, and immunoprecipitation was performed. The crosslinking was reversed, the DNA was purified, and PCR amplification was performed as follows: initial denaturation at 94 °C for 3 min and 28 cycles of denaturation at 94 °C for 30 s, annealing at 65 °C for 30 s, and extension at 72 °C for 30 s. A final extension cycle at 72 °C for 10 min was added to the end of the program. The oligonucleotides used for PCR amplification were 5′-AGAAGTGAGCAGGGGGTCGGG-3′ (forward) and 5′-AAGGACCTAC GCGGGCACTG-3′ (reverse).

2.8. Plasmid

The reporter plasmid pGL4/-419-mPrkn, which includes the mouse *Prkn* gene promoter, was constructed as described. A −419/+1 fragment was generated by PCR amplification using mouse genomic DNA and oligonucleotides (forward: 5′-AGAAGTGAGCAGGGGGTCGGG-3′, reverse: 5′-AAGGACCTACGCGGGCACTG-3′). The fragment was then cloned into the pCR 2.1-TOPO transition vector (Invitrogen, Camarillo, CA, USA). To verify the amplicon orientation as well as its correct sequence, single and double restriction enzyme digestions and sequencing were performed. Then, the fragment was cloned into the KpnI/Xhol site of the pGL4.10 [luc2] reporter vector (Promega, Madison, WI, USA) containing the firefly luciferase gene. This plasmid was designated pGL4/-419_mPrkn.

2.9. Cell culture and transfections

SH-SY5Y cells were obtained from American Type Culture Collection (CRL-2266, Manassas, VA, USA). The cells were grown in 100-mm dishes with high-glucose DMEM (Gibco, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (Gibco, Logan, UT, USA) and 1% antibiotic/antimycotic (Invitrogen, Carlsbad, CA, USA) at 37 °C in a humidified incubator with a 5% CO_2 atmosphere. Transfections were performed using Escort IV (Sigma, Saint Louis, MO, USA). Each culture (1×10^6 cells/mL) was transfected with 1, 2.5, 5 or 10 μg of pGL4/-419-mPrkn and 1 μg of pRL-CMV as an internal control. The media was replaced with fresh media containing 10 nM TCDD for 48 h posttransfection. After 48 h, the cells were homogenized by incubation with Passive Lysis Buffer (Promega, Madison, WI, USA) for 15 min at room temperature. A luciferase activity assay was performed using the Dual-Glo Luciferase Reporter Assay System (Promega, Madison, WI, USA) according to the manufacturer's instructions with a Modulus luminometer (Turner Biosystems, Sunnyvale, CA, USA). Blanks were obtained by performing the luciferase activity assay on mock-transfected cells. Firefly luciferase activity levels were normalized by comparison to the activity levels of *Renilla* luciferase.

2.10. Electrophoretic mobility shift assay (EMSA)

Liver and brain tissues from C57BL/6J mouse strain were used to prepare nuclear extracts. Tissues and cells were homogenized in ice-cold buffer (10 mM HEPES, pH 7.9, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1.0 mM DTT, and 0.5 mM PMSF) and incubated for 15 min on ice. Finally, the buffer was complemented with 0.5% IGEPAL CA-630 (Sigma-Aldrich), and the mixes were passed through a 22-gauge needle and centrifuged at 2000 × *g* for 5 min at 4 °C. The supernatant was removed, and the nuclear pellet was homogenized in 20 mM HEPES, pH 7.9, 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA, 1 mM DTT, and 1.0 mM PMSF. Nuclear samples were mixed vigorously for 30 min at 4 °C. The nuclear homogenates were centrifuged at 3000 × *g* for 5 min at 4 °C, and the supernatant was recovered for protein quantification by bicinchoninic acid assay (Sigma-Aldrich).

EMSAs were carried out using a 3′ end-labeled biotin duplex and unlabeled probes. The biotin-labeled reactions were performed according to the manufacturer's instructions (LightShift Chemiluminescent EMSA kit, Thermo Scientific). The EMSA binding reactions contained 10 mM Tris, pH 8.0, 1 mM $MgCl_2$, 5 mM NaCl, 2.5 mM EDTA, 2.5 mM DTT, 4% glycerol, 1.5 μg nuclear protein extract, 10 mM salmon sperm DNA and 16 fmol of each labeled duplex probe. For competition assays, a 500-fold molar excess of the unlabeled duplex probe was added to the mixture. The samples were separated on pre-run native 5% polyacrylamide gels and transferred to nylon membranes (Amersham Hybond-N+, GE Healthcare). DNA crosslinking to the membranes was achieved by membrane exposure to a UV transilluminator (312 nM bulbs) for 15 min. Finally, the complexes were detected by chemiluminescence according to the manufacturer's instructions (LightShift Chemiluminescent EMSA kit, Thermo Scientific). The sequences of the primers used for duplex probes were as follows:

XRE1-forward: 5′-TGCGCCCGCCTGGCTCGC-3′, XRE1-reverse: 5′-GCGAGCCAGGCGGGCGCA-3′; XRE consensus-forward: 5′-CTCGAA CTCACGCAACTCCGT-3′, XRE consensus-reverse: 5′-CGGAGTTGCGTG AGTTCGAGC-3′; XRE consensus mut-forward: 5′-CTCGAACTCACTCA ACTCCGT-3′, and XRE consensus mut-reverse: 5′-CGGAGTTGAAGTGA GTTCGAGC-3′.

2.11. Statistical analysis

The results are presented as the mean values ± standard deviation (S.D.). The statistical significance of the data was evaluated using Student's *t*-test. In all cases, the differences between the groups were considered to be statistically significant when the *p* value was less than 0.05.

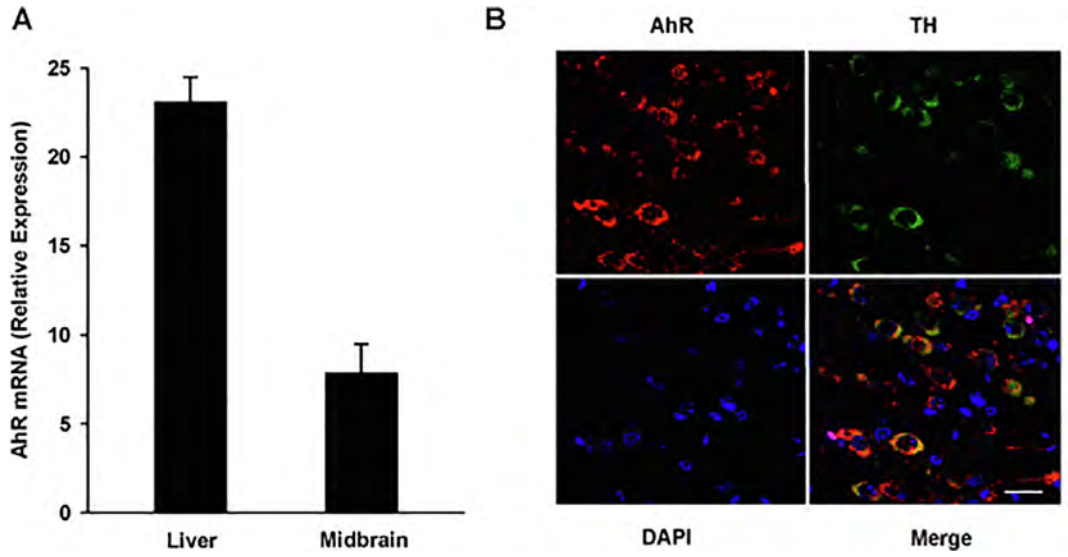

Fig. 1. AhR is expressed in the mouse ventral midbrain and DA neurons. A) Total RNA was extracted from the ventral midbrain region and liver of sacrificed mice. AhR mRNA levels were determined by qPCR and normalized to 18S ribosomal RNA. The results are expressed as the mean ± S.D. of samples from three different mice. B) Representative confocal microscopy images of AhR expression in the ventral midbrain region. AhR, TH and DAPI were visualized as red, green, and blue, respectively. Scale bar: 25 μM.

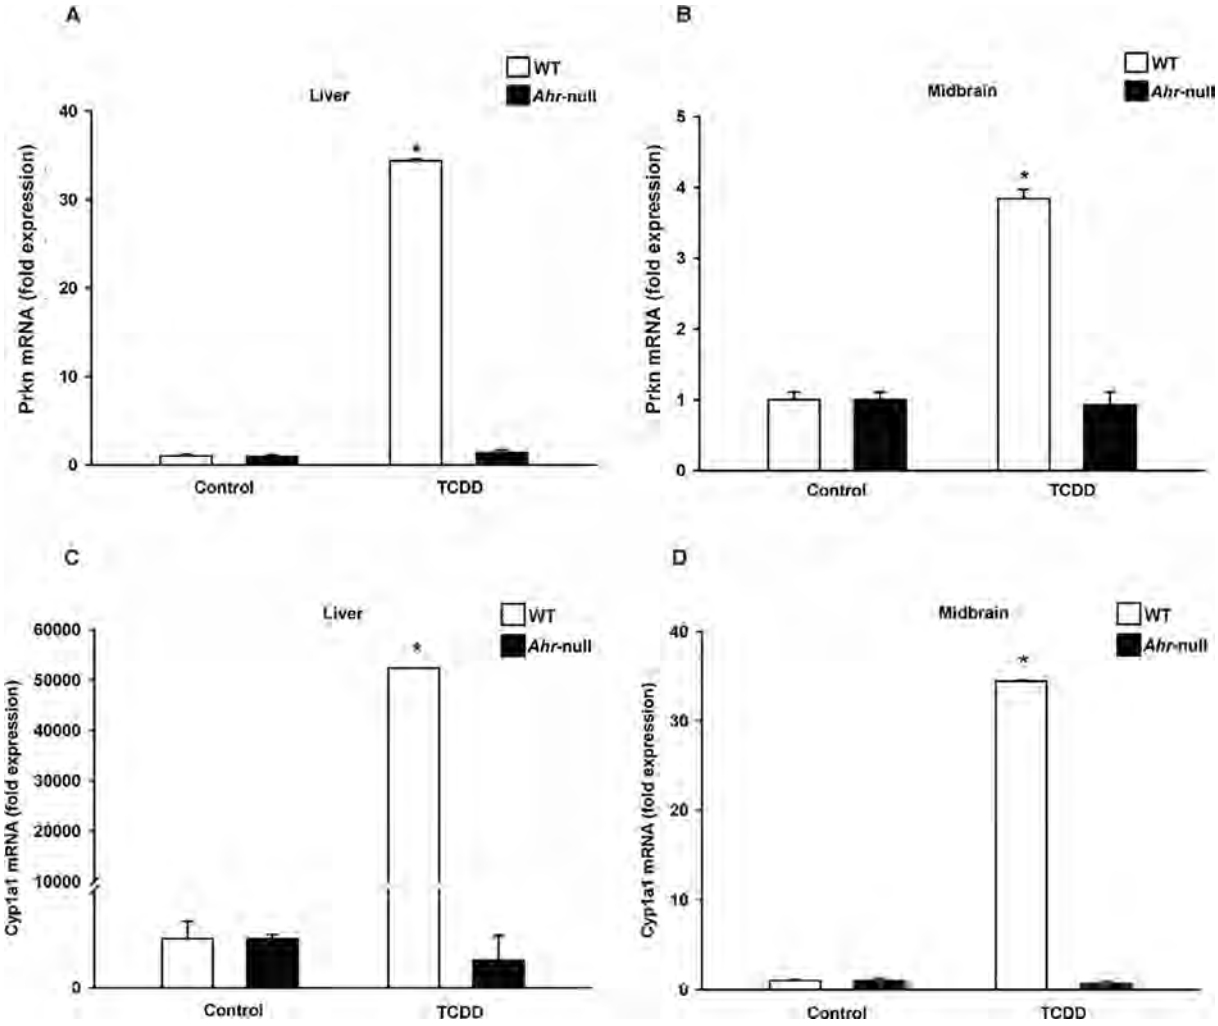

Fig. 2. AhR-dependent induction of *Cyp1a1* and *Prkn* mRNA in the ventral mouse liver and ventral midbrain. Wild-type (WT) and *Ahr*-null mice were treated with a single oral dose of TCDD or corn oil as vehicle. Total RNA was extracted from the liver and ventral midbrain region, and *Prkn* (A and B) and *Cyp1a1* (C and D) mRNA levels were determined by qPCR and normalized to 18S ribosomal RNA. The results are expressed as the mean ± S.D. of samples from three different mice. *$p < 0.05$, treatment *vs.* control.

INFORME DE LABORES 2019

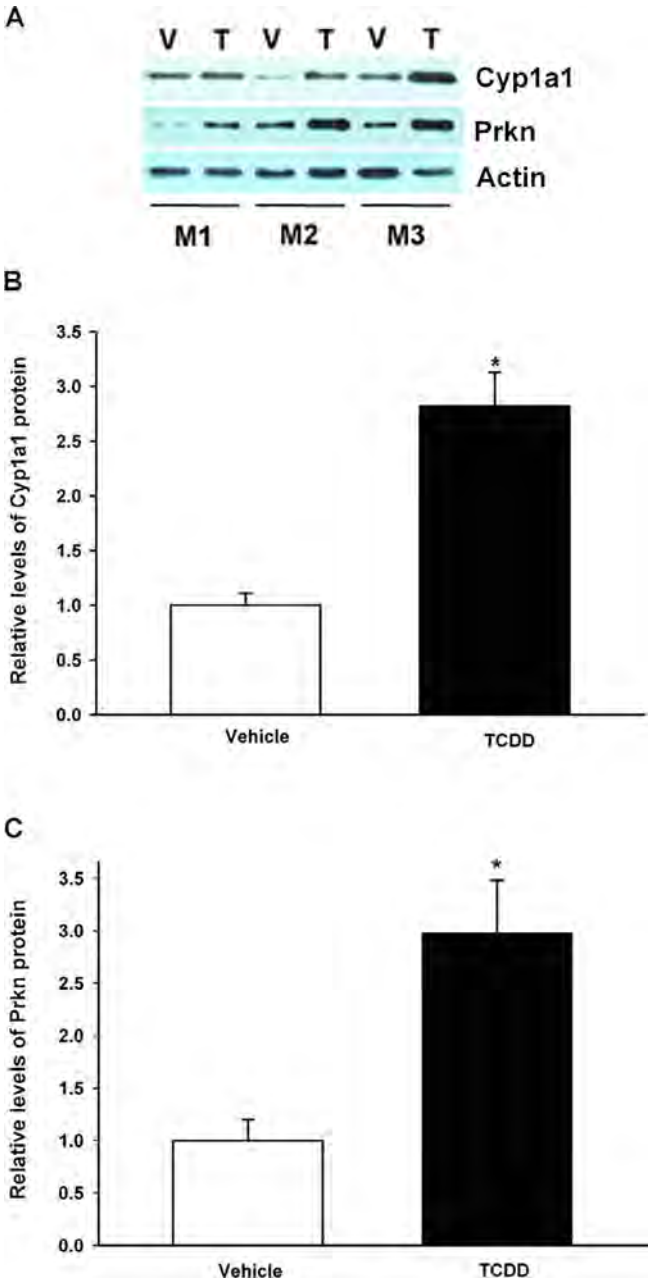

Fig. 3. TCDD treatment induced Cyp1a1 and Prkn protein levels in the mouse ventral midbrain. Wild-type mice were treated with a single oral dose of TCDD (T) or corn oil as vehicle (V), and Cyp1a1 and Parkin protein levels were determined by western blotting. Beta actin was used as a loading control (A). Relative Cyp1a1 (B) and Prkn (C) protein levels. The results are expressed as the mean ± S.D. of samples from three different mice (M1, M2, M3). *$p < 0.05$, treatment *vs.* control.

3. Results

Initially, AhR expression in the mouse ventral midbrain and DA neurons was evaluated. *AhR* mRNA was detected in the mouse ventral midbrain region at one-third of the level in the liver (Fig. 1A). Since the AhR expression is highest in the liver, the observed levels in the ventral midbrain are substantial. We then determined whether AhR protein is expressed in DA neurons. AhR protein was detected by immunofluorescence in the SNc of the adult mouse brain and the signal colocalized with that of tyrosine hydroxylase, a marker of dopaminergic neurons (Fig. 1B).

Compared to vehicle treatment, TCDD, an AhR agonist, induced 32- and 3.7-fold increases in the expression of *Prkn* mRNAs in the mouse liver and ventral midbrain, respectively (Fig. 2A and B). This induction was AhR-dependent, since no induction of *Prkn* mRNA was observed in TCDD-treated *Ahr*-null mouse liver and ventral midbrain. As expected, AhR activation induced expression of its canonical target gene, *Cyp1a1,* in both the liver and ventral midbrain region and the induction was also AhR-dependent (Fig. 2C and D).

Then, the Prkn and Cyp1a1 protein levels in the mouse ventral midbrain region were evaluated. Compared to vehicle treatment, TCDD treatment increased Prkn protein levels by approximately 3-fold (Fig. 3A and C). Similarly, a 3-fold increase in Cyp1a1 protein was observed (Fig. 3A and B).

The above studies confirm that AhR is expressed in the mouse ventral midbrain, particularly in DA neurons, and indicate that AhR activation upregulates *Prkn* mRNA and Prkn protein. These results prompted us to investigate and characterize the molecular mechanisms of AhR-dependent Parkin induction. *In silico* analysis of the mouse *Prkn* gene promoter was carried out (Fig. 4). Several response elements were identified. Of particular interest for the present study are the three putative concensus AhR binding sites, known as xenobiotic response elements (XREs), located −37, −54 and −349 bp from the *Prkn* transcription start site. ChIP revealed that AhR indeed binds to the *Prkn* gene promoter after TCDD treatment (Fig. 5A, lane 4). Moreover, a basal interaction between AhR and the *Prkn* gene promoter was also observed (Fig. 5A, lane 3), suggesting that this AhR may also be involved in the control of basal *Prkn* expression possibly through its activation by endogenous ligands.

To determine whether AhR binding to the *Prkn* promoter results in its transactivation, a luciferase reporter plasmid (pGL4/-419-mPrkn), driven by the mouse *Prkn* promoter, was constructed and transfected into SH-SY5Y human neuroblastoma cells. A dose response of increased luciferase expression from 1.0 to 10 µg of transfected plasmid was found after 10 nM TCDD treatment, up to a 3-fold increase with 10 µg of the reporter construct, relative to vehicle-treated cells (Fig. 5B).

According to the *in silico* study, among the three XREs identified, XRE1 exhibited the highest score. Therefore, the interaction between AhR and XRE1 was investigated by EMSAs. The addition of nuclear extracts from mouse livers and ventral midbrains treated with TCDD to the XRE1 motif resulted in the formation of a DNA-protein complex as represented by the shifted band (Fig. 6A-B, lane 2). This binding was specific since an excess of unlabeled XRE1 or consensus XRE probes blocked formation of this complex (Fig. 6A-B lanes 3 and 4), whereas an unlabeled mutated consensus XRE probe did not compete with the labeled XRE1 probe (Fig. 6A-B lane 5). Together, these results indicate that treatment with TCDD promotes AhR binding to XRE1, transactivates the *Prkn* gene promoter and induces *Prkn* mRNA and Prkn protein expression.

Next, we sought to determine whether the AhR-dependent increase in Parkin levels is associated with a decrease in the protein levels of their target substrates. For this purpose, WT and *Ahr*-null mice were treated with TCDD, and Snca protein levels in the ventral midbrain region were determined by western blot. After TCDD treatment, WT mice exhibited an approximately 10-fold decrease in α-synuclein protein levels compared to vehicle treatment (Fig. 7), and this change was significant. In contrast, this effect was not observed in *Ahr*-null samples.

4. Discussion

A deficit in Parkin levels and/or function have been associated with the etiology of several neurodegenerative disorders, including PD. Mutations in the human *PRKN* gene result in autosomal-recessive early-onset parkinsonism, and reduced Parkin expression has been linked to late-onset PD. Conversely, the overexpression of Parkin *in vitro* and *in vivo* protects DA neurons from a variety of cellular stressors that produce oxidative stress, excitotoxicity, mitochondrial dysfunction, endoplasmic reticular stress, apoptosis, and proteotoxicity [21,22]. Thus,

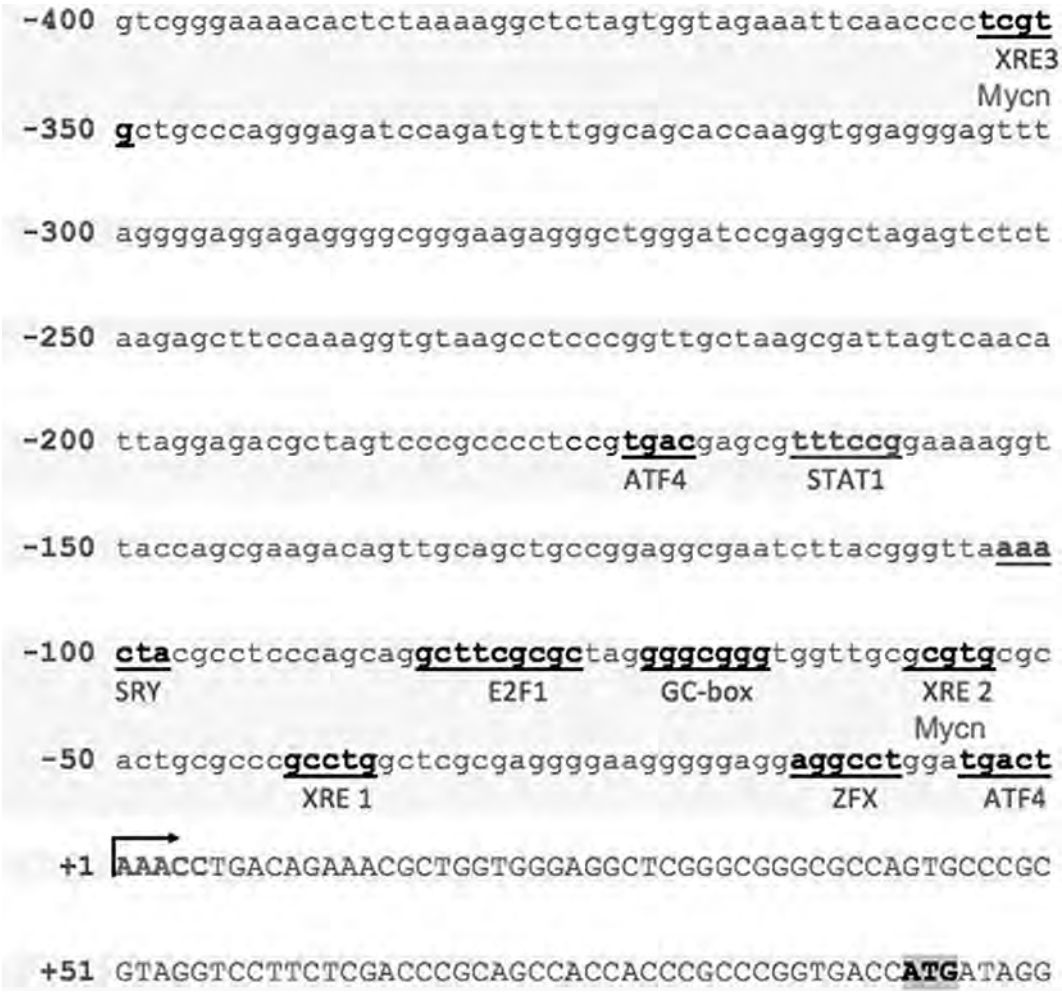

Fig. 4. Analysis of the 5′ region of the mouse *Prkn* gene. The 5′ region of the mouse *Prkn* gene was analyzed *in silico* to identify binding sites for known transcription factors (underlined). XRE: xenobiotic response element, Mycn: Mycn proto-oncogene neuroblastoma-derived response element, ATF4: activating transcription factor 4 response element, STAT1: signal transducer and activator of transcription 1 response element, SRY: sex-determining region Y factor response element, E2F: E2F transcription factor response element, GC box, and ZFX: zinc finger protein X-linked response element. The transcription start site is indicated by the arrow and the translation start site codon is indicated by shading.

gaining insight into the molecular mechanism that direct Parkin expression is crucial for the design of novel treatments based on the induction of Parkin levels.

Here, we show that Parkin is transcriptionally upregulated by TCDD via AhR activation. First, we demonstrated that this transcription factor is expressed in the mouse ventral midbrain, particularly in DA neurons. Considering that the liver is among the organs and tissues with the highest levels of AhR, the levels of its transcript in the mouse ventral midbrain were substantial; the levels in the ventral midbrain were one third of those observed in liver, suggesting that AhR has important functions in this brain region.

The induction of *Cyp1a1* mRNA in the ventral midbrain after TCDD treatment indicates that TCDD crosses the blood-brain barrier and reaches brain tissues to activate AhR. Similar to *Cyp1a1* but to a lesser extent, TCDD promotes the overexpression of Parkin. In both cases, the effect is AhR-dependent since no induction is observed in *Ahr*-null mice. At the protein level, compared to vehicle treatment, TCDD treatment results in a 3-fold induction in Prkn expression. These results clearly demonstrate that the activation of AhR upregulates *Prkn* gene expression.

The *in silico* analysis of the *Prkn* gene promoter identified 3 putative AhR binding sites, namely, XRE1, XRE2, and XRE3, which are located −37, −54 and −349 bp, respectively, from the transcription start site. The Prkn gene promoter in *Drosophila melanogaster* contains a binding site for AhR [18] and the human *PRKN* promoter contains 3 AhR binding sites, suggesting that the gene encoding Parkin may be under the control of AhR in several diverse species and thus this Ahr-driven signaling pathway must be of developmental and/or physiological consequence.

ChIP, EMSA, and transactivation studies confirmed that TCDD promotes AhR recruitment to the *Prkn* gene promoter, inducing Parkin expression. ChIP also showed an interaction between AhR and the promoter under control conditions, that is, without TCDD treatment. The above results suggest the possible presence of an endogenous ligand and that AhR may also control basal Parkin expression.

Prkn is transcriptionally regulated by the restriction of trophic factors and nutrients [23], p53 [24], activating transcription factor 4 (ATF4) [25], and N-myc (Mycn) [26]. Consistent with this, the *in silico* study identified the presence of ATF4 and Mycn binding sites. No p53 responsive elements were recognized because they are located in intron 1 and –3332 bp from the ATG site. Of particular interest is that Mycn and AhR share similar responsive elements within the *Prkn* promoter gene. In contrast to AhR, Mycn, a critical transcription factor involved in neural development [27], downregulates Parkin expression. The latter occurs in the context of differentiation when Parkin expression is observed in the latest stages of embryonic development and when Mycn expression is the lowest [26]. These data suggest that Mycn may negatively control Parkin expression by blocking AhR binding to Mycn/

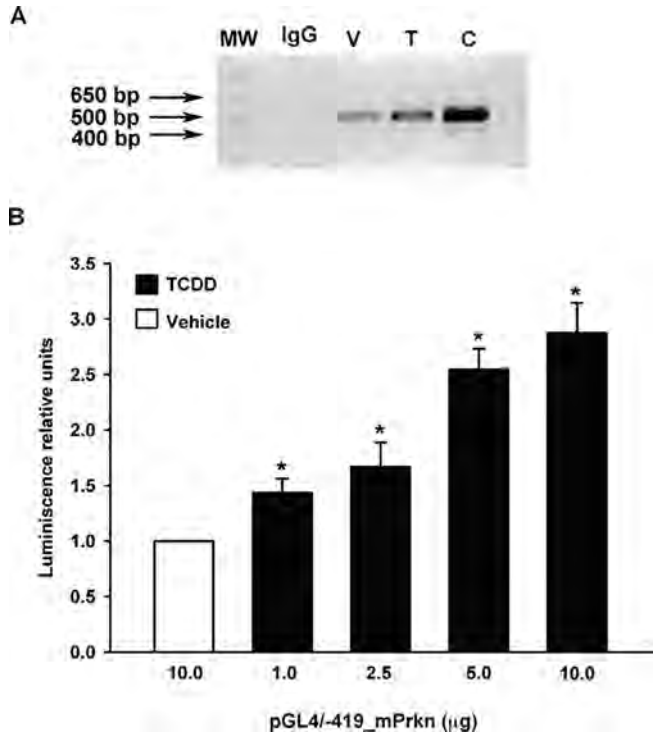

Fig. 5. AhR binds and transactivates the *Prkn* promoter gene. A) ChIP analysis of AhR binding to the mouse *Prkn* gene promoter region. Material for immunoprecipitation was obtained from the brain tissues of mice treated with corn oil as vehicle (V, lane 3) or a single oral dose of TCDD (T, lane 4). PCR products corresponding to the −407/+74 bp region of the *Prkn* gene promoter were generated. Genomic DNA was used as the positive control (C, lane 5) and IgG antibody was used as the negative control (IgG, lane 2). MW (lane 1) represents molecular weight markers. A representative gel of two independent experiments is shown. B) The luciferase activity of SH-SY5Y cells (1×10^6) transfected with 1, 2.5, 5 or 10 μg of the pGL4/-419_mPrkn vector containing the firefly luciferase open reading frame under the control of the mouse *Prkn* gene promoter and treated with 10 nM of TCDD or DMSO (vehicle) for 48 h was determined. The luciferase activity was normalized to *Renilla* luciferase activity and is expressed as the mean ± S.D. of three independent experiments. * $p < 0.05$, control *vs.* treatment.

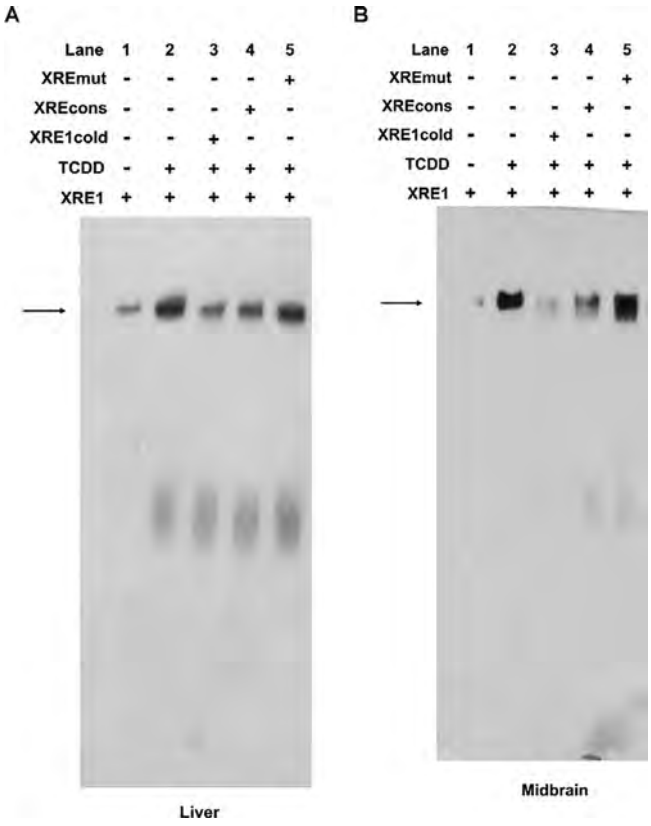

Fig. 6. EMSA analysis of protein binding to the putative XRE1 identified in the *Prkn* gene promoter. Nuclear extracts from the livers (A) or ventral midbrains (B) of mice treated with corn oil (lane 1) or 250 μg/kg TCDD (lanes 2–5) were incubated with a labeled putative XRE1 probe only (lane 2), with a labeled putative XRE1 probe plus a 500-fold molar excess of an unlabeled putative XRE1 probe (lane 3), with the putative XRE1 labeled probe plus an unlabeled consensus XRE probe characterized from the mouse *Cyp1a1* gene (lane 4), or with a labeled putative XRE1 probe plus an unlabeled mutated consensus XRE probe characterized from the mouse *Cyp1a1* gene (lane 5). The arrow indicates the shifted bands. The image is representative of 2 independent experiments. The nuclear extract was obtained from the ventral midbrain from 3 mice.

AhR responsive elements.

Additionally, a sex-determining region Y factor (SRY) response element located −98 bp from the transcription start site was identified. Immunohistochemical studies showed that SRY is expressed in DA neurons and that 6-OHDA induces its expression, while its knockdown exacerbates cell death produced by ROS [28]. It would not be unexpected for the reported SRY protective response to be mediated, at least in part, by the induction of Parkin expression. Similarly, the induction of ATF4 plays an important neuroprotection role against rotenone-induced DA neuronal death, presumably through the induction of Parkin levels [29].

TCDD treatment results in a significant decrease in the protein levels of α-synuclein (Snca) in the mouse ventral midbrain in an AhR-dependent manner. Snca function is not well understood, but it may play a role in synaptic functioning and neuroplasticity by regulating neurotransmitter release. It is present in several brain regions, including the SNc [30], and its progressive accumulation in cells leads to the degeneration of nigrostriatal circuits, resulting in several neurodegenerative diseases, such as PD. Cell stress, mutations, and posttranslational modifications disrupt the native Snca conformation exposing the central hydrophobic motif leading to its misfolding and aggregation. Particularly, phosphorylation at serine 129 (S129) has been associated with Snca fibrillation and the formation of cytoplasmic inclusions [31].

Snca clearance is carried out by the ubiquitin-proteosome system (UPS). However, there is no evidence indicating that S129-Snca is a parkin substrate. In contrast, in association with UbcH7, parkin ubiquitinate and promotes the proteasome degradation of *O*-linked glycosylated Snca [32]. Therefore, the decrease in Snca protein levels observed in the present study may be, in part, the result of the degradation of the *O*-linked glycosylated forms.

We previously reported that activation of AhR also results in UbcH7 induction together with a decrease in synphilin-1 (Sncaip) protein levels in the mouse ventral midbrain [16]. These data, together with those reported here, suggest that AhR-mediated increased Parkin and UbcH7 levels may be responsible for the decreased of both the *O*-linked glycosylated Snca and Sncaip protein levels. Snca degradation is also carried on by the autophagy-lysosomal pathway. We have reported recently that TCDD treatment, in an AhR-dependent way, induce the lysosome degradation of NFκB [33]. Thus, it is possible that the observed decrease in Snca is also due to lysosomal degradation.

The above may explain the parkinsonian effects derived from dieldrin exposure [34], a pesticide that has AhR antagonist properties [35]. On the other hand, AhR agonists such as beta-naphthoflavone and chemical mixtures containing AhR agonists such as cigarette smoke protect against MPP^+-induced dopamine depletion [36]. In fact, several epidemiological studies have reported a negative association between PD and cigarette smoking [37,38].

In addition to TCDD and beta-naphthoflavone, a highly toxic

INFORME DE LABORES 2019

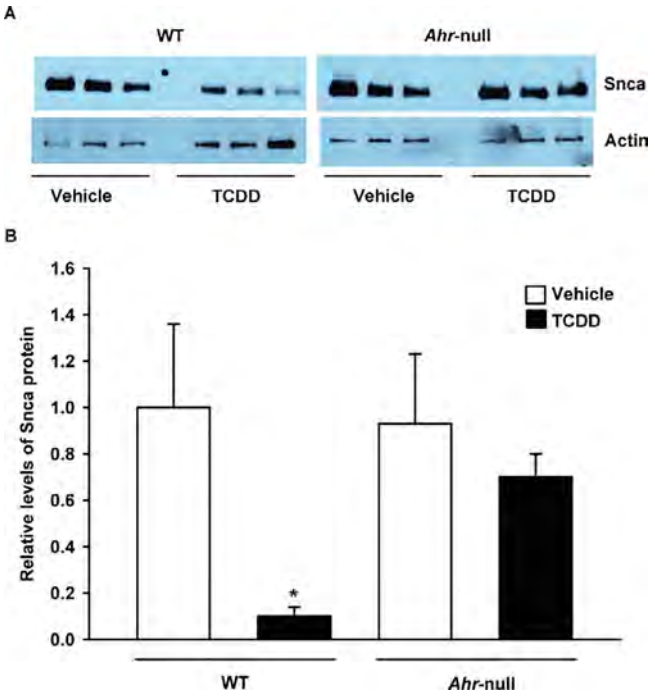

Fig. 7. AhR activation by TCDD results in a decrease in Snca protein levels in the mouse ventral midbrain. Wild-type (WT) and *Ahr*-null mice were treated with a single oral dose of TCDD or corn oil as vehicle, and Snca protein levels were determined by western blotting. Beta actin was used as a loading control (A). Relative Scna protein levels (B). The results are expressed as the mean ± S.D. of samples from three different mice. *p < 0.05, treatment *vs* control.

compounds, several endogenous or natural products such as kynurenine, FICZ (6-formylindolo (3,2b) carbazole), ITE (2-(1′H-indole-3′-carbonyl)-thiazole-4-carboxylic acid methyl ester) and I3C (indole-3-carbinol) act as AhR agonists. In particular, tangeritin, a citrus flavonoid with AhR agonistic activity [39], protects against parkinsonian effects induced by 6-OHDA in a rat model [40]. Similarly, carnosic acid, a diterpene with AhR agonist activity that is found in rosemary extract [41], protects SH-SY5Y cells from 6-OHDA-induced apoptosis [42].

Several investigations have shown that Parkin, in addition to playing a role in neuronal function, may act as a tumor suppressor gene. Mutations in the *PRKN* gene have been reported in colorectal and gastric cancer, lung carcinoma and breast cancer [43,44], while its overexpression inhibits the growth of colon [45], hepatocarcinoma [46], breast [47] and glioblastoma cancer cells [48]. Therefore, the induction of Parkin levels may have an effect on the development of carcinogenic processes.

Taken together, our findings provide *in vivo* and *in vitro* evidence suggesting that Parkin is transcriptionally upregulated by AhR, which is associated with reduced protein levels of Snca in the mouse ventral midbrain. The already established protective role of Parkin in DA neuron survival together with the present data strongly suggest that treatments designed to induce Parkin expression through the use of nontoxic AhR agonist ligands may prevent and delay the onset and progression of neurodegenerative disorders such as PD.

Received for publication June 13, 2018; accepted January 22, 2019 (ARCMED_2018_143).

Background and Aims. Atherosclerosis as an inflammatory disease involved in the etiology of cardiovascular disease worldwide, in our days demands an array of different therapeutic approaches in order to soon be able to visualize an effective prevention. Based on an immunotherapeutic approach, we designed a non-invasive vaccine (HB-ATV-8), contained in a micellar nanoparticle composed of lipids and a peptide segment derived from the C-terminus of the cholesterol-ester transfer protein (CETP). Now we extend our successful proof of concept from the rabbit to a porcine model and investigated its effect in an attempt to undoubtedly establish the efficacy of vaccination in a model closer to the human.

Methods. A preclinical trial was designed to study the efficacy of vaccine HB-ATV-8 in pigs (Large White × Landrace). Male experimental animals were fed with standard diet (control), high fat diet (HFD) or the same HFD but treated with HB-ATV-8 (HFD + Vaccine) applied nasally for up to 7 months. All biochemical and enzymatic analyses were performed in peripheral venous blood and thoracic aorta and liver samples examined using conventional, two-photon excitation and second harmonic generation microscopy to identify atherosclerotic and hepatic lesions. mRNA concentrations for *KLF2*, *ACTA2*, *SOD1, COL1A1* genes and protein levels for PPARα and ABCA1 were quantified in aorta and liver respectively using qPCR and Western blot analysis.

Results. The administration of vaccine HB-ATV-8 induced anti-CETP IgG antibodies and reduced atherosclerotic and hepatic lesions promoted by the high fat diet. In addition, plasma triglyceride levels of vaccine treated pigs fed the HFD were similar to those of control group, in contrast to high concentrations reached with animals exclusively fed with HFD. Moreover, HFD promotes a tendency to decrease hepatic PPARα levels and increase in aorta gene expression of *KLF2*, *ACTA2*, *SOD1 and COL1A1*, while vaccine application promotes recovery close to control values.

Conclusions. Vaccine HB-ATV-8 administration constitutes a promissory preventive approach useful in the control of atherogenesis and fatty liver disease. The positive results obtained, the non-invasive characteristics of the vaccine, the simple design employed in its conception and its low production cost, support the novelty of this therapeutic strategy designed to prevent the process of atherogenesis and control the development of fatty liver disease.

INFORME DE LABORES 2019

Introduction

Atherosclerosis is considered an inflammatory disease of the arterial wall that leads to cardiovascular disease (CVD), a common cause of death in the world according to WHO (1). Epidemiological studies have indicated that among the main risk factors associated with atherosclerosis there is an increased plasma level of low density lipoproteins cholesterol (LDL-C) associated to a decreased plasma concentration of high density lipoprotein cholesterol (HDL-C) (2−4). Nevertheless, the relationship between the concentration of the different plasma lipoproteins and its probability to develop atherosclerosis, is still unclear (5,6). Considering that a reduction of CVD nowadays should be directed towards prevention rather than treatment, there has been an important effort to reinforce measures mainly directed to a change in lifestyle and eating habits in order to impede the onset of atherosclerosis (7,8). Although this approach should be considered central in all prevention efforts, it has contributed little to the prevention of CVD in most countries of the western world (9,10).

From the pharmacologic point of view, although statins for years have offered a way to decrease the plasma concentration of LDL-C by acting upon the biosynthesis pathway of cholesterol, this approach has not been successful enough based on the fact that the number of deaths related to CVD associated with atherosclerosis continues to increase (11,12). Therefore, treatment of atherosclerosis exclusively based on a cholesterol lowering therapy still has to prove a significant efficacy in reducing CVD.

In consequence, considering this process is characterized by the accumulation of fat in the intima of arteries where innate and adaptive immunity play an important role in the process of atherogenesis (13,14), modulation of the immune response has attracted attention as a strategy for its prevention and treatment helping to restore the homeostasis of lipid metabolism and counteract an inflammatory state (15,16). In this sense, the study of several possibilities that contemplate potential proteins have been identified for their ability to decrease morbidity and mortality associated with the progression of atherosclerosis (17,18). Among the diverse strategies employed, the cholesteryl-ester transfer protein (CETP) has been studied as a potential therapeutic target (19−21). CETP promotes the mobilization of cholesteryl-esters, triglycerides and phospholipids between HDL and lipoproteins containing apolipoprotein B (ApoB) (LDL and VLDL) (22). Corresponds to a 66−74 kDa plasma glycoprotein that is mainly expressed in the liver and secreted into the bloodstream where it becomes associated to lipoproteins (23). Population studies have shown that a decreased concentration and/or reduced CETP activity are associated with increased HDL-C levels (23−25), and although several studies present a less clear correlation (26,27), most of them show that subjects presenting a low plasma CETP concentration show a lower probability to develop a cardiovascular event. In support of these findings, there are several reports indicating that a group of Japanese subjects while lacking CETP, present high HDL-C levels, low LDL-C levels and a low incidence of CVD (21,28).

The nasal administration of vaccine HB-ATV-8 composed of a micellar nanoparticle preparation has been designed as an immunotherapy to decrease CETP activity *in vivo*. Vaccine nanoparticles incorporate a 12 amino acid synthetic peptide corresponding to the C-terminal domain of CETP added of an N-terminal cysteine and a key mixture of lipids including caldarchaeol (29,30). As previously reported by us, the use of lysophosphatidylcholine allows the peptide to be kept in a key α-helical conformation (31,32), achieving at the same time structural stability and immunogenicity (33,34). Therefore, here we present an easy, cheap and efficient way to produce immunogenicity by applying a nanoparticulate preparation on the surface of the nasal mucosa.

Previous work from our group employing cholesterol-fed rabbits demonstrated that the nasal administration of vaccine HB-ATV-8 significantly reduces atherosclerotic lesions in the aorta, decreasing in parallel the presence of non-alcoholic fatty liver disease (NAFLD) in association with liver fibrotic lesions (16). This data might be considered important taking into account that CVD has been shown to be the leading cause of death in patients with NAFLD (35,36).

Now, before initiating the clinical phases for vaccine HB-ATV-8 to define safety and efficacy, we have extended our proof of concept to an animal model closer to human and studied the effect of therapeutic vaccine HB-ATV-8 in the pig as the experimental animal. Since the pig closely resembles the human in many traits including its anatomy, physiology, biochemistry and ultimately lifestyle (37−39), it has been considered for years an excellent non-primate model to study atherosclerosis. Therefore, the present study has been conducted for seven months employing pigs in an attempt to closely resemble conditions for the development of atherogenesis and fatty liver in the human.

Materials and Methods

Vaccine HB-ATV-8

Vaccine HB-ATV-8 (Patents US9539312, MX347400 B) contains as immunogen a synthetic peptide that corresponds to the carboxy-end amino acids H486−S496 of CETP (29,30). This peptide conjugated into a micellar nanoparticle system includes three of the four key residues that support lipid binding and transfer capacity (40). Micelles are composed of lipids derived from the cell membrane of *Thermus aquaticus*, mainly caldarchaeol. L-α-Phosphatidylcholine (PC) and 1-lauroyl-2-hydroxy-sn-glycero-3-phosphocholine (lyso-C_{12}PC) (31,32). These components

INFORME DE LABORES 2019

have been shown function as humoral adjuvants promoting a strong cytotoxic T-cell immune response characterized by a long-term memory (41–43).

Experimental Animal Procedures

The present study includes fifteen castrated male pigs (Large White x Landrace) housed at the Specific Pig facility (Barcelona, Spain). All animal procedures and experiments were performed in accordance with the Guide for the Care and Use of Laboratory Animals (NIH) and approved by the Deparment d'Agricultura, Ramaderia, Pesca, Alimentació i Medi Natural, de la Generalitat de Calalunya, and the Specific Pig Ethics Committee. The qualified staff of Specific Pig fed the animals, nasally administered the vaccine, collected blood samples, monitored their well-being, sacrificed the animals and collected tissues at the end of the experiment.

Pigs were housed at 10–24°C on a 12:12 h light/dark cycle in 3.32 m^2 pens (3–4 animals/pen) with a dry, non-toxic, absorbent and pathogen-free bed. The animals had free access to water and fed once daily. At the beginning of the protocol the average weight of animals corresponded to 40 kg. The study was based on three experimental groups: *Control group* (CT, $n = 3$) corresponds to pigs fed a standard diet (Porcs creixement 1, Pinallet) composed of 15.8% calories from protein, 3.5% from carbohydrates, and 3.7% from fat were kept for 4 ($n = 1$) and 7 months ($n = 2$). *High-Fat Diet group* (HFD, $n = 6$) corresponds to pigs fed a high-fat atherogenic diet (HFD) (SDS, 824100 Porcine Western, Dietex, France) for 4 ($n = 4$) and 7 months ($n = 2$). The diet contained 44% calories from fat (15% lard and 2% cholesterol), 16% calories from protein, and 40% calories from carbohydrates. *High-Fat Diet + Vaccine HB-ATV-8 group* (HFD + Vaccine, $n = 6$) corresponds to pigs fed the high-fat atherogenic diet that received vaccine HB-ATV-8 (300 µg) nasally administered twice a week for 4 ($n = 4$) and 7 months ($n = 2$). Blood samples from each experimental animal were taken every four weeks, and the experiment followed in two stages (4 and 7 months) as mentioned above where a certain number of animals at these specific times were anesthetized by intramuscular administration of ketamine (10–33 mg/kg) and midazolam (0.3–0.5 mg/kg), and euthanized with a sodium pentobarbital overdose (50–80 mg/kg, IV). Figure 1 summarizes the experimental protocol followed.

Plasma Lipid Profile and Enzyme Activity Measurements

Fifteen milliliters of peripheral venous blood were collected from the cranial vena cava at the beginning of the study and in a monthly basis till the end of the experiment. Serum and plasma-EDTA samples were used for biochemical and enzyme activity measurements, and the remaining biological material stored at –80°C until analysis. Zoologic Veterinaris laboratory (Barcelona, Spain) performed all lipid and enzymatic measurements. The lipid profile was measured by enzymatic methods following the manufacturers' instructions (Gernon platform, Ral, Spain). Plasma enzyme activity for aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase and total protein concentration were measured by standardized and commercially available colorimetric assays (Gernon platform).

Histological Examination

At the time of euthanasia, the thoracic aorta and liver samples from the right lobule were collected and a portion of these samples fixed in 10% formaldehyde. Samples were embedded in paraffin and stained with hematoxylin-eosin (H&E) and Masson's trichrome stain. The remaining tissue was frozen in liquid nitrogen and stored at −80°C until further analysis. Histological results were obtained by reviewing five different optical fields of view where percentages represent the frequency of the characteristics observed within each group.

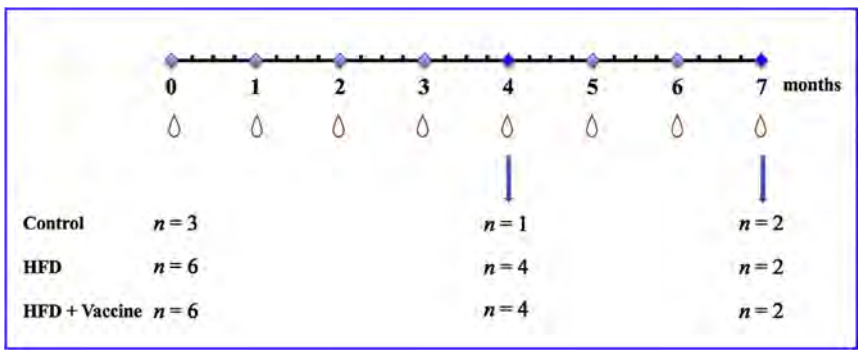

Figure 1. Experimental design. Control group (CT, $n = 3$); one animal from this group sacrificed at month 4 and the remaining two at month 7. High-fat diet group (HFD, $n = 6$); four animals from this group sacrificed at month 4 and the remaining two at month 7. High fat diet + vaccine treatment group (HFD + Vaccine, $n = 6$); four animals from this group sacrificed at month 4 and the remaining two at month 7. Blood samples were taken every month. HFD + vaccine group were administered with vaccine HB-ATV-8 twice a week.

INFORME DE LABORES 2019

Classification of atherosclerotic lesions was performed according to the guidelines of the American Heart Association (AHA) (44). The six aortic lesion types defined by the AHA are: (type I) isolated macrophage foam cells; (type II) intracellular lipid accumulation; (type III) type II changes and small extracellular lipid pools; (type IV) type III changes and presence of an extracellular lipid core; (type V) presence of a lipid core and a fibrotic layer or multiple lipid cores and fibrotic layers, areas of calcification; (type VI) all previous findings plus the presence of areas of hematoma/hemorrhage and thrombus.

Liver sections were evaluated considering histopathological characteristics for NAFLD: steatosis, inflammation, ballooning, and fibrosis (45,46) and data reported as presence or absence of these characteristics.

Two-photon Excitation Microscopy and Second-harmonic Generation Microscopy

Two-photon imaging was performed using a galvanometer-based scanning system LSM 710-Zeiss and a Ti: sapphire laser (Coherent) employing a wavelength of 850 nm (2.5% of laser power) for H&E stained aorta and liver slides. Second-harmonic generation imaging was performed using a wavelength of 900 nm (12% of laser power) and a BP 420−480 nm filter (Zeiss). Images were acquired using water immersion objectives; C-Apochromat 10x and W Plan-Apochromat 20x, with a 40x optical zoom for liver slices.

Anti-CETP Titer Determination

IgG antibody titer for CETP was measured by ELISA. Briefly, plates were coated with CETP synthetic peptide H486-S496, blocked and incubated with pig serum (1:100), a goat horseradish peroxidase-conjugate anti-pig IgG, and tetramethylbenzidine. OD was measured at 450 nm.

Protein Expression Analysis

Liver samples were homogenized in cold RIPA buffer (Thermo Fisher Scientific, MA, USA) supplemented with protease inhibitors (Roche, Rotkreuz, Switzerland). Total protein concentration (serum and liver extracts) was measured using the DC Protein Assay (Bio-Rad, CA, USA). Serum proteins were separated by SDS-PAGE using 8% gels and transferred to PVDF membranes (Immobilon-P, Millipore, MA, USA) to be analyzed by Western blot. Blots were incubated overnight with rabbit anti-CETP (Thermo Fisher Scientific, MA, USA) or mouse anti-ACTB antibodies (Santa Cruz Biotechnology, CA, USA). Also, membranes for liver extracts were incubated with mouse anti-PPARα, anti-ABCA1 and anti-GAPDH antibodies (Santa Cruz Biotechnology, CA, USA). Immunoreactive proteins were visualized with the Immobilon Western Chemiluminiscent HRP reagent (Millipore, MA, USA). Blots were quantified using the Image J software (http://rsb.info.nih.gov/ij/) and results presented as the CETP/ACTB (β-actin) ratio for serum protein and PPARα or ABCA1/GAPDH ratio for liver extracts.

Quantitative PCR Measurements

Total RNA was extracted from the thoracic aortas with Trizol reagent (Thermo Fisher Scientific, MA, USA). 1 μg of total RNA was used to synthesize cDNA using the iScript cDNA synthesis kit (Bio-Rad, CA, USA) and cDNA diluted to perform qPCR experiments. Expression of Krüppel-like factor-2 (*KLF2*), smooth muscle alpha (α)-2 actin (*ACTA2*), superoxide dismutase 1 (*SOD1*), collagen type I alpha 1 (*COL1A1*) and the housekeeping gene *ACTB* was determined by qPCR using the PowerUp Sybr Green Master Mix 2X (Applied Biosystems, CA, USA) on an ABI PRISM 7000 Sequence Detection cycler. Primer sequences are reported as supplementary material as well as relative levels of mRNA calculated as $2^{-\Delta\Delta Ct}$ (Supplementary Table 1).

Statistical Analysis

Data are expressed as mean±S.E.M. Statistical differences among study groups were calculated using ANOVA or Kruskal-Wallis tests, depending on the distribution of variables. p values ≤0.05 were considered significant. Analysis of data was performed with the SPSS v20 program (SPSS, Chicago, USA).

Results

The nasal administration of vaccine HB-ATV-8 induced the formation of anti-CETP IgG antibodies in the group of pigs fed a HFD where the rise in antibody titer became evident after the fourth month of treatment and remained at a high level until the end of the study (Figure 2A). Although the CETP serum concentration was kept at the same level throughout the study in the three groups of experimental animals (Figure 2B), the body weight of pigs fed a HFD was higher compared to those fed a standard diet regardless of whether they received the treatment or not (Figure 2C).

Since it is known that CETP is able to modify the serum level of the different types of lipoproteins by mobilizing cholesteryl-esters and triglycerides, we evaluated if the administration of vaccine HB-ATV-8 altered the serum level for these lipids. As expected, it was found that HFD fed pigs showed a steady increase of total cholesterol, LDL, HDL cholesterol and triglycerides (Figure 3). Interestingly, the only parameter that was significantly modified by the administration of vaccine HB-ATV-8 corresponds to triglycerides that remained at levels similar to the control group (Figure 3D). The serum level for total proteins and

INFORME DE LABORES 2019

the activity for liver function enzymes such as transaminases and alkaline phosphatase remained stable without statistically significant differences among groups (Supplementary Table 2).

At the end of the experiment, thoracic aorta and liver samples were prepared and examined by conventional light microscopy together with two-photon excitation and second harmonic generation microscopy. Figure 4 shows representative images for samples of the thoracic aorta of pigs belonging to each one of the three experimental groups studied. As expected, aortas from pigs fed the standard diet showed a normal vessel structure. In contrast, pigs fed a HFD show lipid droplets and foam cells in the media and the intima layers of the aorta and an increase of vascular smooth muscle cells (VSMC) in the intima layer (Figure 4A and B) and present type II and III atherogenic

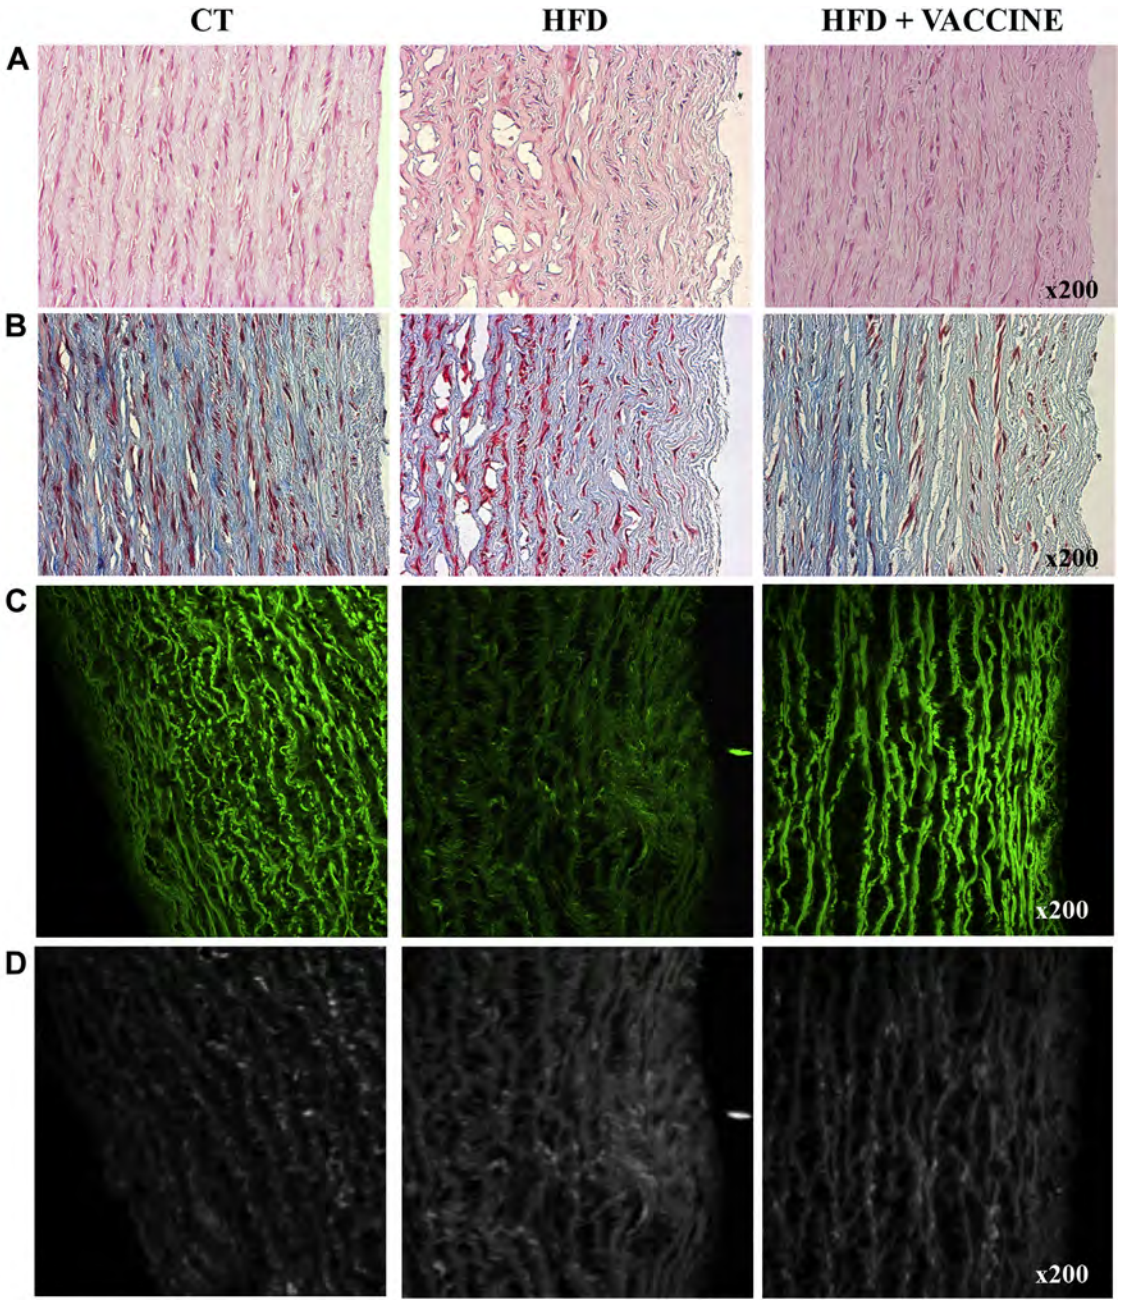

Figure 4. Vaccine HB-ATV-8 prevents the formation of atherosclerotic lesions induced by a HFD. INFORME DE LABORES 2019

lesions (Table 1). Moreover, collagen sheets observed in a widely distributed and spaced fashion, when studied with Masson's trichrome stain show a disordered and unevenly spaced arrangement. This can be clearly observed when the same samples are analyzed by two-photon excitation and second harmonic generation microscopy (Figure 4C and D). Using these imaging techniques, the connective fiber disorder found in aortas of pigs fed a HFD becomes evident denoting an important disarray among the different cell types that compose the vessel wall (Figure 4C and D). In contrast, the group of pigs that received the same HFD but was treated with vaccine HB-ATV-8 exhibit a decreased presence of lipid droplets and foam cells in the intima and media layers, and a smaller number of VSMC in the intima layer, similar to that shown in animals from the control group. More importantly, by two-photon excitation and second harmonic generation microscopy, a better ordered and a less spaced collagen fiber array together with a close to normal cellular architecture is observed (Figure 4C and D). Moreover, 50% of HB-ATV-8 treated pigs do not show any atherosclerotic lesions in their aortas and the remaining 50% only presented type I atherosclerotic lesions, in contrast to animals from the HFD group that showed type II or type III lesions (Table 1).

In order to obtain a better understanding at the molecular level of the histology changes observed with treatment, we analyzed the aortic expression of several genes known to be involved in vascular function such as the Krüppel-like factor-2 (*KLF2*), smooth muscle alpha-actin-2 (*ACTA2*), superoxide dismutase 1 (*SOD1*) and collagen type I alpha 1 (*COL1A1*) (Figure 5). KLF2 corresponds to an atheroprotective transcription factor that regulates expression of several vasoactive endothelial genes involved in the regulation of normal constriction/dilation of VSMCs (47), whereas SOD1 protects cells against cytotoxicity by scavenging superoxide radicals while being also involved in endothelial function by protecting nitric oxide release (48). *COL1A1* has been studied on the fact that corresponds to the most abundant protein associated to collagen fibrils (49). Furthermore, *ACTA2* has been employed as a cell marker for smooth muscle and associated to several occlussive diseases (50,51). So, consistent with tissue damage observed in our histology analysis associated to the HFD, there is a tendency for mRNA levels of these four genes to be upregulated in the aorta when compared to tissue from the control group (Figure 5). Interestingly, in all cases when gene expression is studied in the HFD group that received vaccine HB-ATV-8, the tendency is to go back to levels found associated to aortas from the control group (Figure 5).

We next assessed whether pigs fed a HFD present the typical hepatic alterations observed in NAFLD. Figure 6 shows sections of liver tissue from experimental animals of each group, displaying areas of hepatocytes around the central lobular vein. Hepatic tissue from control pigs presents the normal lobular histological characteristics. In contrast, hepatocytes from livers coming from pigs fed a HFD show microvesicular fat accumulation and signs of ballooning and inflammation. Interestingly, when the HFD + Vaccine group was examined, the frequency of these pathological features was considerably reduced (Table 2). It is important to mention that when compared to our previous findings employing a rabbit model (16), the current results show a less dramatic effect that might be related to the fact that the porcine model is considered refractory to develop not only fatty liver disease but also atherosclerosis in the same way as humans do (52). Nevertheless, when liver slides are studied by two-photon excitation and second harmonic generation microscopy, experimental animals from the HFD + Vaccine group, in comparison to the group that did not receive the vaccine, showed a decreased collagen deposition around the perisinusoidal and periportal areas and in general less fibrosis showing images close to the ones found in control tissue (Figure 6C and D).

Again, in order to initiate the exploration at the molecular of events that might be taking place with the administration of vaccine HB-ATV-8, we measured in liver tissue protein expression for the ATP-binding cassette transporter (ABCA1) defined as a cholesterol transporter that plays an important role in the homeostasis of cholesterol in the liver (53), and PPARα, reported to mediate fatty acid metabolism

in the hepatocyte (54). Our analysis shows that although ABCA1 apparently is not significantly modified neither on animals fed with a HFD nor animals fed the HFD plus vaccine administration, there is a tendency for PPARα to increase in pigs fed a HFD that received the vaccine when compared to the HFD and control groups (Figure 7). These findings might support the possibility that a molecular compensatory effect at the cellular level might not only be carried out by the anti-CETP antibody but also by the peptide itself or one of the lipid components of vaccine HB-ATV-8.

Discussion

Since immunomodulation of key proteins that control the metabolism of cholesterol has been proposed as a prophylactic tool to treat atherosclerosis, vaccine HB-ATV-8 has been designed as a therapeutic strategy to reduce the development of atherosclerosis by generating autoantibodies against CETP. With support on our successful proof of concept carried out in the rabbit, vaccine HB-ATV-8 now has been tested in a porcine model. The pig as an experimental animal has gained interest in recent years since it has been shown that the evolutionary distance among many animal models used today, especially between rodents and humans, is a distant one (37). Preclinical studies performed in murine models can be useful in identifying new biochemical mechanisms or molecules and provide a platform for pharmacological development; nevertheless, as shown in the literature in many cases translation to a clinical setting has proven to be a difficult one. In contrast, the pig and the human share many characteristics, such as a similar anatomy and cardiovascular physiology, a situation that explains why cardiac output, mean arterial pressure and stroke volume are almost equivalent (55). Although the process of atherogenesis in pigs is difficult to develop given that many strains of farm pigs along time have been normally selected for an increase in protein deposition rather than fat accumulation (56), a HFD supplemented with cholesterol eventually promotes the development of artery lesions similar to those observed in the atherosclerotic disease in the human (5,57,58). Therefore, taking into account these considerations, the pig model can be considered an optimal model for the study of atherosclerosis and associated diseases such as NAFLD (59). Employing this experimental model and the use of a novel nanoparticle composition that serves as an immunogen when placed in the nasal mucosa, our study shows that modulation of the immune response continues to be a promising approach in the prevention of atherogenesis.

The present study shows that intranasal administration of vaccine HB-ATV-8 induces anti-CETP IgG antibodies, in turn reducing in parallel the presence of atherosclerotic lesions and hepatic damage in pigs fed a HFD. These results are also related to the fact that serum triglycerides remain at control values, in contrast to the not treated animal group fed a HFD. Even though triglycerides are not considered

atherogenic, it is well known that serum levels for this family of lipids are considered as a biomarker for CVD risk. This can be partially explained by their direct association with remnant lipoproteins and ApoCIII, a proinflammatory and proatherogenic apolipoprotein that inhibits the binding of ApoE and ApoB to proteoglycans and hepatic receptors, preventing clearance of these type of lipoproteins and therefore favoring their accumulation in the endothelium (60–63).

During an early stage of atherogenesis, cholesterol and other lipids penetrate the intima of arteries where their accumulation induce an inflammatory state and the activation of the immune system. As a consequence, macrophages infiltrate the tissue, start internalizing cholesterol and originate the formation of foam cells (44). Subsequently, foam cells are lysed, releasing lipids that further accumulate in the extracellular matrix. To decrease toxicity due to the extracellular deposition of lipids (64,65), VSMCs

Fibrosis reported in these samples was mainly portal or perisinusoidal and portal/periportal fibrosis.
[a]Microvesicular steatosis.

migrate and begin internalizing excess lipid in support of macrophage function. Although VSMCs are responsible for remodeling the arterial wall, a prolonged state of oxidative stress causes their trans-differentiation to macrophage-type cells (66). These cells are able to phagocytize and present antigens, favoring the inflammatory state (67,68). Moreover, the structure of the arterial wall specifically depends on a delicate equilibrium between the synthesis and degradation of extracellular matrix proteins such as collagen and elastin, where an acute change in this equilibrium might play an important role during the process of atherogenesis. In this sense, an uncontrolled degradation of proteins of the extracellular matrix carried out by proteases such as metalloproteinase-1 and -9, might induce further vascular damage. This in turn promotes atherogenesis through the trans-endothelial migration of leukocytes, migration and proliferation of VSMCs, neovascularization, vascular cell apoptosis, and finally the formation of a neointima that might progress until the rupture of the aortic wall takes place (69). Together with cells of the immune system involved in atherosclerosis such as monocytes converted into macrophages, new studies have pointed to mast cells and stellar cells as critical cell types important in collagen degradation and smooth muscle survival (70). Mast cells produce and release matrix metalloproteases together with proinflammatory molecules such as interferon and interleukin-6 inhibiting the proliferation of smooth muscle cells and also promoting the process of apoptosis (70–73).

Since the use of two-photon excitation and second harmonic generation microscopy has been extremely useful to study the extracellular matrix and to visualize collagen fibers in association to a classical light microscopy, the study of viable arteries *ex vivo* gives us a better understanding of the functionality and dynamic behavior of the artery wall (74,75). During the course of our study, we observed that vaccinated animals fed a HFD did not show the clear disarray of extracellular matrix observed in the aortas of

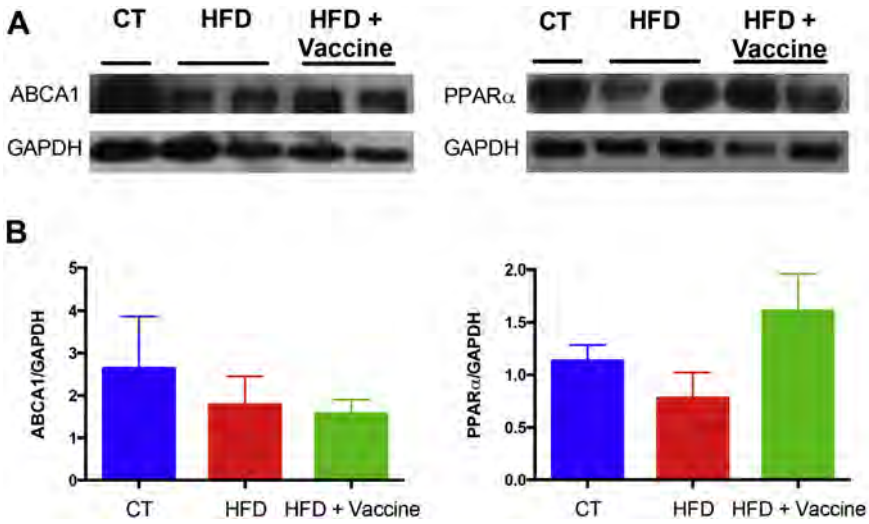

Figure 7. Vaccine HB-ATV-8 effect on hepatic PPARα and ABCA1 concentration. (A) Western blot analysis of samples obtained from one representative control animal and two representative samples from the HFD and HFD + vaccine groups. (B) Semicuantitative protein correlation between expression of ABCA1 and PPARα with GAPDH. Control group (CT, n = 3), high fat diet group (HFD, n = 6), and high fat diet + vaccine treatment group (HFD + Vaccine, n = 6). Data represented as mean ± S.E.

INFORME DE LABORES 2019

animals that were only fed a HFD without vaccination. This phenomenon is shown to be accompanied by an increased expression of *KLF2, ACTA2, COL1A1 and SOD1* mRNA's in the aortas of animals fed exclusively the HFD. Interestingly, this increase in mRNA levels is reversed close to control values in animals fed a normal diet when the HFD plus vaccination group is studied, suggesting that vaccine HV-ATV-8 might be also considered as a modulator of anti-atherosclerotic signals. It is well known that a HFD induces vascular dysfunction upregulating pathways associated to the production of reactive oxygen species (ROS), oxidative stress, and release of proinflammatory adipokynes/cytokynes (76–78). KLF2 inhibits both the expression of inflammatory cytokynes and the production of adhesion molecules such as VCAM-1 and E-selectin, known to be critical for leukocytes recruitment and extravasation (79,80). In addition, aortas from pigs fed a HFD show a disordered pattern of collagen fibrils, that to a certain extent, is less apparent in aortas isolated from animals fed the HFD plus vaccination, also in agreement with results showing a tendency to present a lower mRNA concentration and synthesis of type I collagen. Interestingly, during the development of an atherosclerotic plaque, the extracellular matrix composition of a vessel undergoes pronounced changes, where VSMCs initially showing a contractile phenotype are transformed to present a synthetic phenotype with the consequent increase in the deposit of types I and III collagen, elastin and fibronectin (49).

On the other hand, steatohepatitis and atherosclerosis share several characteristics such as lipid accumulation and the development of an inflammatory state (45,81). During the present study, pigs fed a HFD in addition to the presence of atherosclerotic changes, also developed hepatic disease characterized by microvesicular steatosis, ballooning, cellular inflammation, and fibrosis. Two-photon and second harmonic generation imaging clearly show the enormous difference in collagen deposition observed in liver tissue obtained from the group of animals exclusively fed the HFD and those treated simultaneously with vaccine HB-ATV-8. In general, experimental animals fed the HFD independently if they received or not the vaccine, do not show macrovesicular steatosis. This phenomenon is most probably due to the relatively short period of time used to carry out the study before animal sacrifice (56). Nevertheless, the presence of inflammation and fibrosis was less evident in the HFD + Vaccine group in comparison to HFD fed pigs.

The tendency for PPARα to increase in liver cells of animals fed a HFD that received the vaccine supports an explanation for the reduced level of plasma triglycerides found in this group of animals. PPARα considered a transcription factor that regulates the expression of genes involved in VLDL production, lipid trafficking and triglyceride-rich lipoprotein clearance, apparently helps suppress the acute-phase response and inflammation in the liver (82–84) and in conjunction with PPARβ/δ, shown to improve steatosis, inflammation and fibrosis in preclinical models of NAFLD (83,85).

Since our findings show that vaccine HB-ATV-8 decreases fat accumulation and most probably an inflammatory state in the artery wall and liver, it is important to point out that even though an auto-anti-CETP antibody titer was clearly detected around 4 months of treatment, at this time the effect was already observed. We also hypothesize that in addition to the regulation of lipid transport carried out by CETP due to the effect of the auto-anti-CETP antibody, there might be additional protective mechanisms that could be also related to a direct effect given by one of the components of the vaccine preparation, such as the peptide itself. This possibility is supported by studies of a series of peptides that promote the efflux of cholesterol from cells (86). Our group has also shown using cultured macrophages, a decrease in foam cell formation and down-regulation of CD36 and ACAT-1 when the peptide itself is tested (87,88). Evidence also shows that several other peptides interacting with endothelial cells, VSMCs, monocytes and/or macrophages, might be used for therapeutic purposes in the control of atherosclerosis (89–91). Since the HFD group independently if vaccinated or not maintain the same gain in body weight along the study, we speculate that vaccine HB-ATV-8 might also promote the accumulation of lipids in other tissues such as the adipose tissue. Current experiments are being carried out to establish this possibility.

Among the series of drugs offering to decrease the risk of cardiovascular disease by increasing the serum concentration of HDL-C, several CETP inhibitors obtained by chemical synthesis have been studied (92). Several other strategies include the use of fibrates (93) and antioxidants (94), but at the end also apparently ineffective to decrease the risk of CVD. Considering CETP as a plasma protein that transfers cholesteryl-esters among lipoproteins, specifically HDL to VLDL and LDL, it has been described as a molecule that promotes atherogenesis; therefore, the potential inhibition of its activity by new molecules has attracted attention in an effort to increase HDL-C and decrease coronary artery disease (95). Nevertheless, the use of these chemically synthesized compounds in the strategy to inhibit CETP has shown to be troublesome (92,95,96). Torcetrapib was the first CETP inhibitor to be tested in Phase 3 clinical trials, but had to be prematurely terminated due to a series of cardiovascular problems and mortality associated with non-cardiovascular events (97–100) such as infection and off-target aldosteronism as presented in the ILLUMINATE, RADIANCE and ILUSTRATE trials (97,100,101). These studies showed an increase in HDL-C and a decrease in LDL-C but no impact in the presence of atheroma lesions (100,102).

During the Phase 2 clinical trial of CETP inhibitor dalcetrapib, the study had to be stopped due to off-target side

INFORME DE LABORES 2019

effects and ineffectiveness shown by a non-significant effect on plasma LDL-C levels despite a moderate increase in HDL-C (103). Also, the OUTCOMES phase 3 trial had to be halted due to a lack of clinically meaningful efficacy (104). Although evacetrapib also improved lipoprotein biomarker distribution, treatment did not result in a lower rate of cardiovascular events among patients with high-risk vascular disease (105). So far, anacetrapib seems to show a better effect on various coronary events studying patients presenting atherosclerotic vascular disease but only under intensive statin therapy (106). Taken these data together, due to the presence of side effects and off-target activity, there seems that chemically synthesized CETP inhibitors need more time to be completely understood.

The example of torcetrapib could be considered a prototypical one since we now know that CETP binding sites for this molecule are shared with proteins of the Plunc family including an isoform of CETP named by our group as CETPI and identified as a lipopolysaccharide binding protein (107). According to our results, an non-specific binding phenomenon might have been directly related to sepsis and the mortality rate shown in the ILLUMINATE trial (108−110) since torcetrapib might have had an unknown secondary effect disabling the main function of CETPI directly related with the inactivation of LPS in plasma.

In contrast to the several strategies discussed in this study used to inhibit the function of CETP, the induction of an immune response by self-generating anti-CETP antibodies shows many advantages above other approaches to treat the process of atherogenesis (20,111−113). The present investigation studying a porcine model corroborates our previous reports showing that intranasal therapeutic vaccine HB-ATV-8 is effective in the control of the process of atherogenesis and the development of fatty liver disease, associated to important advantages such as simplicity of design and application combined to a low production cost.

Conclusion

Considering that for many years no new synthesis of lipid metabolism modulator molecules have been successfully introduced into clinical practice, the immunological approach using the generation of autoantibodies against key proteins involved in the physiopathology of atherosclerosis have come into play. Among the several immunological approaches used to inhibit CETP function, vaccine HB-ATV-8 seems to be the only one that offers non-invasive intranasal vaccination employing a micellar nanoparticle preparation composed of a mixture of common lipids and a peptide together with the use a simple delivery device. Since vaccination ameliorates atherosclerotic and hepatic lesions caused by a HFD improving triglyceride metabolism and promoting atheroprotective and anti-inflamatory signals, vaccine HB-ATV-8 offers a brand new approach to prevent the process of atherogenesis and associated NAFLD in the human.

Acknowledgments

This study was supported by grants from CONACyT, Mexico (255778) and PAPIIT-UNAM (IN205717), Mexico awarded to J.M-O. Support also came from CONACyT (grants 219327, 222227 and 233172) awarded to Bioextracto S.A. de C.V. and development grant HB08 received from Hamol Biosolutions LLC. R.G-V received a postdoctoral fellowship from UNAM. Authors thank Yazmín Ramiro-Cortés for expert advice with microscopy techniques, the Molecular Biology Unit at IFC, UNAM; members of the Oligonucleotide and DNA Sequencing Unit at IBT, UNAM; and Jorge Bravo-Martínez for fruitfull discussions and help with graphical art. We appreciate the generous donation of several monoclonal antibodies from Santa Cruz Biotechnology. This study is dedicated to the memory of Ale.

Abstract

Membrane microdomains or lipid rafts compartmentalize cellular processes by laterally organizing membrane components. Such sub-membrane structures were mainly described in eukaryotic cells, but, recently, also in bacteria. Here, the protein content of lipid rafts in *Escherichia coli* was explored by mass spectrometry analyses of Detergent Resistant Membranes (DRM). We report that at least three of the four *E. coli* flotillin homologous proteins were found to reside in DRM, along with 77 more proteins. Moreover, the proteomic data were validated by subcellular localization, using immunoblot assays and fluorescence microscopy of selected proteins. Our results confirm the existence of lipid raft-like microdomains in the inner membrane of *E. coli* and represent the first comprehensive profiling of proteins in these bacterial membrane platforms.

Introduction

Cell membranes not only confine the boundaries of cells, but also provide highly specialized lipid platforms involved in many cellular processes [1]. For instance, the most studied lipid assemblies of eukaryotic membranes are the lipid rafts, which are liquid-ordered (gel-like) lipid clusters enriched in sphingolipids and cholesterol. Lipid rafts are able to float and diffuse in the lateral plane of the cell membrane and fuse together forming larger aggregates [2]. They provide platforms for the assembly and proper functioning of many protein complexes, which are mainly involved in signal transduction, vesicle trafficking, cytoskeleton rearrangement, and ion channel regulation [3–6]. Cholesterol is known to increase the thickness and to regulate the fluidity of lipid bilayers, and it is considered as an essential lipid component of lipid rafts. Other common constituents of lipid rafts are the flotillins, which belong to a family of proteins that contain the Stomatin/Prohibitin/Flotillin/HflK/C (SPFH) domain. These proteins appear to be essential for the orchestration of processes related to lipid raft formation, and are used as lipid raft markers [4,5,7]. SPFH-domain containing proteins are widely distributed in most bacterial genera. In *Bacillus subtilis* they were found to act as the scaffold for

decision to publish, or preparation of the manuscript.

Competing interests: The authors have declared that no competing interests exist.

proteins that reside in raft-like membrane microdomains [8]. Moreover, the formation of such membrane microdomains in *B. subtillis* was found to be functionally associated with a signaling pathway involved in regulation of biofilm formation and with the Sec protein translocation apparatus [8–11]. However, the membrane *of B. subtillis*, like those of most bacteria, does not contain cholesterol, and it has been suggested that other lipids, such as farnesol or farnesol-derived polyisoprenoids, might promote an increased rigidity in the microdomains [12].

Lipid raft-like domains have been also identified in other bacteria, such as *Staphylococcus aureus*, *Borrelia burgdorferi*, *Bacillus anthracis*, *Helicobacter pylori* and *Escherichia coli* [9,13–17]. *B. burgdorferi* and *H. pylori* possess cholesterol as a membrane component, even though they do not carry out *de novo* sterol biosynthesis. Instead, both bacteria obtain cholesterol from the host epithelial cells to generate glyco-cholesterol derivatives, which are incorporated into the bacterial membranes. Interestingly, both bacterial species appear to form cholesterol-containing membrane microdomains that are assembled into the outer membrane [15,16].

The close packing of lipids in the liquid-ordered phases, typically found in lipid rafts, prevents its solubilization by cold non-ionic detergents. Therefore, the study of lipid rafts, in a variety of eukaryotic and prokaryotic organisms, has been based on the extraction of detergent resistant membranes (DRM). Although detergent resistance in itself does not necessarily reflect preexisting raft domains, results obtained from DRM analysis have often been consistent with those obtained by other approaches, such as direct imaging or functional analysis [18,19]. Thus, DRM isolation provides a useful tool for the study of potential protein-lipid raft associations.

In recent studies, proteomic analyses of DRMs have been carried out in *B. subtilis*, *S. aureus*, *B. burgdorferi* and *H. pylori*, and the results suggest that bacterial membrane microdomains, like eukaryotic lipid rafts, play important roles in various cellular processes, such as membrane transport, secretion and virulence [9,16,20–23]. Nevertheless, even though several proteomic analyses of *E. coli* membranes have been carried out [24–28], there are no data regarding the composition or protein content of raft-like microdomains from this model bacterium. Here, we report that some 80 proteins, involved in transport, protein secretion, energy metabolism, cell maintenance and signaling, were found to be enriched in DRM. Among these proteins were HflC, HflK, and YbbK (QmcA), three of the four SPFH-containing proteins encoded by the *E. coli* genome, that are generally used as lipid raft markers. Thus, the first comprehensive proteomic profile of DRMs from *E. coli* is reported, providing information about the cellular processes that may be associated with lipid rafts in this organism.

Materials and methods

Bacterial strains, plasmids, and growth conditions

E. coli strain MG1655 was chosen as the genetic background of all created strains because it is a reference *E. coli* strain, and because we recently reported a DRM isolation protocol using this strain [17]. Chromosomal tagging of *hflC*, *hflK*, *qmcA*, *yqiK* and *yidC* genes was achieved by PCR and homologous recombination of the amplification products using the lambda red recombinase system [29,30], resulting in strains IFC5019 (*hflC*::*ha*-Cm^r) [17], IFC5021 (*hflK*::*ha*-Cm^r), IFC5022 (*qmcA*::*3xFLAG*-Kn^r), IFC5023 (*yqiK*::*3xFLAG*-Kn^r) and IFC5024 (*yidC*::*3xFLAG*-Kn^r). All oligonucleotides used in PCR amplification reactions are shown in S1 Table. Strain IFC5025 (*hflC*::*ha qmcA*::*3xFLAG yqiK*::*3xFLAG*-Kn^r) was constructed by two successive transfer steps of the *qmcA*::*3xFLAG*-Kan^r and *yqiK*::*3xFLAG*-Kan^r alleles from strains IFC5022 and IFC5023 into strain IFC5019 by P1*vir* transduction. In some cases, antibiotic resistance marker was eliminated by expressing the FLP recombinase from plasmid pCP20 [29]. Similarly, strains IFC5026 (*qmcA*::*mCherry*-Kn^r) and IFC5027 (*yidC*::*mCherry*-

Cm^r) were generated by lambda red recombinase-facilitated homologous recombination of PCR amplified products using primers pair pFluor-ybbK-Fw / pKD-ybbK-Rv and plasmid pMXFL1 [17] as template or yidC-Fluor-Fw / pKD-yidC-Rv and pMXFL2 [17] as template, respectively.

To construct plasmid pMX549, expressing a *glnP-mCherry* fusion under the control of the L-arabinose-inducible promoter *ara*, the *glnP* and *mCherry*, coding sequences were PCR amplified using the primer pair Glnp-EcoRI-Fw / Glnp-SacI-Rv and chromosomal DNA from MG1655 as the template, and the primer pair YfpcfSacI / YfPcr1HindIII and plasmid pCHYC-4 [31] as the template, respectively. The two amplified DNA fragments were SacI digested and ligated together, and the product was used as template in a PCR reaction with primers Glnp-EcoRI-Fw and YfPcr1HindIII. Then, purified PCR product was digested with EcoRI and HindIII and cloned into the same restriction sites of pMX020 [32], resulting in plasmid pMX549. To construct plasmid pMX550 (*glnP-mCherry*), a 2.7 Kb DNA fragment containing the *ara* promoter and the *glnP-mCherry* fusion, obtained from plasmid pMX549 by ClaI and HindIII digestion, was cloned into NruI and HindIII restriction sites of plasmid pACT3 [33]. To construct plasmids pMX551 (*acrA-mCherry*), pMX552 (*aas-mCherry*) and pMX553 (*rbbA-mCherry*), the *acrA*, *aas* and *rbbA* coding DNA sequences were PCR amplified, using the primer pairs Acra-NdeI-Fw / Acra-SacI-Rv, Aas-NdeI-Fw / Aas-SacI-Rv, and Rbba-NdeI-Fw / Rbba-SacI-Rv, respectively, and chromosomal DNA from MG1655 as template, and cloned into NdeI and SacI sites of plasmid pMX550. To construct plasmids pMX554 (*acrA-3xFLAG*), pMX555 (*aas-3xFLAG*) and pMX556 (*rbbA-3xFLAG*), a DNA fragment carrying the 3xFLAG coding sequence upstream the kanamycin resistance cassette was amplified by PCR using primers 3xFLAG-SacI-Fw and 3xFLAG-HindIII-Rv, and plasmid pSUB11 [30] as template. Then, purified PCR product was digested with SacI and HindIII and cloned into the same restriction sites of plasmids pMX551, pMX552 or pMX553, respectively. A schematic work-flow of the above constructed plasmids is presented in S1 Fig. All DNA fragments cloned from PCR-amplified material were sequenced to check that no undesired base changes had been introduced. DNA sequence analysis was performed by the "Unidad de Biologia Molecular" at IFC, UNAM.

E. coli strains were routinely grown in LB medium at 37˚C. When necessary, ampicillin, kanamycin, or chloramphenicol was used at a final concentration of 100, 50 or 25 μg/ml, respectively.

DRM isolation

DRM fractions were obtained as described previously [17]. Briefly, exponential phase growing *E. coli* cells were treated with 10 μg/ml ampicillin to generate filamented cells that were harvested, resuspended in buffer A (1 M sucrose, 0.2 M Tris-HCl [pH 8.0]), and treated with 2 mM EDTA and 12.5 μg/ml lysozyme for 10 min. Next, spheroplasts were obtained by adding sterile water to reach a sucrose concentration of 0.1 M. Spheroplasts, whose formation was confirmed by phase-contrast microscopy, were harvested, resuspended in ice-cold buffer B (20 mM Tris-HCl [pH 7.2], 50 mM NaCl, 5 mM EDTA) containing 20% w/w sucrose, and passed through a French pressure cell. Inner membrane (IM) vesicles were isolated from the spheroplast lysate by ultracentrifugation (~113,000xg) in a discontinuous sucrose gradient (20–50% w/w). IM-containing fractions were pooled and recovered by ultracentrifugation, and 500 μg of protein was mixed with ice-cold Triton X-100 (Pierce, Rockford, IL, USA), resulting in a final detergent concentration of 1% w/v and in a detergent:protein ratio of 8:1, and incubated for 30 min on ice. The DRM fraction were obtained by flotation in a continuous OptiPrep (Axis-Shield, Oslo, Norway) gradient after ultracentrifugation (~173,000xg), concentrated by ultracentrifugation (~106,000xg), and stored at -80˚C.

Protein digestion with trypsin

Proteins in IM or DRM samples were precipitated with trichloroacetic acid (TCA) by adding 100 μl of 10X TE buffer (100 mM Tris-HCl, 10 mM disodium EDTA, pH 8.0) and 100 μl of 72% TCA to samples with 20 μg of total protein. After 2 h of incubation on ice, proteins were pelleted by centrifugation at 14,000 rpm at 4 ˚C for 10 min, washed with 1 ml of cold acetone and dried at room temperature for 20 min. Precipitated proteins were solubilized in 10 μL of 6 M urea, reduced by with 2.5 μL of reduction buffer (45 mM DTT, 100 mM ammonium bicarbonate) for 30 min at 37 ˚C, and alkylated by adding 2.5 μL of alkylation buffer (100 mM iodoacetamide, 100 mM ammonium bicarbonate) for 20 min at 24 ˚C in the dark. Before trypsin digestion, 20 μL of water was added to reduce the urea concentration to 2 M. Protein digestion was performed by adding 10 μL of trypsin solution (5 ng/μL of trypsin sequencing grade from Promega, 50 mM ammonium bicarbonate), samples were incubated at 37 ˚C for 18 h, and the reaction was stopped by adding 5 μL of 5% formic acid. Protein digests were dried down by vacuum centrifugation and stored at -20 ˚C.

LC-MS/MS analysis

Prior to LC-MS/MS analysis, protein digests were resolubilized under agitation in 10 μL of 0.2% formic acid for 15 min. Desalting and cleanup of the samples was done by using C18 ZipTip pipette tips (Millipore, Billerica, MA). Eluates were dried down in a vacuum centrifuge and then resolubilized under agitation in 10 μL of 2% ACN and 1% formic acid for 15 min. The peptide mixture was separated by LC using C18 reversed phase column with a high-pressure packing. A 75 μm i.d. Self-Pack PicoFrit fused silica capillary column (New Objective, Woburn, MA) was packed with the C18 Jupiter 5 μm 300 Å reverse-phase material (Phenomenex, Torrance, CA), and this column was installed on the Easy-nLC II system (Proxeon Biosystems, Odense, Denmark). The separated peptides were directly electrosprayed into a Linear Trap Quadropole (LTQ) Orbitrap Velos (ThermoFisher Scientific, Bremen, Germany) equipped with a Proxeon nanoelectrospray ion source. The solutions used for chromatography were 0.2% formic acid (Solvent A) and 100% ACN/0.2% formic acid (Solvent B). Samples were loaded on-column at a flowrate of 600 nL/min and eluted with a 2-slope gradient at a flowrate of 250 nL/min. Solvent B first increased from 2 to 40% in 100 min and then from 40 to 80% B in 20 min.

LC-MS/MS data acquisition was accomplished using a seventeen-scan event cycle comprised of a full scan MS for scan event 1 acquired in the Orbitrap. The mass resolution for MS was set to 60,000 (at m/z 400) and used to trigger the sixteen additional MS/MS events acquired in parallel in the linear ion trap for the top sixteen most intense ions. Mass over charge ratio range was from 360 to 1700 for MS scanning with a target value of 1,000,000 charges and from ~1/3 of parent m/z ratio to 2000 for MS/MS scanning with a target value of 10,000 charges. The data dependent scan events used a maximum ion fill time of 100 ms and 1 microscan. Target ions already selected for MS/MS were dynamically excluded for 31 s after 2 counts. Nanospray and S-lens voltages were set to 1.3–1.8 kV and 50 V, respectively. Capillary temperature was set to 250 ˚C. MS/MS conditions were: normalized collision energy, 35 V; activation q, 0.25; activation time, 10 ms.

Database search

Raw data files of fragmentation spectra were converted to *mzXML* files by RawConverter software tool [34] and compared against the MG1655 *E. coli* strain sequence (4,306 entries) of the UniProt database (downloaded on August 18, 2017; Proteome ID: UP000000625), using the Comet search engine in the Trans Proteome Pipeline (TPP) suite [35] with the following

parameters: The ion-mass tolerances of monoisotopic peptide precursor and fragmentation products were 3 Da and 1 Da respectively, without correcting for isotope errors. Oxidation of methionines (+16) was considered as the only variable modification, and two missed cleavages were allowed. Peptide assignations were validated with PeptideProphet, filtering out peptides with a probability under 0.7. A protein was considered to be positively identified when ProteinProphet probability was >0.99, and at least three unique peptides were assigned (S2 Table). The spectra count for each inner membrane protein from an IM sample and the average value from two biological replica of DRM fraction were analyzed and used to determine which proteins were enriched in lipid rafts (S3 Table).

In silico analyses

Prediction of number of the transmembrane (TM) domains and signal peptides was carried out using the TOPCONS server (http://topcons.cbr.su.se/) [36]. Lipoprotein signal sequences and lipoprotein inner or outer membrane association were predicted using the LipoP 1.0 Server (http://www.cbs.dtu.dk/services/LipoP/) [37]. Amphipathic in-plane membrane anchor was predicted using Amphipaseek tool of NPS@ server [38].

Immunoblotting

Equal volumes (10 μl) of representative fractions from OptiPrep gradients were separated by SDS-PAGE (10% polyacrylamide gel), and the proteins were transferred to a Hybond-ECL filter (Amersham Bio-sciences). The filter was equilibrated in TTBS buffer (25 mM Tris, 150 mM NaCl, and 0.1% Tween-20) for 10 min and incubated in blocking buffer (5% w/v milk in TTBS) for 1 h at room temperature. Monoclonal antibodies against HA or 3XFLAG epitope were added at a dilution of 1:10,000 and incubated for 1 h at room temperature. The bound antibody was detected by using anti-mouse IgG antibody conjugated to horseradish peroxidase (Sigma Aldrich) and the Immobilon Western detection system (Millipore). It has to be mentioned that immunodetection of HflC-HA and YbbK-3Flag was carried out on all independently generated membrane fractions, including the ones used for proteomics. Immunodetection of all other protein markers was carried out on at least three independently generated membrane fractions, but not the ones used for proteomic analysis.

Fluorescence microscopy

E. coli cells carrying either AcrA-mCherry, YidC-mCherry, HflC-mCherry, QmcA-mCherry, Aas-mCherry or RbbA-mCherry fusion, were grown in LB medium at 37 ˚C to an optical density at 600 nm (OD_{600}) of 1.5, and aliquots of the cell cultures (2 μl) were immobilized on glass slides previously covered with freshly made M9 medium 1% agarose pads [39]. Cells were observed under an upright microscope (Eclipse E600, Nikon) equipped with an oil-immersion objective lens microscope (100x, NA 1.47). mCherry fluorescence was exited with an X-Cite 120 light source system, using a Chroma filter 39010, and images were acquired with a Hamamatsu ORCA-ER cooled-CCD camera controlled with QCapture Pro (version 6.0) software (QImages). Phase contrast and mCherry fluorescence images were taken at 40 ms and 500 ms exposure, respectively, and processed with ImageJ software [40]. Fluorescence images were subjected to background subtraction using a rolling ball radius of 20 pixels, and fluorescence signals were colored in red, before copying the relevant selections to an image editor software.

Results

Preparation of DRM fractions from *E. coli* membranes

In a recent study, we reported the existence of lipid raft-like microdomains within the plasma membrane of the Gram-negative bacteria *E. coli* [17]. The composition and protein cargo of these lipid platforms, however, remain elusive. In order to explore the proteome of these membrane microdomains, we isolated detergent-resistant membranes (DRM), which is the procedure that is typically used for the analysis of lipid rafts of both eukaryotic and prokaryotic cells [19,41]. Because Gram-negative bacteria, such as *E. coli*, in addition to the cytoplasmic or inner membrane (IM) are surrounded by an outer membrane (OM), which is naturally resistant to solubilization by detergents [42,43], the use of OM-free IM as the starting material is required if pure DRM are to be obtained [17]. A schematic illustration for DRM isolation is presented in Fig 1A. Briefly, giant spheroplasts of strains IFC5025 and IFC5021, harboring chromosomal HA- or FLAG-tagged hybrids of the four known SPFH-domain proteins of *E. coli*, namely HflC, HflK, YqiK and QmcA (YbbK), were generated and lysed by passing them through a French Press. IMs were isolated by ultracentrifugation in discontinuous sucrose gradients, and treated with cold Triton X-100 at a detergent:protein ratio of 8:1. Finally, detergent treated IMs were separated by ultracentrifugation in OptiPrep gradients. DRMs, because of their low density, are able to float on density gradients [44], and, therefore, the visible opaque band settled in the upper part of the gradient (Fig 1A), containing the DRM fraction, was recovered and stored for further analysis. It is worth mentioning that the DRM protein content represented approximately 10% of the initial protein in IM. Proteins in detergent-sensitive membranes (DSM), present in the lower fractions of the gradient were also recovered for immunoblotting assays.

Subsequently, the above collected fractions were probed for their content of the SPFH-domain proteins, namely HflK, HflC, QmcA and YqiK. This was performed because proteins containing the SPFH-domain have been shown to be associated with DRMs in both eukaryotic and bacterial membranes, and are therefore used as lipid raft markers [3,9]. Immunoblot analysis revealed that HflC, HflK and QmcA were partitioned principally into the DRM fraction (Fig 1B), whereas YqiK, which was marginally detected in IM, was not detected along the OptiPrep gradient (not shown). It is likely that the low *yqiK* expression results in not-detectable amounts of YqiK protein in DRM fractions. Interestingly, QmcA, and at a lesser extent HflK, were also detected in DSM fractions, suggesting that the conditions used to obtain DRMs were stringent enough to avoid false positives. Alternatively, populations of membrane rafts with different rigidity may exist, such that these proteins partition into both raft and non-raft membrane regions, depending on the cell physiology, as previously reported [45]. Nevertheless, the presence of the three membrane raft-marker proteins in the DRM fraction corroborates the suitability of our procedures for DRM isolation.

Proteomic analysis of DRM fraction from *E. coli*

To identify proteins residing in DRM fractions, LC-MS/MS analyses of the obtained IMs and DRMs were conducted. The obtained results were filtered by excluding proteins represented by less than three unique peptides, resulting in the identification of 785 proteins. These proteins were grouped depending on their subcellular localization according to the Uniprot database (S2 Table). Even though the IMs were separated from the OMs and cytosolic proteins, the portion of proteins annotated as IM residents was only 52.23% (420 proteins) of the identified proteins (Fig 2A). On the other hand, 5.73% (45 proteins) corresponded to OM proteins, whereas 12.72% (100 proteins) and 4.45% (35 proteins) represented cytosolic and periplasmic

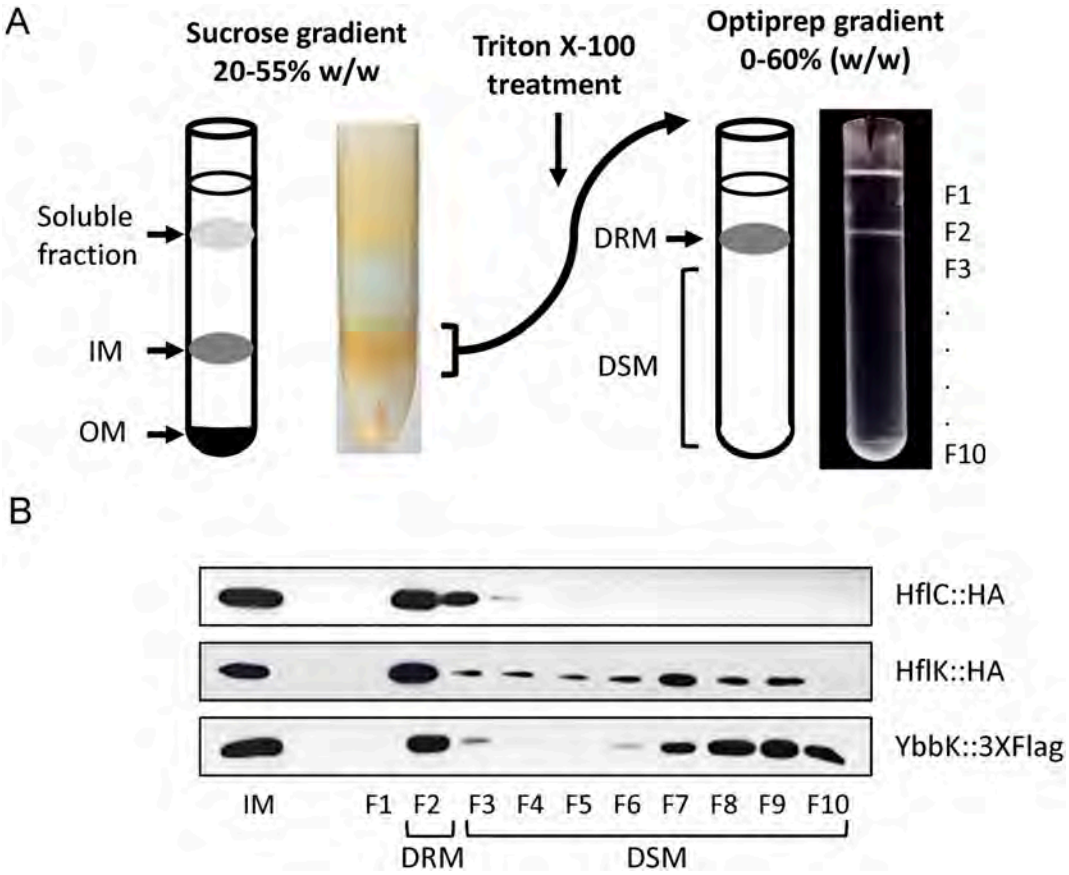

Fig 1. DRM preparation. (A) Schematic illustration of inner-membrane separation by density gradient ultracentrifugation. A spheroplast lysate was loaded on a discontinuous sucrose gradient (20–50% w/w) (cartoon on the left and photography of gradient on the right). The fraction matching to approximately 45% w/w sucrose, corresponding to IM, was separated and treated with ice-cold Triton X-100. The mixture was then loaded on an OptiPrep gradient and ultracentrifuged (cartoon on the left and photography of OptiPrep gradient on the right). Ten 1ml fractions were collected from the top to the bottom of the tube (F1 to F10). DRMs were recovered from F2 whereas DSMs were recovered from lower fractions. (B) IM sample and OptiPrep gradient collected fractions were analyzed by Western blot using specific antibodies against HflC-HA, HflK-HA or QcmA-3xFLAG as described in Materials and Methods section. A representative immunoblot from at least three entirely independent experiments is shown for each protein.

https://doi.org/10.1371/journal.pone.0223794.g001

proteins, respectively. The remaining 23.54% (185 proteins) represented proteins with unknown localization (Fig 2A). Inspection of the relative abundance of spectra indicated that the number of peptides corresponding to IM proteins in DRM were slightly higher than in the IM sample (66.76% and 62.36%, respectively), whereas peptides corresponding to OM proteins were greatly enriched (~ 5 times) in DRM in comparison to the IM (24.46% and 5.40%, respectively) (Fig 2B and 2C). This is expected because of the intrinsic detergent-resistance of OMs. In contrast, the amount of peptides corresponding to proteins with cytosolic or periplasmic localization diminished significantly in DRM as compared to the IM (1.22% and 9.14%, respectively for the cytosolic proteins and 1.22 and 3.89%, respectively for the periplasmic proteins) (Fig 2B and 2C). It is probable that some cytosolic or periplasmic proteins could weakly associate with the IM, and were released after detergent treatment. It has to be mentioned that approximately 19% and 5% of the identified peptides in IM and DRM, respectively, corresponded to proteins with unknown localization, and therefore the above mentioned relative abundance of proteins may vary.

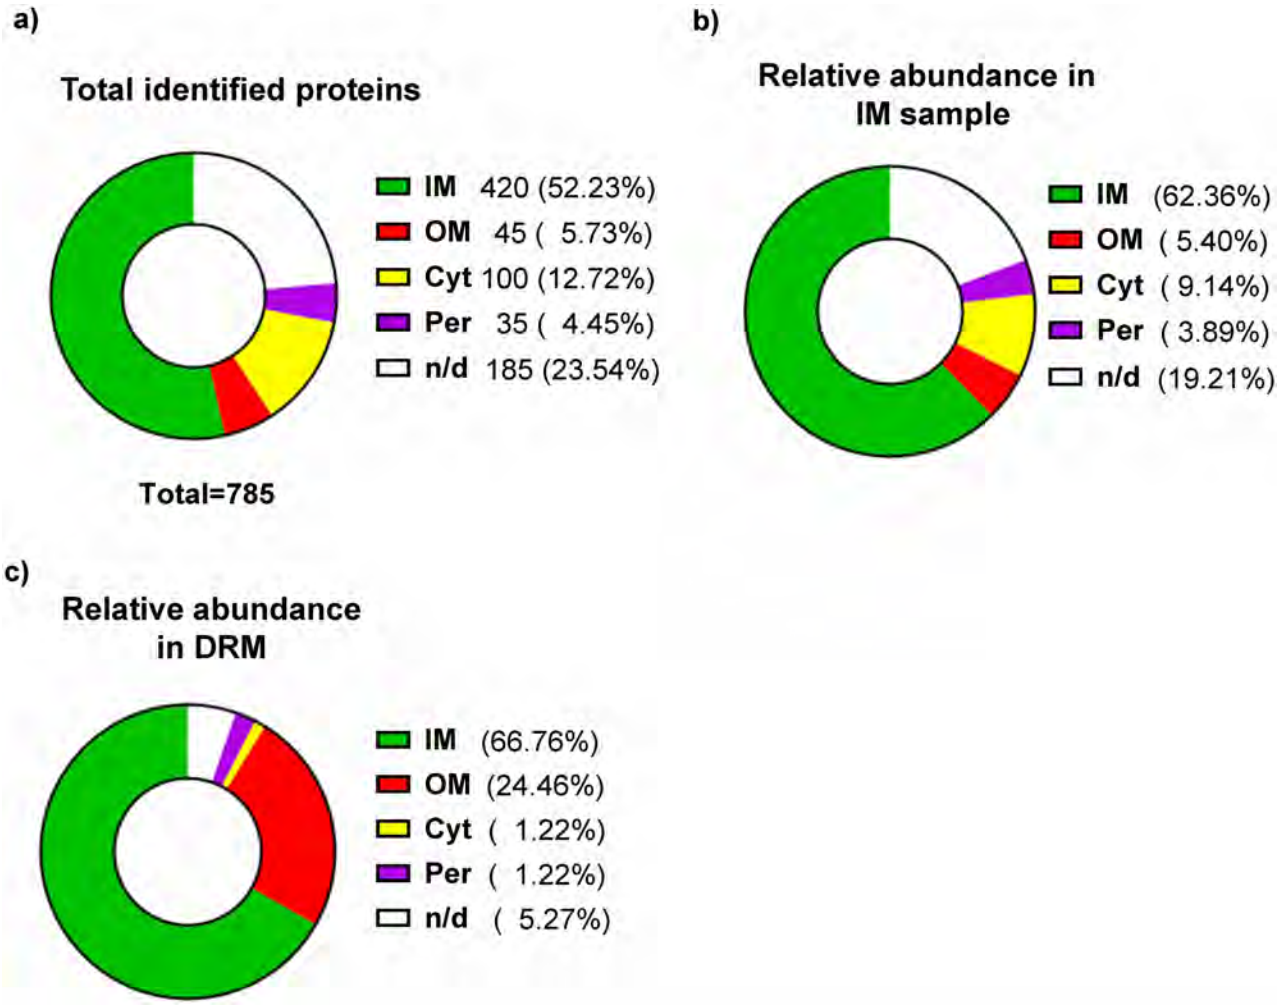

Fig 2. Distribution of identified proteins according to subcellular location. (A) Total proteins identified in inner membrane and DRM samples. (B) Relative abundance of peptides in IM sample. (C) Relative abundance of peptides in DRM samples. IM: Inner membrane proteins, OM: outer membrane proteins, Cyt: cytosolic proteins, Per: periplasmic proteins, n/d: proteins without localization data.

https://doi.org/10.1371/journal.pone.0223794.g002

Next, we examined which of the identified proteins were enriched in DRM, suggesting that they may be components of lipid raft-like membrane microdomains. To this end, the spectral counts obtained from the IM sample were subtracted from the ones obtained from the DRM sample, for each of the 420 IM identified proteins. We argued that if, for a given protein, the difference is positive, this protein may reside in a membrane with higher resistance to the detergent treatment, and, therefore, could be considered as a possible resident of membrane microdomains. On the other hand, if the difference is negative, it would suggest that the protein is located in a membrane sensitive to detergent treatment and, therefore, would not be considered as DRM resident. The distribution of the spectra differences for the 420 IM-proteins is shown in Fig 3 and the values in S3 Table. Subsequently, proteins with a difference of less than 10 were excluded and only proteins with a difference of 10 or higher were considered as putative lipid raft components, permitting us to identify 80 proteins (Tables 1–7). As expected, among these proteins were found the SPFH-containing proteins HflK, HflC and QmcA. A functional classification of the identified proteins shows that the *E.*

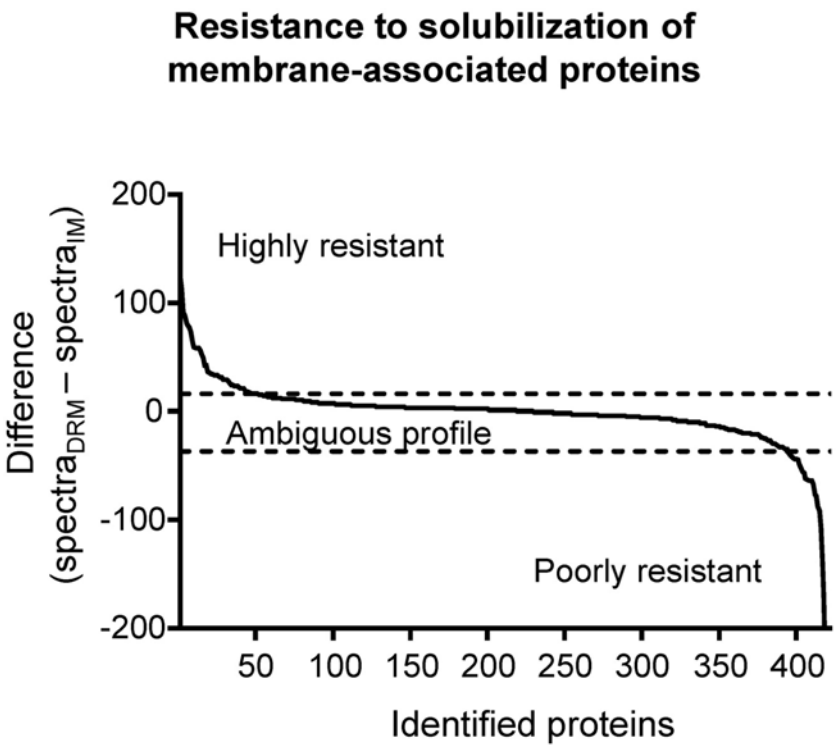

Fig 3. Distribution of identified IM associated proteins according to their detergent solubilization resistance profile. The resistance profile of each protein was determined by calculating the difference between spectra counts obtained from DRM and IM samples. A cut-off of at least 10 positive difference spectra (+10) was used to identify a potential lipid raft associated protein, resulting in 80 selected proteins.

https://doi.org/10.1371/journal.pone.0223794.g003

coli membrane rafts were mainly enriched in proteins involved in membrane transport, energy metabolism, cell wall metabolism, secretion, and, to a lesser extent, in signaling and scaffolding, reminiscent to those observed for other bacterial membrane microdomains [9,16,20–23]. Noteworthy, among the 80 DRM-enriched proteins, 17 lacked an apparent transmembrane segment. This could be due to their association with membrane-anchored proteins, as is the case for AcrA, which interacts with AcrB on its periplasmic face, forming a multidrug efflux pump complex. Alternatively, periplasmic proteins carrying a lipoprotein signal peptide (SPII) can be covalent linked to membrane lipids by their N-terminal. Our prediction indicates that 8 of the 17 soluble proteins harbor this lipoprotein signal peptide. Finally, proteins could be attached to the membrane by amphipathic helices (in-plane membrane helices, or IPM), which appear to be present in almost half of the total DRM-enriched proteins (Tables 1–7).

DRM-enriched proteins localize in membrane foci in *E. coli* cells

To investigate whether the DRM-enriched proteins displayed expected localization patterns within membrane foci, C-terminal mCherry fusions of 6 proteins, 4 of which exhibited a high detergent resistant profile (AcrA, YidC, QmcA and HflC) and 2 not identified in DRM fractions (Aas and RbbA), were generated, and their localization in live cells were detected by epifluorescence microscopy. HflC was used as a control because it contains the SPFH-domain (lipid raft-marker) and its polar localization was previously determined [17]. It was observed that AcrA-mCherry and YidC-mCherry accumulated on the poles of cells, similarly to HflC-

mCherry (Fig 4), indicating that these proteins are lipid raft residents. Also, the mCherry fusion of QmcA, another lipid raft-marker protein that was enriched in DRM fractions, appeared as discrete foci with both polar and lateral localization. In contrast, both Aas-mCherry and RbbA-mCherry, which were not identified in DRM fractions, were distributed throughout the membrane, reinforcing the suggestion that these proteins were not associated with lipid raft microdomains. Then, we examined the detergent resistance profile of the membranes in which the above selected proteins are located. To this end, cells carrying 3xFLAG-fusions were obtained and used for IM isolation and Triton X-100 treatment. After separation in OptiPrep gradients, fractions were analyzed by Western blot analysis using anti-Flag antibodies. As expected, AcrA-3xFLAG, YidC-3xFLAG, QmcA-3xFLAG and HflC-3xFLAG were mainly found in the floating DRM fractions, whereas Aas-3xFLAG and RbbA-3xFLAG were present in the soluble fractions at the bottom of gradients. Thus, these results indicate that proteins with higher differences in the number of spectra counts between DRM and IM could be associated to lipid raft-like membrane microdomains in *E. coli*, validating our proteomic analysis and their identification as membrane microdomain-residents.

Discussion

During the past 10 years increasing attention has been drawn to the study of lipid raft-like structures in bacterial membranes. Such membrane microdomains have been identified in *B. subtilis*, *S. aureus*, *B. burgdorferi*, *H. pylori* and *E. coli* [9,13,15–17]. The herein presented results provide the first comprehensive profile of the lipid raft proteome of *E. coli*, providing information on membrane protein organization in this important model bacterium. An important step in our approach was the isolation of *E. coli* inner membranes prior to detergent treatment, in order to minimize the contamination of outer membrane proteins. This is because OMs resist detergent treatment and coincide at the same floatation density in Opti-Prep gradients. In fact, a ~ 5% of OM-protein contaminants in the isolated IMs were still found in our proteomic analysis, similarly to that reported in previous studies [24,25,28]. As

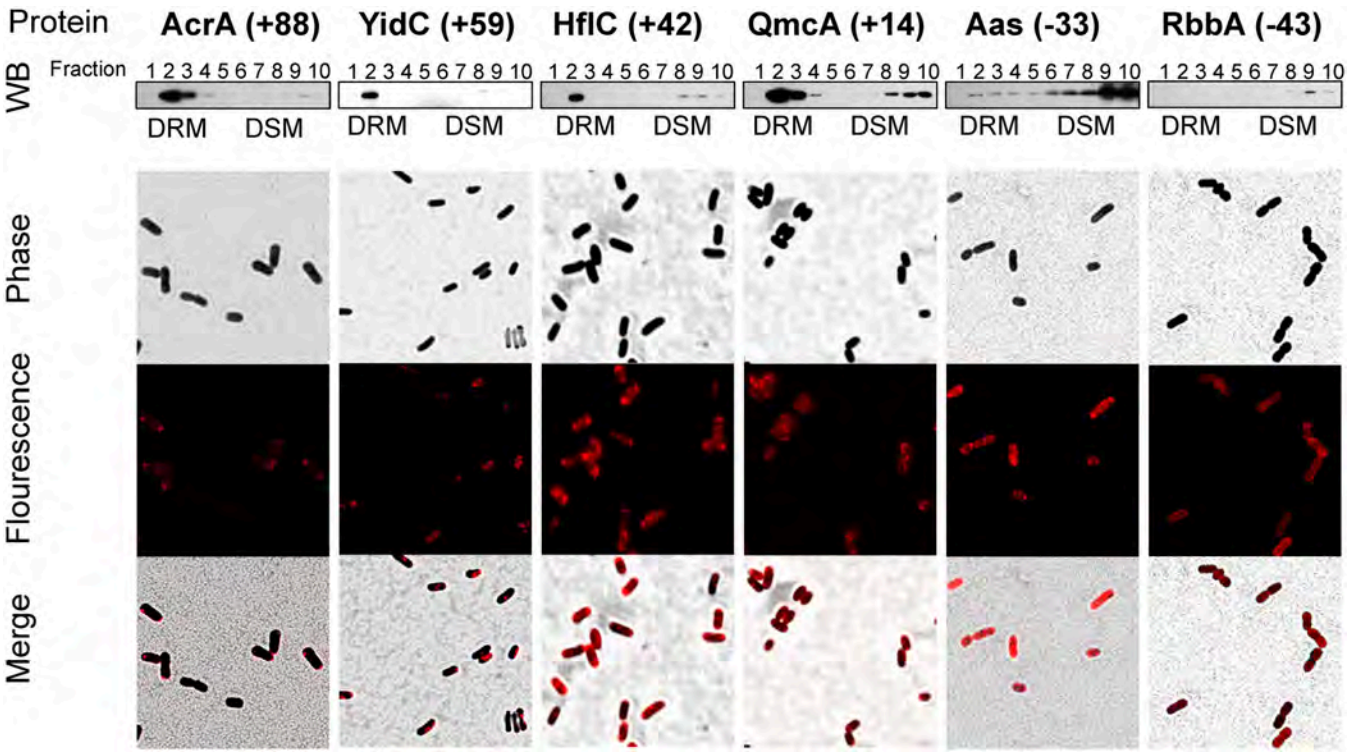

Fig 4. Distribution in OptiPrep gradients and *in vivo* localization of selected lipid raft associated proteins. Top panels: Western blot analysis of DRM (F2) and DSM fractions (F3 to F10), obtained from strains carrying either the AcrA-3xFLAG, YidC-3xFLAG, HflC-HA, QcmA-3xFLAG, Aas-3xFLAG or RbbA-3xFLAG coding sequence allele. A representative immunoblot from at least three entirely independent experiments is shown for each protein. Bottom panels: phase contrast microscopy (top), fluorescence microscopy (middle) and merge (bottom) of living *E. coli* cells carrying either AcrA-mCherry, YidC-mCherry, HflC-mCherry, QmcA-mCherry, Aas-mCherry or RbbA-mCherry are shown. Values in parentheses are differences in spectra counts between DRM and IM samples.

https://doi.org/10.1371/journal.pone.0223794.g004

expected, these contaminants were notably enriched in the DRM fractions. For interpreting our mass-spectrometry data, a difference of 10 or higher between spectra obtained from DRM and IM samples (spectraDRM—spectra$_{IM} \geq 10$) was used to assign lipid raft residency to each protein. In total, 80 proteins were identified as DRM components, and among them were found three of the four *E. coli* SPFH-containing proteins that are typically used as lipid raft markers. Using the above criterion, the location in DRM of proteins producing many spectra (*i.e.* most abundant proteins) is emphasized, whereas proteins poorly represented in the proteomic analysis, although important, may be neglected. An alternative approach could be the use of the ratio between peptide counts in DRM and IM samples. For instance, a ratio of 1.5 or higher (spectra$_{DRM}$ / spectra$_{IM} \geq 1.5$) could be used as a criterion to determine enrichment of a protein in DRM. In this case, several proteins (>75) that were discarded in the above analysis could qualify as possible microdomain components, while only 14 of the previously deemed DRM-located proteins failed to meet this criterion. However, proteins with few peptides identified in IM could mislead the interpretation of the proteomic analysis. Taking this into account, 17 additional proteins could be designated as putative lipid raft components if values of spectra$_{DRM}$ / spectra$_{IM} \geq 1.5$ and spectraDRM—spectra$_{IM} > 5$ were considered (S4 Table). Interestingly, YqiK, the only SPFH-containing protein that was not identified by our proteomic analysis, belongs to a group of membrane proteins that has been shown to be particularly elusive to identification by mass spectrometry [25].

In addition to the SPFH-domain containing proteins (lipid raft markers), proteins committed to protein secretion and membrane insertion (e.g. SecY, SecG, YajC, YidC) were identified as putative raft constituents, comparable to those reported for *B. subtilis*, *B. burgdorferi*, S. *aureus* [20–22]. Likewise, proteins with transport functions were well represented in DRM fractions. These include members of the superfamily of ATP-binding cassette (ABC) transporters, multidrug efflux complexes, and members of the family of phosphoenolpyruvate-dependent sugar phosphotransferase systems (sugar-PTS). This is consistent with previous studies that have identified transporters as common components of lipid microdomains in *B. subtilis*, *B. burgdorferi* [20,21]. Moreover, the location and function of several eukaryotic ABC transporters, involved in multidrug resistance, have been found to be controlled by their presence in lipid rafts from tumor cells [46]. Interestingly, the ABC transporter MsbA, an essential protein involved in the translocation of lipid A-core from the inner leaflet to the outer leaflet of the IM [47], exhibits a high similarity to mammalian multidrug resistance proteins (MDR) [48]. MDR-1, a member from the latter, which shares a 30% amino acid sequence identity and 46% similarity to MsbA, was also found to be structurally and functionally associated with lipid rafts [49]. Thus, the association of MsbA and other ABC transporters with raft-like microdomains in *E. coli* could highlight the co-evolution of transporter complexes and lipid rafts, establishing a suitable microenvironment for proper transport functions.

On the other hand, *E. coli* complexes involved in energy metabolism exhibited differential resistance detergent profiles. For instance, all identified components of cytochrome bo_3 and cytochrome *bd* terminal oxidases were enriched in DRM, indicating that these complexes are lipid raft residents. In contrast, NADH-quinone oxidoreductase I components (NuoJ, NuoA, NuoM, NuoH, NuoN, NuoL, NuoB and NuoI), the NADH-quinone oxidoreductase II (Ndh), and components of the ATP-synthase complex, which are functionally associated with terminal oxidases in the electron transport chain, were not enriched in DRM fractions, suggesting that components of a given metabolic pathway could be differentially partitioned into lipid rafts in a point of time.

In spite of the widely established idea that the lipid rafts are implicated in the orchestration of processes related to signal transduction in both eukaryotes and prokaryotes [9,19,50], the only two bacterial histidine kinases associated with lipid rafts, so far, are KinC and WalK from

B. subtilis and *S. aureus*, respectively [9]. Here, we identified the sensor kinase of the CusSR two-component system, which regulates the expression of genes involved in copper uptake, as a lipid raft resident. Also, the histidine kinase DcuS, which participates in the control of expression of genes involved in the C4 dicarboxylates catabolism, was found to be enriched 7.5-fold in DRM in comparison with IM. However, this protein was not selected as a raft resident due to its low spectra representation, which was only 1 and 7.5 peptides from IM and DRM, respectively. The absence of bacterial sensor kinases in proteomic analyses of lipid rafts may be due to their very low expression, hampering their identification in membrane samples [25]. Thus, the organization of signaling pathways involving sensor kinases into membrane microdomains remains to be determined.

Although the proteomic analysis of DRMs may provide important data regarding the characteristics of lipid rafts, it is important to emphasize that proteins whose localization in DRM fractions was not validated by experimental approaches must be interpreted with caution. For instance, to support the results of our proteomic analysis, we probed the distribution of selected proteins in live cells, by fluorescence microscopy. As expected, proteins that were enriched in DRM were observed as discrete foci, principally in cell poles, whereas proteins not identified in DRM were widely distributed in the cell membrane. Moreover, the results of immunodetection assays of the selected proteins were in agreement with the proteomic and microscopy analyses. While localization of proteins within foci does not necessarily involve active recruitment to lipid rafts and could implicate other elements such as the bacterial cytoskeleton, the combination of the identification of a given protein, by proteomic analysis, immunodetection, and fluorescence microscopy localization, strongly suggests that such protein could be a *bona fide* lipid raft resident. Nevertheless, the mechanism by which proteins are partitioned into membrane microdomains, as well as the functional consequences of this recruitment remains unclear and in need of further investigation.

Finally, an attracting issue in the study of bacterial lipid rafts is their lipid composition. In eukaryotic membranes, cholesterol increases membrane thickness and reduces its fluidity by improving the close packing of the longer and saturated acyl chains of sphingolipids. This promotes the segregation of sphingolipids from glycerophospholipids and leads to raft formation. However, most bacteria lack sterols and sphingolipids, and other specialized lipid species, such as farnesol [12], polyisoprenoid lipids (carotenoids) [9], or cyclic polyisoprenoid lipids (hopanoids) [51] have been proposed to functionally and structurally replace cholesterol in ordered membrane microdomains. Nevertheless, neither of these lipid species has been found to be present in *E. coli* membranes. Thus, a comparative lipidomic analysis between DRM and DSM fractions obtained from *E. coli* inner membrane is of foremost interest.

CARACTERIZACIÓN COGNITIVA Y CONDUCTUAL DE UNA MUESTRA DE ADOLESCENTES CONSUMIDORES DE INHALABLES DE LA CIUDAD DE MÉXICO

COGNITIVE AND BEHAVIORAL CHARACTERIZATION OF A SAMPLE OF INHALANTS-CONSUMING ADOLESCENTS FROM MEXICO CITY

Abstract

Inhalants are one of the drugs of choice for young people in Mexico City. Its consumption usually begins in a critical period of brain development, associated with processes of myelination and synaptic refinement. There is insufficient information on the cognitive, behavioral and emotional characteristics of inhalants-consuming adolescents. The objective of this study was to determine the neuropsychological profile of the executive functioning of a group of adolescents having Inhalant Use Disorder and to explore the presence of concomitant mental health risk behaviors. Thirty-one adolescents with Inhalant Use Disorder were evaluated through a large test battery for the exploration of executive functioning and a scale on mental health risk behavior. The results show the coexistence of important cognitive and behavioral alterations that are of great relevance for therapeutic treatment of this disorder.

Keywords: Inhalants, adolescence, executive cognitive functioning, mental health.

Resumen

Los inhalables constituyen una de las drogas de preferencia de los jóvenes de la Ciudad de México. Su consumo inicia generalmente en un período crítico de desarrollo cerebral asociado a procesos de mielinización y refinamiento sináptico. Hay sin embargo, insuficiente información sobre las características cognitivas, conductuales y emocionales de los adolescentes que consumen esta droga. El objetivo de este estudio fue determinar el perfil neuropsicológico del funcionamiento ejecutivo de un grupo de adolescentes con trastorno por consumo de inhalables y explorar la presencia de conductas de riesgo para la salud mental. Treinta y un adolescentes con trastorno por consumo de inhalables se evaluaron mediante una amplia batería de pruebas para la exploración del funcionamiento ejecutivo y una escala sobre conductas de riesgo para la salud mental. Los resultados muestran la coexistencia de alteraciones cognitivas y conductuales de gran relevancia para el manejo terapéutico de este trastorno.

Palabras clave: Inhalables, adolescencia, funciones ejecutivas, salud mental.

Correspondencia: Dra. Nadia García González
nadiag.him@gmail.com

El consumo de inhalables se identificó en la década de 1960 como un problema de salud en la población marginada o en situación de calle en México. Con los años ha ocurrido una propagación importante en el país de su uso intencional para conseguir efectos psicoactivos y en la actualidad se observa entre personas de todos los estratos socioeconómicos (Medina-Mora et al., 2015).

Estudios epidemiológicos recientes describen que el 71% de los consumidores de inhalables iniciaron su consumo antes de los 17 años, es decir, durante la adolescencia (Villatoro-Velázquez et al., 2017), período crítico por las transformaciones importantes que acontecen en las estructuras cerebrales (Casey et al., 2005). Los principales cambios en la arquitectura neuronal durante esta etapa de vida ocurren en áreas prefrontales y en la compleja conectividad de éstas con otras regiones cerebrales, asociadas a funciones de regulación y control conductual, cognitivo y emocional (Blakemore & Choudhury, 2006; Lozano & Ostrosky, 2011). Se ha sugerido que el principal beneficio de estos procesos de maduración cerebral durante la adolescencia es brindar oportunidad para la conformación de conexiones sinápticas funcionales con base a las necesidades conductuales y ambientales del sujeto (Flores, 2012) y que esta remodelación cerebral si bien permite una mayor eficiencia de la actividad neural y funcionamiento cognitivo, es la que hace a los adolescentes más vulnerables a las adicciones y los desórdenes psiquiátricos (Crews & Boettinger, 2009; Hackman & Farah, 2008).

Los inhalables contienen una gran variedad de sustancias químicas, entre sus compuestos orgánicos principales se encuentra el tolueno, compuesto altamente neurotóxico, con efectos sumamente negativos sobre la mielina y la transmisión sináptica. La mayoría de las investigaciones se han realizado en consumidores adultos crónicos y describen síndromes cerebrales difusos, desmielinización, y atrofia asociados a deterioro cognitivo (Rosenberg et al., 2002; Takagi et al., 2008). Algunas investigaciones realizadas en población adolescente muestran que hay presencia de daños en la arquitectura cerebral desde edades tempranas, por ejemplo Aydin et al. (2009) reporta menor volumen en diversas regiones bilaterales de la corteza prefrontal en adolescentes expuestos a altas concentraciones de tolueno respecto a un grupo control y Yücel et al. (2010) describe una menor anisotropía fraccional en las regiones del hipocampo y el esplenio del cuerpo calloso.

El abordaje de la problemática del consumo de inhalables en la población adolescente desde una perspectiva neuropsicológica ha sido pobre a pesar de que algunas investigaciones han informado la presencia de deficiencias significativas en el funcionamiento cognitivo en estos usuarios con respecto a grupos controles y a usuarios de otras drogas (Scott & Scott, 2013; Takagi et al., 2011). De acuerdo a los datos reportados por dichas investigaciones, los daños cognitivos se caracterizan principalmente por deterioro de la memoria, la atención y una disminución en la velocidad de procesamiento de información. Por otra parte, también son insuficientes los estudios que investigan la coexistencia de alteraciones mentales en la drogodependencia a inhalables en individuos menores de edad, pese a que se ha señalado la existencia de una alta prevalencia de comorbilidad psiquiátrica en la población general de consumidores de esta sustancia (Perron & Howard, 2009; Wu & Howard, 2007).

En la presente investigación se tiene como sujetos de estudio una muestra de adolescentes cuyo uso intencional y problemático de inhalables es considerado de acuerdo al Manual Diagnóstico y Estadístico de los Trastornos Mentales DSM-5 como un trastorno por consumo de inhalables. Este trastorno se caracteriza por un deterioro clínico significativo manifestado por un período no menor a doce meses, en el cual el consumo recurrente lleva al individuo a problemas sociales, a la reducción de sus actividades diarias e incluso al riesgo físico (APA, 2013). Las principales directrices que guían esta investigación son determinar el perfil neuropsicológico del funcionamiento ejecutivo de un grupo de adolescentes con trastorno por consumo de inhalables y explorar la presencia de conductas de riesgo para la salud mental concomitante. En este estudio partimos del supuesto, de acuerdo a la literatura científica precedente, que los adolescentes consumidores de inhalables presentan alteraciones significativas en el funcionamiento ejecutivo y una alta tasa de comorbilidad psiquiátrica. Ambos aspectos repercuten significativamente en el proceso de la drogodependencia y en la respuesta del individuo al tratamiento (Robles-Martínez et al., 2017), por lo que una caracterización detallada del estado cognitivo y conductual de esta población puede contribuir al

desarrollo de estrategias específicas de intervención que eleven la efectividad en los tratamientos.

MÉTODO

Participantes

Los adolescentes fueron reclutados por conveniencia en seis Centros de Integración Juvenil (CIJ) para la atención de jóvenes consumidores de drogas distribuidos en la Ciudad de México. Se invitó a participar en el estudio a todos los adolescentes que acudieron a estos CIJ durante el período de mayo de 2016 a Diciembre de 2017 que cumplían con los siguientes criterios de inclusión: edad entre 10 y 17 años de edad, duración del consumo de inhalables igual o mayor a un año, frecuencia de consumo mínima de varias veces a la semana, escolaridad mayor a cuarto grado de primaria y vivir en un entorno familiar. Se excluyeron del estudio a los individuos con diagnóstico de trastorno psicótico actual, discapacidad intelectual, trastorno por consumo de otras sustancias adictivas y antecedentes patológicos prenatales y perinatales.

Instrumentos

Entrevista estructurada

La entrevista fue elaborada en función de tres objetivos: a) obtener datos sociodemográficos de interés de los participantes, b) conocer la historia del consumo de drogas: edad de inicio, duración, frecuencia, drogas utilizadas y c) reunir información cualitativa sobre las motivaciones del consumo de los inhalables y percepción del impacto de éste en la salud mental.

Evaluación de las funciones ejecutivas

La evaluación de las funciones ejecutivas se realizó a través de la Batería de Funciones Ejecutivas y Lóbulos Frontales, BANFE-2 (Flores, Ostrosky-Solís & Lozano, 2014). Está batería evalúa diversos procesos cognitivos y cuenta con datos normativos en población mexicana de acuerdo a la edad y la escolaridad. A continuación se enlistan las pruebas empleadas y las funciones principales que evalúan.

- Laberintos: Planeación de la conducta viso-espacial y respeto de reglas.
- Señalamiento autodirigido: Memoria de trabajo viso-espacial en una tarea autodirigida.
- Ordenamiento alfabético de palabras: Memoria de trabajo verbal.
- Resta consecutiva: Capacidad para desarrollar operaciones mentales consecutivas e inversas.
- Clasificación de cartas: Capacidad para generar una hipótesis de clasificación, cambiar de forma flexible el criterio de clasificación (flexibilidad mental) y mantener una conducta en relación a reforzamiento positivo.
- Generación de clasificaciones semánticas: Capacidad de abstracción y nivel de productividad en relación al número de categorías producidas.
- Efecto Stroop (dos modalidades o tareas): Inhibición de una respuesta automatizada.
- Fluidez verbal: Capacidad de producir fluidamente verbos en un lapso corto de tiempo.
- Juego de cartas: Toma de decisiones que implican evaluación de relaciones de riesgo – beneficio.
- Selección de refranes: Abstracción del significado, comprensión del sentido figurado.
- Torre de Hanoi: Planeación secuencial. Implica la realización de pasos intermedios para llegar a una meta.
- Metamemoria: Capacidad para realizar juicios predictivos sobre la capacidad de memoria y ajustes del juicio de acuerdo al desempeño (monitoreo y control).
- Memoria de trabajo viso-espacial: Capacidad de memoria de trabajo viso-espacial para seguir un orden específico.

Evaluación conductual

Para la descripción de las conductas de riesgo para la salud mental se empleó la traducción y adaptación mexicana (Albores-Gallo et al., 2007) de la versión más reciente del Cuestionario sobre la Conducta Infantil CBCL

elaborado por Achenbach & Rescorla (2007) la cual tiene una confiabilidad test-retest de .84 y confiabilidad interna para el total de problemas de .97. Este cuestionario para padres está constituido por 113 ítems que se clasifican en escalas comparables con los criterios diagnósticos del DSM-IV. El cuestionario abarca conductas infantiles asociadas a problemas de ansiedad, depresión, trastorno por déficit de atención e hiperactividad, quejas somáticas, conductas oposicionistas desafiantes y conductas agresivas y delictivas. Cada uno de estos ítems se encuentra configurado con tres opciones de respuesta: falso (0), algunas veces (1), y muy cierto (2).

Procedimiento

Los adolescentes fueron reclutados por trabajadores profesionales de los CIJ con experiencia en los trastornos de conductas adictivas tomando en cuenta los objetivos del estudio y los criterios de elegibilidad. Posteriormente, los sujetos interesados en compañía de algún familiar pasaron por un proceso de consentimiento donde el entrevistador proporcionaba información más detallada relativa a la confidencialidad del estudio, los riesgos y beneficios, las pruebas psicométricas, la duración del estudio, etc. y recababa información relevante por medio de una entrevista estructurada sobre la historia del consumo de sustancias adictivas. En ese encuentro se les aplicaba la Escala de Inteligencia para Niños, WISC-IV (Wechsler, 2007) o la Escala de Inteligencia para Adultos WAIS-IV (Wechsler, 2013), en dependencia de la edad del sujeto, para descartar la presencia de discapacidad intelectual, mientras que sus familiares respondían preguntas sobre el neurodesarrollo y la Escala sobre Conducta Infantil CBCL. A los voluntarios que cumplían con todos los criterios de investigación, se les administró en una segunda sesión la Batería de Funciones Ejecutivas y Lóbulos Frontales BANFE-2. Todos los procedimientos del estudio fueron llevados a cabo individualmente y se realizaron en un lugar privado y sin distractores proporcionados por las instituciones involucradas. La aplicación de las pruebas se realizó por profesionales de la psicología con experiencia en el uso de éstas. El tiempo promedio de contacto con los participantes fue de una hora y media por sesión. Todos los procedimientos del protocolo fueron aprobados por el Comité de Investigación Científica del Centro de Integración Juvenil. El procesamiento y tratamiento estadístico de los datos se realizó mediante el programa SPSS versión 21.0.

RESULTADOS

Análisis descriptivo de la muestra

La muestra quedó constituida por 31 adolescentes con una edad media de 15 años, que incluía 25 hombres y 6 mujeres. Dos individuos fueron excluidos del estudio debido a puntuaciones del cociente intelectual inferiores a 70 que indicaba la presencia de discapacidad intelectual y uno por interrupción voluntaria de la evaluación. El 81% de los sujetos reportó inhalar más de tres veces a la semana productos rebajadores de pintura, acetona y gasolina y un 19% reportó hacer uso además de pinturas, desodorantes y pegamentos. La edad media del inicio del consumo fue de 13.02 (*DT* = 1.7). El tiempo de consumo promedio fue de 24 meses, el tiempo mínimo fue de 12 meses y el máximo de 60 meses.

El 61% de la muestra reportó consumo de otras drogas aunque en menor frecuencia que los inhalables. En la Tabla 1 se pueden observar las características del policonsumo. El 53.3% de la muestra reportó cese del consumo de drogas apenas unos días atrás y el 20% abandono de éstas desde hacía un mes. El 10% de la muestra reportó no consumir drogas desde hacía tres meses, mientras que el 16.6% de los participantes mencionó no haber logrado suspender su uso. El 66% de la muestra describió uno o dos intentos fallidos por abandonar la droga antes de solicitar ayuda profesional.

Tabla 1. Reporte sobre el consumo de drogas

	Número de sujetos
Solo inhalables	12
Inhalables y alcohol	5
Inhalables y mariguana	6
Inhalables, alcohol y mariguana	2
Inhalables y cocaína	1
Inhalables, mariguana y cocaína	2
Inhalables, alcohol, mariguana y cocaína	3

Nota: Drogas usadas sistemáticamente (de varias veces por semana a casi diario).

El nivel educativo promedio de los participantes fue de 8.1 (*DT* = 1.1) años. Las principales motivaciones descritas que dieron al inicio del consumo de inhalables fueron mitigar malestares emocionales (63% de los entrevistados), la mayoría de los cuales se vinculaban con problemas familiares así como fines recreativos (curiosidad y diversión con amigos). A la pregunta ¿a qué problemas le ha llevado su consumo? la respuesta más frecuente fue: a conflictos en el ámbito familiar (63%) seguida de peleas en la escuela y en la calle (20%). Los problemas cognitivos autoreportados por los voluntarios fueron: fallos en la memoria en el 77% de ellos, problemas de atención en el 70%, pobre control de los impulsos en el 64%, alteraciones en el lenguaje expresivo en el 48%, dificultades en la toma de decisiones en el 48% y lentitud en el pensamiento también en el 48%. Respecto a su estado emocional el 70% de los participantes autoreportó sentir ansiedad y el 48% mencionó sentimientos de depresión.

Análisis del funcionamiento ejecutivo

La batería neuropsicológica de funciones ejecutivas y lóbulos frontales BANFE-2, permite obtener un perfil individual, que describe las habilidades e inhabilidades del evaluado. Las puntuaciones naturales de las pruebas se transforman en puntuaciones normalizadas con una media de 10 y una desviación estándar de 3. A partir de estos parámetros la prueba permite determinar si el individuo tiene un funcionamiento ejecutivo normal alto, normal, con alteraciones leves a moderadas o con alteraciones severas para cada una de las subpruebas. En la Tabla 2 se muestra por cada subprueba el porcentaje de participantes que puntuó en los cuatro grados de clasificación del funcionamiento ejecutivo y la clasificación de acuerdo a las puntuaciones promedios de la muestra.

De acuerdo a los resultados en la batería BANFE-2 hubo una gran variabilidad en el funcionamiento ejecutivo de los participantes. Los resultados obtenidos mostraron la presencia de adolescentes con puntuaciones dentro del rango de alteraciones leves a moderadas así como dentro del rango de alteraciones severas en todas las pruebas, sin embargo, tomando en cuenta las puntuaciones medias del grupo, el perfil cognitivo tiende a la normalidad en la mayoría de éstas.

Las puntuaciones medias evidencian por otra parte, algunos déficits importantes en el funcionamiento ejecutivo. El bajo rendimiento en la prueba de laberintos, específicamente las dificultades para acatar la regla de no atravesar o tocar las paredes al resolver el ejercicio, pudiera indicar un pobre control de los impulsos. En la tarea de ordenamiento alfabético en el nivel de mayor dificultad (nivel 3), la puntuación media de los participantes se situó dentro del perfil de alteraciones leves a moderadas. Esta tarea está dirigida a evaluar la capacidad de memoria de trabajo verbal y la puntuación media obtenida apunta hacia una pobre retención y dificultad para la manipulación mental de palabras en esta muestra de adolescentes. También se encontraron déficits en los participantes en la capacidad de inhibición de una respuesta automática, pues los puntajes medios en la cantidad de errores Stroop se situaron en el perfil de alteraciones leves a moderadas. Las funciones cognitivas menos afectadas de acuerdo al perfil general de funcionamiento ejecutivo de la muestra fueron la fluidez verbal y la memoria de trabajo visoespacial.

Se realizó un análisis de correlación de Pearson para analizar si la edad de inicio del consumo, el tiempo y la frecuencia del mismo, se relacionan con el rendimiento de los participantes en las tres tareas en las cuales se observó un perfil de desempeño promedio de alteraciones leves a moderadas. Los valores de la *p* de Pearson se pueden observar en la Tabla 3. No se halló correlación entre las variables del consumo y el número de errores cometidos por atravesar paredes en la prueba de laberintos. Tampoco se halló vínculo entre éstas y los errores de inhibición en la prueba Stroop, pero se observó asociación entre la edad de inicio del consumo de inhalables y la frecuencia del mismo con el desempeño en el nivel máximo de la prueba ordenamiento alfabético. Una menor edad de inicio del consumo y el uso más frecuente de esta droga, se asocia con un menor rendimiento en esta tarea. Estos resultados apuntan a que la frecuencia y la edad de inicio del consumo de inhalables influyen en el desarrollo de la memoria de trabajo verbal.

Al correlacionar de manera cualitativa los datos arrojados por la BANFE-2 con el autoreporte de los participantes sobre los efectos percibidos del consumo de inhalables en el funcionamiento cognitivo, observamos congruencia entre ambos datos, pues como ya habíamos descrito, más del 50% de los participantes mencionó tener problemas en la memoria y pobre

control de impulsos lo cual fue confirmado a través de la evaluación neuropsicológica.

Resultados de la evaluación conductual

El Cuestionario sobre la Conducta Infantil CBCL (Achenbach, 2001) permite obtener valores numéricos para cada una de las siguientes escalas o subdominios: problemas afectivos, ansiedad, problemas somáticos, trastorno por déficit de atención e hiperactividad, conducta oposicionista desafiante y problemas de conducta. El puntaje obtenido para cada una de las escalas queda ubicado en uno de 3 rangos posibles: menor del percentil 93, entre el percentil 93 y el 97 y mayor al percentil 97. Los datos clínicamente significativos son los dos últimos, entre el percentil 93 y 97, que se considera un rango límite en el cual los sujetos tienen un riesgo medio de presentar los problemas a los que hace referencia la escala en comparación con otros niños/as de su edad. Un percentil superior a 97 indica un riesgo alto de presentar el problema. En la figura 1 se muestra el porcentaje de sujetos en cada rango por cada una de las escalas.

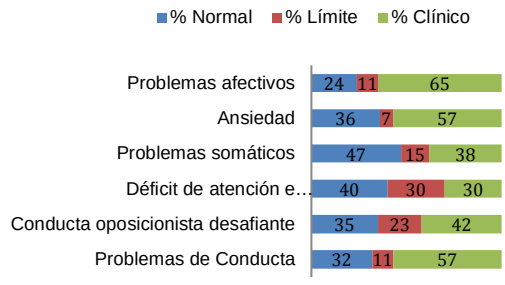

Figura 1. Porcentaje de sujetos en los rangos normal, límite y clínico en cada una de las escalas del CBCL

Al analizar las escalas se observó que más del 50% de los evaluados presentaban conductas clínicas asociadas a problemas afectivos, ansiedad y problemas de conducta. La puntuación media del grupo en la escala de problemas afectivos fue superior al percentil 97 equivalente a un rango clínico que indica un alto riesgo de padecer tal psicopatología. En el resto de las escalas las puntuaciones se ubicaron entre los percentiles 93 y 97 correspondiente con un rango límite o un riesgo medio de padecer los problemas de salud mental explorados. En ninguna de las escalas se obtuvo un percentil medio inferior a 93 mostrando una gran prevalencia de alteraciones conductuales en la muestra evaluada de adolescentes consumidores de inhalables. Cualitativamente se puede distinguir que la alta prevalencia de problemas afectivos y ansiedad detectada a través de las subescalas correspondientes del cuestionario del CBCL, coincide con el autoreporte de los participantes en la entrevista estructurada quienes en su mayoría mencionaron presentar ansiedad y síntomas depresivos.

Se analizó la relación entre las variables sobre el consumo de inhalables y las escalas del cuestionario CBCL. Se encontró poca relación entre dichas medidas (tabla 4). La edad de inicio, el tiempo y la frecuencia de consumo no mostraron asociación con los problemas afectivos, el Trastorno por déficit de atención e hiperactividad y las conductas oposicionistas desafiantes. Se halló una asociación significativa pero moderada entre la edad de inicio del consumo de inhalables y la ansiedad y el tiempo de consumo y la presencia de problemas somáticos y problemas de la conducta. A menor edad de inicio del consumo de inhalables mayor sintomatología ansiosa y a mayor tiempo de consumo mayor número de problemas somáticos y de conducta.

Tabla 4. Correlación de Pearson entre variables sobre el consumo de inhalables y las escalas del CBCL

	Edad de inicio del consumo	Tiempo de consumo	Frecuencia de consumo
Problemas afectivos	-.11	.10	.04

DISCUSIÓN

El presente estudio estuvo dirigido a la determinación del perfil neuropsicológico del funcionamiento ejecutivo de un grupo de adolescentes con trastorno por consumo de inhalables y la exploración de la presencia concomitante de conductas de riesgo para la salud mental. Nuestros resultados no muestran la presencia de un déficit generalizado en el funcionamiento ejecutivo en los adolescentes y apuntan más bien hacia alteraciones neuropsicológicas específicas. Concretamente se observaron alteraciones en los procesos de control de impulsos, en la capacidad para inhibir una respuesta cognitiva automática y en la memoria de trabajo verbal. Esta última afectada por la edad de inicio del consumo y la frecuencia de uso de la droga. La memoria de trabajo verbal y el control inhibitorio son funciones cognitivas importantes para la toma de decisiones en la vida cotidiana y para el procesamiento e interiorización de los contenidos terapéuticos (Khurana et al, 2017; Wanmaker Yucel et al., 2008). Estos resultados ayudan a comprender los retos del tratamiento de la adicción a inhalables, pues investigaciones con drogodependientes han señalado que dichos déficits en el funcionamiento ejecutivo se asocian con el abandono del proceso terapéutico y aumentan el riesgo a las recaídas (Lorea et al., 2010; Madoz & Ochoa, 2012).

Pese a que a que el perfil promedio de la muestra apunta hacia déficits cognitivos concretos, hay que destacar que algunos participantes mostraron un perfil más generalizado de deterioro en el funcionamiento ejecutivo. Esta variabilidad en el desempeño neuropsicológico puede deberse a diversos factores como la variabilidad en la historia y patrón de consumo, el período de abstinencia, el consumo de otras drogas además de los inhalables, las diferencias en factores psicosociales como la calidad de la educación e instrucción recibida, etc. cuyo análisis estuvo limitado por el tamaño de la muestra. De manera general nuestros datos señalan la necesidad de una evaluación neuropsicológica como parte del diagnóstico clínico en los adolescentes con trastorno por consumo de inhalables.

El diseño transversal de nuestra investigación es una limitación para conocer si los déficits cognitivos detectados en nuestra muestra existían antes del inicio del consumo. Investigaciones longitudinales en adolescentes describen la presencia de una memoria de trabajo débil y un pobre control de impulsos asociados con el uso progresivo de alcohol y mariguana (Khurana et al., 2013; 2017). Las debilidades cognitivas predictoras del consumo progresivo de alcohol y mariguana reportadas por estas investigaciones coinciden con el deterioro ejecutivo encontrado en nuestra muestra de adolescentes consumidores de inhalables, por lo que es probable que los déficits cognitivos detectados en los participantes existieran antes del trastorno. Se necesitan estudios longitudinales que permitan entender si la presencia de déficits en el funcionamiento cognitivo influye en el desarrollo de la conducta adictiva de inhalables durante la adolescencia

El segundo aspecto a destacar en nuestros resultados fue que encontramos una alta presencia de conductas que indican un alto riesgo a padecer trastornos mentales. Más del 50 % de la muestra presenta indicadores conductuales clínicos asociados a trastornos de la afectividad, ansiedad y problemas de conducta y un porcentaje no menos importante mostró indicadores clínicos de trastorno por déficit de atención y trastorno oposicionista desafiante. Si bien nuestro análisis se basa en medidas de tamizaje y no en un diagnóstico clínico psicopatológico, nuestros datos apuntan hacia una elevada frecuencia de alteraciones mentales en los adolescentes con trastorno por consumo de inhalables. Nuestros datos son coherentes con investigaciones previas que reportan gran comorbilidad psiquiátrica en la población general de consumidores de estas sustancias (Martín-Navarrete et al., 2018; Perron & Howard, 2009; Wu & Howard, 2007) y llaman la atención hacia la gran presencia de ésta en los consumidores más jóvenes.

Al igual que se discutió la posibilidad de que los déficits en el funcionamiento ejecutivo existiesen antes e influyeran en el desarrollo del trastorno por consumo de inhalables, también queda la duda sobre la contribución de las alteraciones detectadas en la salud mental de los participantes en el inicio y curso del trastorno. La mayoría de los participantes expresó que el inicio del consumo de inhalables estuvo motivado por la necesidad de mitigar malestares emocionales pero no se cuenta con información clínica sobre el estado previo de su salud mental para analizar la posible contribución de este factor. Esperamos que investigaciones futuras

longitudinales puedan dar respuesta a estos interrogantes.

Conclusiones

En los adolescentes con trastorno por consumo de inhalables coexisten alteraciones emocionales, conductuales y cognitivas, lo que da muestra de la complejidad de la drogodependencia. Las alteraciones en el funcionamiento ejecutivo y las conductas de riesgo para la salud mental detectadas tienen implicaciones importantes para la prevención, diagnóstico y tratamiento ya que pueden causar la progresión negativa del curso clínico, afectar el mantenimiento de la abstinencia o propiciar la reincidencia en el consumo. La detección y atención temprana de estos aspectos puede ayudar a reducir las implicaciones del consumo a largo plazo, pues la adolescencia brinda una ventana de oportunidad para la recuperación de las funciones dado la gran plasticidad cerebral que la caracteriza. Los resultados obtenidos proporcionan evidencia clara de la necesidad de hacer un diagnóstico individualizado oportuno que incluya no solo factores relacionados con el abuso de la sustancia, sino también del estado cognitivo y la salud mental del adolescente.

Agradecimientos

Los autores agradecen la financiación recibida por el Consejo Nacional de Ciencia y Tecnología CONACYT (CVU 264242, No de becario 222482, No de apoyo 412003) sin la cual no se hubiera podido llevar a cabo el estudio.

Abstract: In the yeast *Saccharomyces cerevisiae*, components of the High Osmolarity Glycerol (HOG) pathway are important for the response to diverse stresses including response to endoplasmic reticulum stress (ER stress), which is produced by the accumulation of unfolded proteins in the lumen of this organelle. Accumulation of unfolded proteins may be due to the inhibition of protein *N*-glycosylation, which can be achieved by treatment with the antibiotic tunicamycin (Tn). In this work we were interested in finding proteins involved in the ER stress response regulated by Hog1, the mitogen activated protein kinase (MAPK) of the HOG pathway. A high gene dosage suppression screening allowed us to identify genes that suppressed the sensitivity to Tn shown by a *hog1*Δ mutant. The suppressors participate in a limited number of cellular processes, including lipid/carbohydrate biosynthesis and protein glycosylation, vesicle-mediated transport and exocytosis, cell wall organization and biogenesis, and cell detoxification processes. The finding of suppressors Rer2 and Srt1, which participate in the dolichol biosynthesis pathway revealed that the *hog1*Δ strain has a defective polyprenol metabolism. This work uncovers new genetic and functional interactors of Hog1 and contributes to a better understanding of the participation of this MAPK in the ER stress response.

Keywords: yeast; Hog1; MAP kinase; endoplasmic reticulum; stress; suppression; unfolded protein response (UPR)

1. Introduction

The synthesis of transmembrane and secreted proteins occurs in ribosomes attached to the endoplasmic reticulum (ER) membrane. In the ER lumen such proteins are subjected to different modifications such as *N*-glycosylation, formation of disulphur bonds and protein folding. Properly processed proteins continue through the secretion pathway in order to be transported to their final location. All organisms are exposed to adverse conditions that decrease the capacity of the ER to fulfill these processes, leading to the production and accumulation of misfolded proteins, inducing a condition known as endoplasmic reticulum stress (ER stress). ER stress triggers a cellular response that includes the unfolded protein response (UPR), which is a conserved signaling pathway present in all eukaryotic cells, including yeast [1], *Dictyostelium discoideum* [2], plants [3], and mammals [4]. In the yeast *Saccharomyces cerevisiae* the UPR consists of an endoplasmic reticulum membrane sensor named Ire1 [5], which in the presence of misfolded proteins oligomerises and autophosphorylates [6,7]; this in turn triggers its cytoplasmic endonuclease activity, which processes the *HAC1* pre-mRNA [8].

INFORME DE LABORES 2019

The spliced mRNA is efficiently translated to produce the transcription factor Hac1 [8,9], which regulates transcription of several target genes, such as those encoding chaperones, glycosylation enzymes and proteases among others [10] in order to alleviate the accumulation of unfolded proteins.

It has been proposed that the UPR is not the only cellular pathway needed to cope with the ER stress [11]. Components of other pathways appear to be required to produce a full cellular response to ER stress inducers; particularly, some components of the high osmolarity glycerol (HOG) pathway have been implicated in the response to ER stress induced by the antibiotic tunicamycin (Tn). This antibiotic is a nucleoside structurally similar to the UDP-*N*-acetylglucosamine and blocks the first step of the *N*-glycosylation catalyzed by the Glucosamine-*N*-acetil phosphotransferase enzyme [12,13]. The HOG pathway is a signaling system involved in survival under hyperosmotic conditions and it consists of two mechanistically different branches connected to a MAPK module, the SLN1 branch and the SHO1 branch, which converge on the scaffold MAPKK Pbs2, which in turn activates the MAPK Hog1 [14–16]. Once activated, Hog1 is translocated into the nucleus [17,18] where it regulates expression of genes whose products are involved in cell cycle arrest and adaptation to high osmolarity conditions.

In order to respond to ER stress induced by Tn, the cell requires the presence of both Pbs2 and Hog1. Additionally, Ssk1, the phosphorelay response regulator of the SLN1 branch, appears to be required for Tn response; however, components of the SHO1 branch seem to be dispensable [12,13]. As mentioned above, the presence of Hog1 is required for a proper response to Tn, but it appears that it does not need to be phosphorylated in order to produce resistance to the ER stress inducer. Indeed, a strain expressing an unphosphorylated form of Hog1 is able to grow in Tn, although not at the wild type level, but clearly above the growth shown by the *HOG1* null mutant [13]. Additionally, treatment with high Tn concentrations for an extended period of time only produces a very weak level of Hog1 phosphorylation that does not trigger its nuclear import [13]. Interestingly, a full cellular response to Tn requires the kinase activity of Hog1, since a point mutation that eliminates its kinase activity produces high sensitivity to Tn [13]. In addition to its participation in the ER stress response, several reports suggest that Hog1 has cytoplasmic activities, for example in the general stress response system [19,20] and in regulation of mitophagy [21,22].

With the aim of increasing knowledge regarding the participation of Hog1 in the ER stress response, we searched for genes whose products can suppress the sensitivity to Tn displayed by a Hog1-deficient strain but not its sensitivity to hyperosmotic stress. With this screening, we not only detected genes that were able to specifically suppress the Tn sensitivity of the *hog1*Δ mutant, but we also found genes that reverted the sensitivity shown by the *hog1*Δ mutant and by the *hac1*Δ mutant.

2. Materials and Methods

2.1. Yeast Strains, Gene Disruptions, and Culture Conditions

The *S. cerevisiae* strains used in this work are shown in Supplementary Table S1. All of them are isogenic to BY4742 or BY4741. The wild type and the single null mutants were obtained from the EUROSCARF collection. Double mutants were constructed by integration of the *NATMX4* cassette (which provides nourseothricin resistance) into the *HOG1* locus of single mutants. The integrating cassette was constructed by PCR using the oligonucleotides DHOG1F and DHOG1R (Supplementary Table S2) and contained the *NATMX4* gene flanked by *HOG1* 5′ and 3′ UTR fragments of 40 base pairs respectively. Integrations of the cassette were performed by homologous recombination. All deletions were confirmed by PCR.

Yeast cells were grown at 30 °C in YPD medium (1% yeast extract, 2% peptone, and 2% glucose) or SD medium (0.67% yeast nitrogen base without amino acids and 2% glucose, supplemented with the required amino acids for plasmid selection). Glucose was substituted by 2% raffinose (Sraf) or 2% galactose (Sgal) according to the requirements of the experiments. When needed, nourseothricin (100 µg/mL) was added to the media. YPGAL was the same as YPD except for the substitution of glucose by galactose.

INFORME DE LABORES 2019

Escherichia coli DH5α strain was used to propagate plasmids. Bacteria were grown at 37 °C in LB medium (1% tryptone, 0.5% yeast extract, and 0.5% NaCl) containing 100 μg/mL ampicillin or 50 μg/mL kanamycin (for library-plasmid selection).

2.2. Stress Assays

Stress sensitivity assays were done by dropping aliquots of 10-fold serial dilutions of early-logarithmic YPD-cell cultures (OD_{600} adjusted to 0.05) on Tn and KCl plates. Plates were incubated at 30 °C for 72 h and scanned. For liquid cultures, cells with the same density were inoculated in triplicate in Honeycomb 2 plates (100 wells). Density readings were recorded every hour during 48 h of incubation at 30 °C in a BioScreen C microplate spectrophotometer (Oy Growth Curves Ab Ltd, Helsinki, Finland). The relative growth rate is the slope value of the linear regression of three independent liquid cultures.

2.3. High Dosage Suppression Screening

A diagram representing the suppression-screening assay is shown in Figure 1. The *hog1*Δ mutant was transformed with a genomic library constructed to specifically perform overexpression screenings in *S. cerevisiae* [23]. The library contains a collection of more than 1000 overlapping genome fragments from the FY4 *S. cerevisiae* strain, cloned into the multicopy pGP564 plasmid. Transformants were plated in selective medium containing 1 μg/mL Tn. Tn resistant clones were streaked on 1 M KCl and those sensitive to high osmolarity were selected. Plasmids from Tn resistant/KCl sensitive cells were extracted and propagated in *E. coli*. The selected plasmids were re-introduced into *hog1*Δ yeast cells for a second round of selection. Ends of the yeast genome inserts were sequenced in order to map the Tn suppressor genome fragments. Standard yeast genetics protocols were used [24].

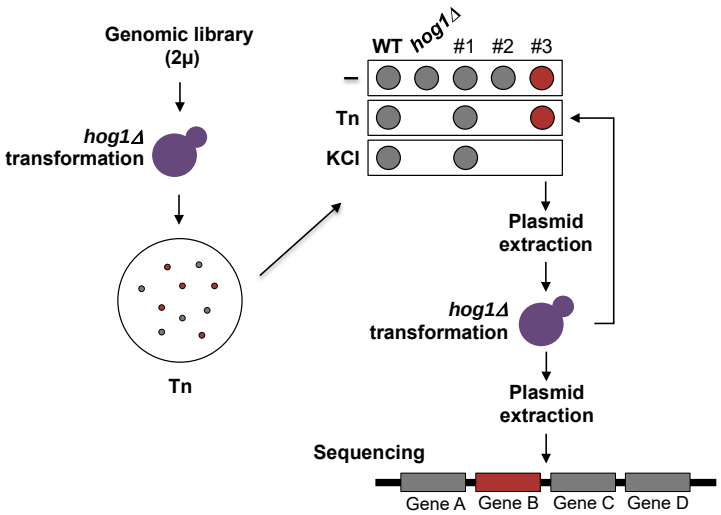

Figure 1. Dosage suppression screening protocol. The *hog1*Δ strain was transformed with a genomic library constructed in a 2 μ plasmid. Yeast cells were plated on selective medium (SD + 25 μg/mL of the required amino acids and nitrogen bases) containing 1 μg/mL Tn. Plates were incubated for 48 h at 30 °C. Colonies that appeared were grown to early-logarithmic phase in liquid selective medium and adjusted to 0.5 OD_{600}. An aliquot of each transformant was dropped onto selective medium containing either 0.5 μg/mL Tn or 1M KCl. Plasmids were purified from the Tn-resistant and KCl-sensitive clones and reintroduced into the *hog1*Δ strain for a second round of selection. Suppressor plasmids were extracted, and the genomic inserts were sequenced.

2.4. Gene Expression

Each ORF contained in the suppression plasmids was cloned with its respective promoter in order to be expressed in yeast cells. Subcloning was done by PCR using oligonucleotides shown in

INFORME DE LABORES 2019

Supplementary Table S2 (only the oligonucleotides for suppressor genes are shown). The PCR products were obtained using genomic DNA of the BY4742 wild type strain as template. The PCR products were cloned into the pGEM-T-Easy vector and then subcloned into the yeast YEp352 vector [25]. The YEp352 clones were used for yeast transformation. All PCR products were sequenced in full.

2.5. Physical Interactions and Construction of the Interaction Network

Physical protein interactions between Hog1 and suppressor proteins were determined by the Bimolecular Fluorescence Complementation (BiFC) assay [26]. Proteins fused to the amino-end (VN) of the fluorescent protein Venus were obtained from the VN-fusion library (Bioneer, Daejeon, Republic of Corea) that is constructed in the BY4741 (*Mata*) strain. Hog1-VC (carboxyl-end of the Venus protein) was constructed by fusing the *HOG1* ORF in frame with the gene encoding VC. The fused gene was integrated into the *HOG1* locus of the BY4742 (*Matα*) strain by homologous recombination. Co-expression of VN and VC fusion constructs was achieved in diploid cells after mating BY4741 and BY4742 recombinant strains. Protein interactions were detected by flow cytometry using the Attune Acoustic Focusing Cytometer. Fluorescence statistics were calculated with the Attune software (version 2.1) and the statistical significance was determined with a Welch *t*-test.

Data of the known interactors for each suppressor gene and *HOG1* were obtained from the BioGRID database (https://thebiogrid.org/) (version 3.4.144), which is a repository of available physical and genetic interactions determined by different low- and high-throughput experimental assays and compiled through comprehensive curation [27]. The physical interaction data were extracted and visualized with Cytoscape [28] according to the protocol previously described [29]. The output interactors, i.e., the proteins that interact with only one node of the network, were eliminated in order to select the proteins connected with at least two other interactors. The network obtained after this reduction was clustered with the force directed layout with default parameters in Cytoscape and the visualization (separation of the nodes) was improved manually. The edges were colored according to the experimental assay that supports each interaction in the database.

2.6. Polyprenol Determination

Yeast cells were grown to mid-logarithmic phase in YPGAL (OD_{600} adjusted to 0.5) and incubated during 2 h with either 1µg/mL Tn or DMSO (Tn dissolvent). Yeast cells were centrifuged and the pellet was washed with water. Polyprenols extraction was performed as previously described [30] with modifications. Yeast cells were resuspended in water and disrupted with glass beads. The lipids were extracted by shaking during 2 h with chloroform/methanol (2:1 *v*/*v*) at RT. The organic phase was collected washed three times with 1/5 volume of 10mM EDTA in 0.9% NaCl and evaporated to dryness. Lipids were resuspended in methanol/water (10:1 *v*/*v*) containing 15% KOH and alkaline hydrolysis was performed during 2 h at 95 °C. Lipophylic products were extracted twice with diethyl ether and evaporated to dryness. The lipids obtained were dissolved in hexane and applied to a silica column equilibrated with hexane. The column was washed with 3% diethyl ether in hexane and the polyprenol fraction was eluted with 17% diethyl ether in hexane. The fraction was evaporated to dryness, resuspended in hexane and subjected to HPLC analysis. Polyprenols detection was performed with a reverse phase Symmetry C18 Waters column (3.5 µm, 4.6 × 75 mm) using a HPLC Waters Alliance e2695/2489/2414 equipment (Milford, MA, USA). Samples were run at 25 °C at a flow rate of 1.2 mL/min in isocratic elution with 55% methanol, 23% isopropanol, and 22% hexane and detected with UV light (210 nm). We used 1 µg/µL of C-90 Dolichol (Dolichol-18) from Larodan Research Grade Lipids (Solna, Sweden) as a standard. Polyprenol concentration corresponded to the area under the curve of each peak, referred to the area under the curve of the internal standard peak and expressed by mg of protein. Mean values, standard deviation, and significance were graphed and analyzed from three independent experiments. Statistical significance was tested with Student *t* test.

INFORME DE LABORES 2019

3. Results

3.1. Isolation of High Dosage-Gene Suppressors of Hog1Δ Tunicamycin Sensitivity

In order to shed light onto the way in which Hog1 participates in the response to ER stress inducers, we designed a dosage-suppression screening to identify genes required for the Hog1-Tn response. For the screening the *hog1*Δ mutant was transformed with a genome library constructed in a high copy plasmid [23] selecting clones resistant to Tn but sensitive to KCl. To this end, yeast transformants were plated in medium containing Tn to isolate cells resistant to the antibiotic; then, the transformants were dropped on plates containing KCl in order to identify the clones that were sensitive to hyperosmotic stress (Figure 1). The suppressor plasmids were extracted from the selected transformants and were reintroduced into the *hog1*Δ mutant to confirm Tn resistance and KCl sensitivity (Figure 1).

With this strategy, we isolated 40 plasmids that conferred resistance to Tn but not to hyperosmotic stress. These plasmids were sequenced to determine the chromosomal region responsible for the suppression. Among these 40 plasmids only 8 different regions were represented (Figure 2A). The regions are distributed in 6 different chromosomes and their size range is from 9 Kb to 12 Kb. Figure 2A summarizes the characteristics of the 40 suppressor plasmids; suppressor 8 was the most represented (14 times), while suppressors 70, 86, and 87 were isolated only one time. The level of Tn sensitivity suppression varied between strains. Sup 11 showed the weakest suppressor level while suppressors 8, 39, and 70 showed the strongest (Figure 2A,B). In our assays we included as a control the *hac1*Δ mutant, which lacks the basic leucine zipper (b-Zip) transcription factor, which regulates the gene transcription in the UPR pathway. This mutant is highly sensitive to Tn (Figure 2B).

Since each chromosomal region contained several ORFs (Figure 2A), we subcloned each of them independently in order to identify the ORF responsible for the suppression. From this assay we identified 8 genes (colored in brown in Figure 2A) that conferred resistance to Tn but not to hyperosmotic stress upon the *hog1*Δ mutant (Figure 2C). The level of suppression varied among the genes. We found differences in sensitivity to Tn and therefore in the growth rate of the *hog1*Δ mutant transformed with the different genes (Figure 2C). The highest growth rate of the *hog1*Δ mutant in Tn was observed with *ALG7*, while the lowest was obtained with *ECM13*. Although *KIN1* was not found as a suppressor in this screening, it was included in this study since it has been reported to be paralogous to *KIN2* [31]. As can be observed, *KIN1* and *KIN2* had the same level of suppression (Figure 2C).

Figure 2. *Cont.*

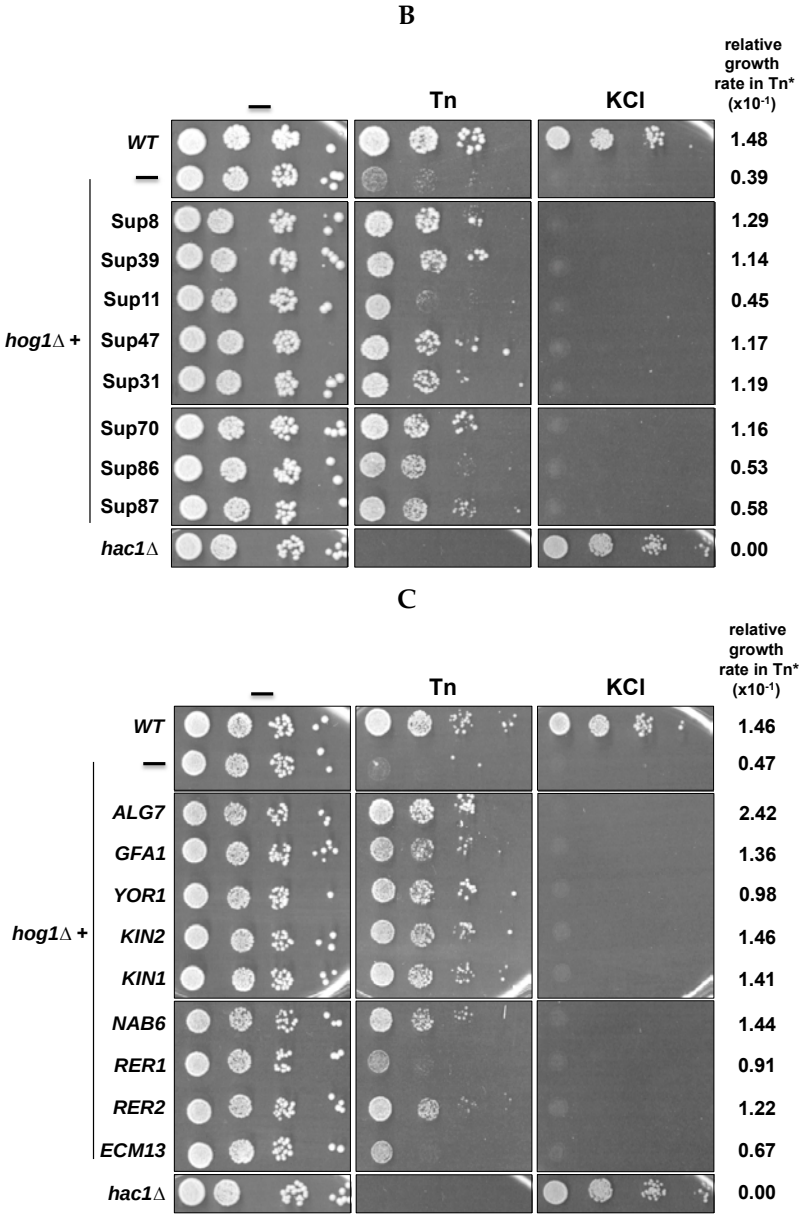

Figure 2. Suppression of the *hog1*Δ Tn sensitivity. (**A**) Schematic representation of the genomic region contained in each suppressor plasmid. Chromosome number and insert coordinates and size are shown. Number of isolated times that each suppressor plasmid was isolated along with its relative suppression level (according to Figure 2B) are indicated. ORF orientation is depicted by the colored arrows. ORFs that show suppressor activity are marked in brown. (**B**) Serial dilution dropping assay of the *hog1*Δ strain transformed with suppressor plasmids. Yeast cells were grown in YPD to early-logarithmic phase and adjusted to 0.5 OD_{600} in fresh YPD. 10-fold serial dilutions were spotted on selective medium (see legend of Figure 1) containing either 0.5 µg/mL Tn or 1 M KCl. The *hac1*Δ mutant was used as Tn sensitivity control. Plates were incubated at 30 °C for 72 h and scanned. (**C**) Genes colored in brown in Figure 2A were subcloned into the multicopy plasmid YEp352 and expressed in the *hog1*Δ strain under the control of their own promoter. A serial dilution assay was performed as described in Figure legend 2B. (*) The relative growth rate is the slope value of the linear regression of liquid cultures made in triplicate and grown in YPD containing 0.5 µg/mL Tn. Liquid cultures were performed in a microplate spectrophotometer at 30 °C with constant shaking. The OD_{600} readings were determined at 1 h intervals during 48 h. *KIN1*, which was not detected in the screening was included in this assay since it is paralogous to *KIN2* (see text).

INFORME DE LABORES 2019

3.2. Genes Can Be Divided into General and HOG-Specific Suppressors of Tn Sensitivity

In order to determine whether the isolated genes were specific suppressors of the Tn-sensitivity observed in the *hog1*Δ mutant, we tested their suppressor activity in mutants of other components of the HOG pathway that have been implicated in the response to ER stress induced by Tn, specifically *PBS2* and *SSK1* [13]. We also introduced the suppressor genes in the *hac1*Δ in order to ascertain whether suppression is or is not restricted to the components of the HOG pathway. We observed that all suppressor genes did confer resistance, to different degrees, upon the *pbs2*Δ and *ssk1*Δ mutants. Interestingly, three genes, *ALG7*, *GFA1* and *YOR1*, also conferred resistance upon the *hac1*Δ mutant (Figure 3). This indicates that *ALG7*, *GFA1* and *YOR1* are general suppressors of Tn sensitivity, while *NAB6*, *KIN1*, *KIN2*, *RER1*, *RER2* and *ECM13* can be considered specific suppressors of the deficiency shown by the mutants of the HOG pathway. The general suppressors were the most represented in the isolated plasmids (30 of 40) (Figure 2B). In contrast, the specific suppressors were represented in only 10 of 40 isolated plasmids (excluding *KIN1*), suggesting that these suppressors can be found more rarely in this kind of screening. Table 1 summarizes the main characteristics of the general and specific suppressors including the proved or putative cellular process where they can be participating (Saccharomyces Genome Database (SGD): www.yeastgenome.org; Gene Ontology (GO) database: www.geneontology.org). Regarding the general suppressors, *ALG7* encodes the UDP-*N*-acetyl-glucosamine-1-P-transferase which catalyzes the first step of *N*-glycosylation and is a direct target of Tn [32,33]; *GFA1* encodes the glutamine-fructose-6-phosphate amidotransferase which participates in the synthesis of chitin, a constituent of the yeast cell wall, and in the synthesis of *N*-acetylglucosamine [34,35]; and *YOR1* codes for an ATP-binding cassette (ABC) transporter located in the plasma membrane [36,37] which participates in cell detoxification processes. Regarding the specific *hog1*Δ suppressors, these include genes that code for proteins with a variety of functions. *NAB6* encodes a protein that binds polyadenylated RNAs which mainly encode proteins destined to the cell wall [38]; *KIN2* and its paralogous *KIN1* encode serine/threonine protein kinases that have been implicated in exocytosis and may also play a role in septin cytoskeleton and cell wall organization [39,40]; *RER2* encodes the *cis*-prenyltransferase involved in the production of dolichol from the isoprenoid lipid farnesyl diphosphate [41]. Dolichol is the acceptor and carrier of oligosaccharides that are transferred to proteins during the folding process. *RER1* encodes a protein known as Retention in the Endoplasmic Reticulum which participates in protein retention in the ER lumen and in retrograde vesicle-mediated transport from Golgi to ER [42,43]; and *ECM13* encodes a protein of unknown function that is upregulated by cell wall damage and appears to be involved in cell wall biosynthesis and architecture [44,45].

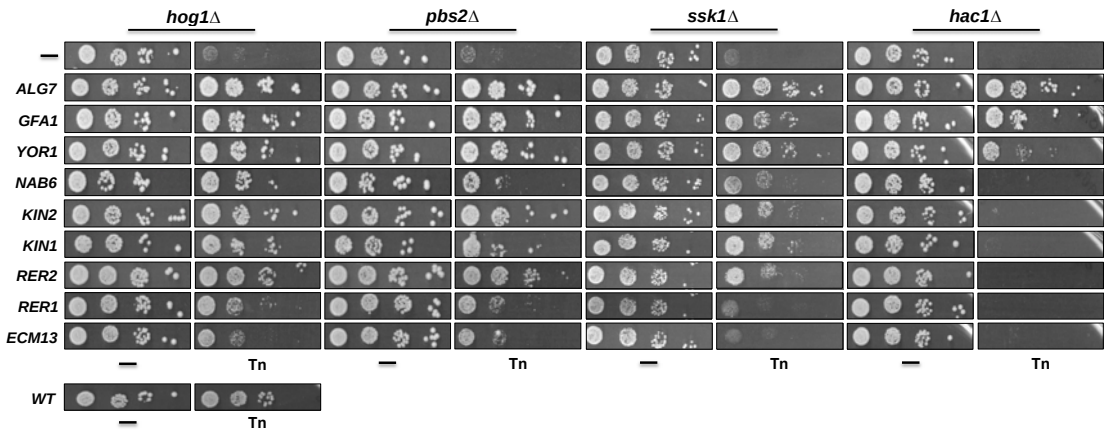

Figure 3. Effect of expression of suppressor genes in the Tn sensitivity of different strains. The suppressor genes were overexpressed in the indicated strains as described in Figure legend 2C. A serial dilution assay was performed as described (Figure legend 2B). Plates were incubated at 30 °C for 72 h and scanned.

INFORME DE LABORES 2019

Table 1. General and specific suppressors and the cellular process where they participate.

Gene	Protein Name	Biological Process	Cellular Component
ALG7	UDP-*N*-acetyl-glycosamine-1-P-transferase	Protein N-linked glycosylation	Endoplasmic reticulum
GFA1	Glutamine-fructose-6-phosphate amidotransferase	Cell wall biosynthesis	Unknown
YOR1	Plasma membrane ATP-binding cassette (ABC) transporter	Xenobiotic transport	Plasma membrane
NAB6	Putative RNA binding protein	Binds to poliA RNAs	Cytoplasm
KIN2	Serine/threonine protein kinase	Exocytosis	Plasma membrane
KIN1	Serine/threonine protein kinase	Exocytosis	Plasma membrane
RER2	Cis-prenyltranferase	ER to Golgi vesicle-mediated transport. Protein glycosilation	Endoplasmic reticulum
RER1	Retention in the endoplasmic reticulum	ER to Golgi vesicle-mediated transport. Protein retention in the ER lumen. Retrograde vesiclemediated transport, Golgi to ER	COPI-coated vesicle vacuole
ECM13	Protein induced by traetment with methoxypsoralen and UVA irradation	Cell wall biosynthesis?	Unknown

3.3. Inactivation of Some Suppressor Genes Confers Sensitivity to Tn

We next evaluated whether the inactivation of some of the suppressor genes affects cell growth in Tn and KCl. In this assay we did not include *ALG7*, *GFA1*, and *RER2* null mutants since *ALG7* and *GFA1* are essential genes and the *rer2*Δ mutant has a severe growth impairment. It was evident that disruption of *YOR1*, *NAB6*, and *KIN2* induced sensitivity to Tn at the highest concentration tested (1 µg/mL), while sensitivity was barely detected at lower concentrations (Figure 4). Disruption of *RER1* also induced sensitivity to Tn but to a lesser extent compared to disruption of *YOR1, NAB6*, and *KIN2*, while inactivation of the *ECM13* gene did not affect growth in Tn. In contrast to the *kin2*Δ mutant, the *kin1*Δ mutant showed very low sensitivity to Tn. As expected, none of the null mutants of the suppressor genes showed growth defects when they were plated on 1M KCl (Figure 4). Additionally, we detected that inactivation of *YOR1*, *NAB6*, *KIN2*, and *KIN1* in a *hog1*Δ background increased the sensitivity to Tn shown by the *hog1*Δ mutant (Figure 4), suggesting that they might participate in Hog1 independent pathways during the Tn response. In contrast, inactivation of *RER1* and *ECM13* did not affect the Tn sensitivity of the *hog1*Δ mutant, suggesting that they may be components of the same pathway.

INFORME DE LABORES 2019

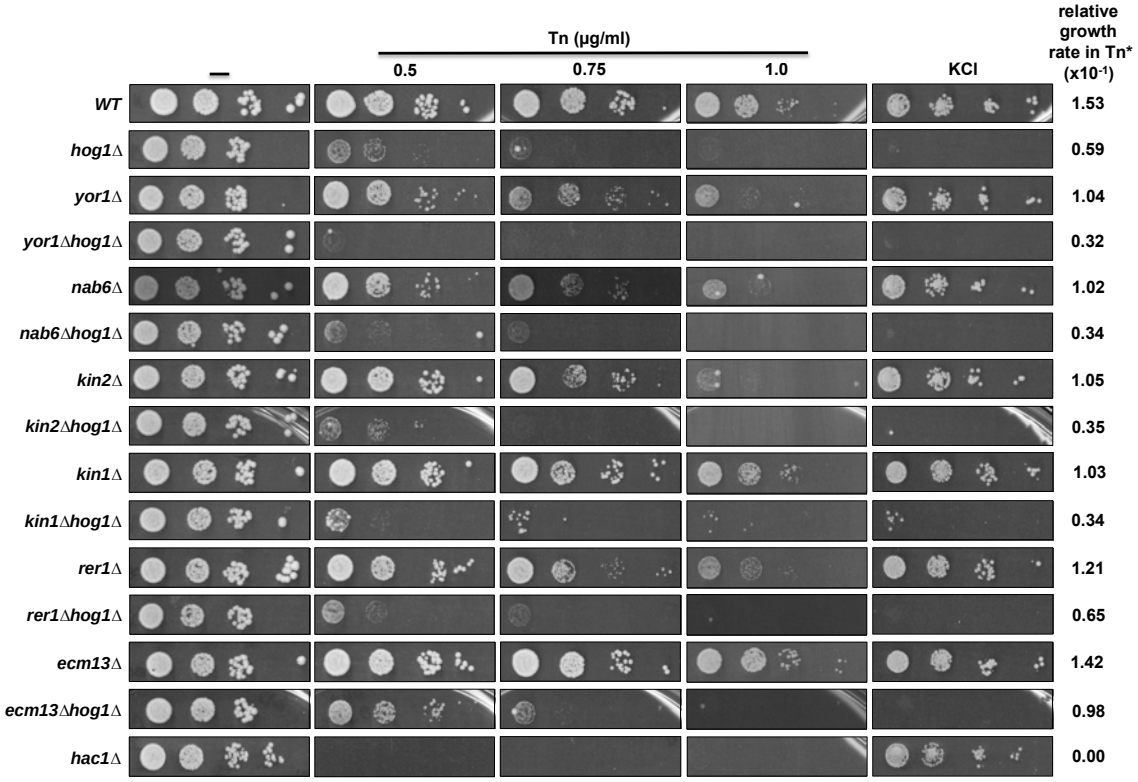

Figure 4. Effect of the inactivation of the suppressor genes on Tn sensitivity and their epistatic interaction with *HOG1*. Single mutants of each suppressor ORF (obtained from the EUROSCARF collection) and the double mutants (constructed as described in the methods section), were tested in different concentrations of Tn or 1M KCl. Yeast cells were grown in YPD and plated as described in Figure legend 2B. Plates were incubated at 30 °C for 72 h and scanned. (*) Relative growth rate was determined from growth at 0.5 µg/mL Tn as described in Figure legend 2.

3.4. Suppressor Genes may Form an Interaction Network with HOG1

The genes that suppress the Tn sensitivity of the *hog1*Δ strain do not appear to encode canonical interactors of Hog1. However, it could be that a putative interaction with one or more suppressor proteins would occur in conditions that induce ER stress. Therefore, we looked for physical interactions between Hog1 and the specific suppressor proteins in the presence of Tn. Using Hog1 as bait and the specific suppressor proteins Nab6, Kin1, Kin2, Rer1, Rer2, and Ecm13 as prays we performed a Bimolecular Fluorescence Complementation (BiFC) assay to detect physical interactions. As expected, none of the suppressor proteins tested appeared to interact physically with Hog1 with and without Tn exposure (Supplementary Table S3), although the fluorescence displayed by the Kin2-Hog1 and Rer2-Hog1 pairs under un-induced conditions was slightly higher than the negative control (Supplementary Table S3). This observation suggests that the suppressors could require one or more intermediates to associate physically with Hog1.

In order to determine whether or not the suppressor genes could participate in functional processes required to cope with the ER stress induced by Tn, we constructed a physical interaction network based on available data from the BioGRID database (Figure 5). This analysis showed that five suppressors, namely Kin1, Kin2, Rer2, Gfa1, and Nab6 may indeed interact with Hog1 through one intermediate. For Kin1, Rer2, and Gfa1, the intermediate protein is Ssb2, a cytoplasmic chaperon of the Hsp70 family that is involved in protein folding processes [46]. Interestingly, Rer2 may also have a physical interaction with Hog1 through Gis2, a RNA binding protein present in processing bodies and stress granules, which contain translationally repressed RNAs [47]. Although the suppression mechanism cannot be deducted from the structure of the interaction network, it provides relevant information

INFORME DE LABORES 2019

regarding proteins that belong to pathways linked with the ER stress response and not previously associated with Hog1.

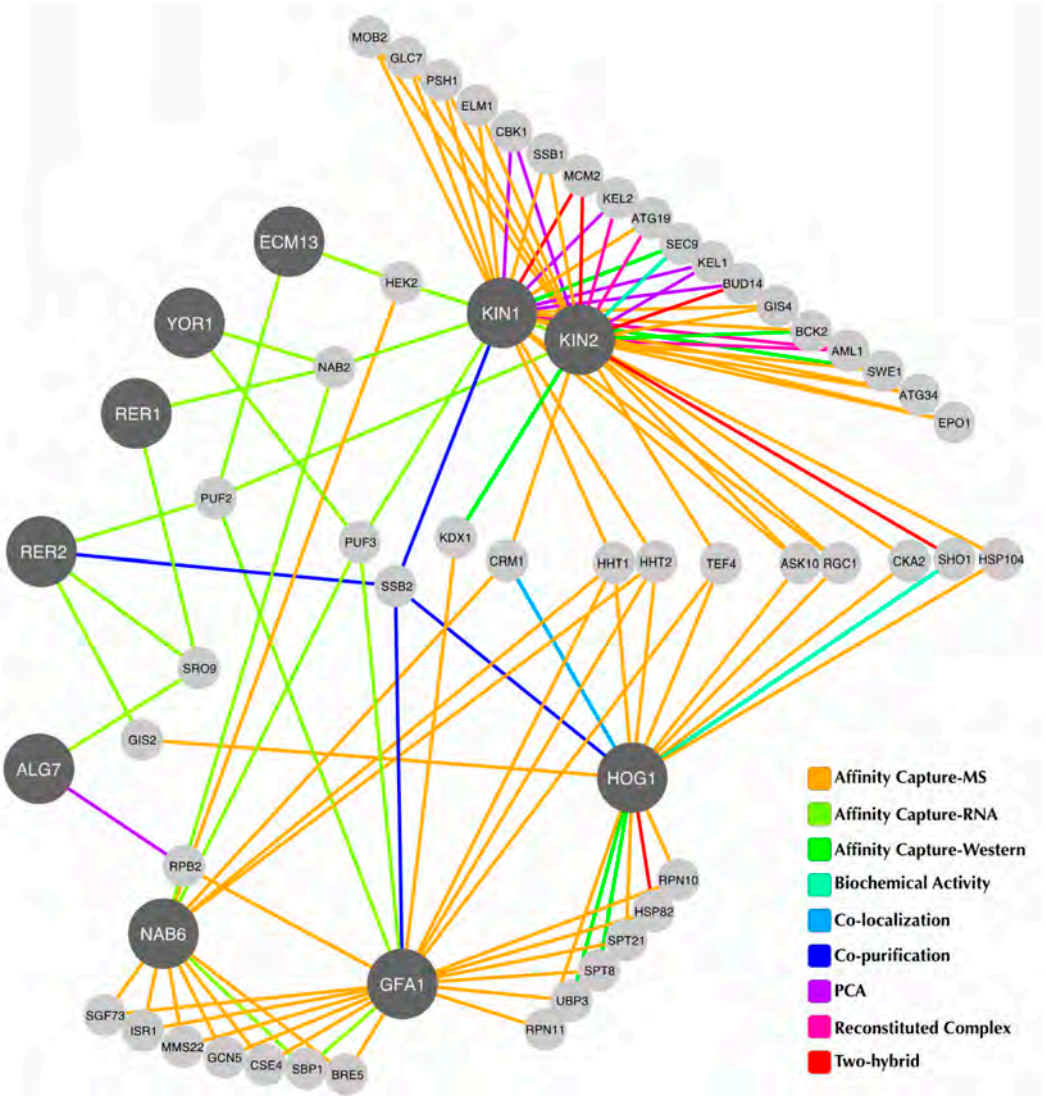

Figure 5. Physical interaction network. Physical interactions of suppressor proteins and Hog1 as deduced from the BioGRID database and visualised with Cytoscape. The network was constructed according to the criteria described in the methods section. Hog1 and suppressor proteins are depicted with dark grey circles. The connecting lines represent the physical interactions and are colored according to the experimental assay that supports each interaction. Known interactors found in the database are colored in light grey.

Since *SSB2* encodes a chaperon of the Hsp70 family that participates in protein folding and appears to be an important interaction node for Rer2 and Kin1 we evaluated its involvement in the ER stress response. We observed that the mutant lacking Ssb2 showed resistance to Tn at the same level as the wild type strain (Figure 6), however overexpression of *RER2*, *KIN1*, and its paralog *KIN2* in the *ssb2*Δ mutant increased its resistance to Tn, while overexpression of *RER1* and *ECM13* did not (Figure 6). This observation indicates that *RER2*, *KIN1*, and *KIN2* interact genetically with *SSB2*, and also validates the proposed physical interaction network.

INFORME DE LABORES 2019

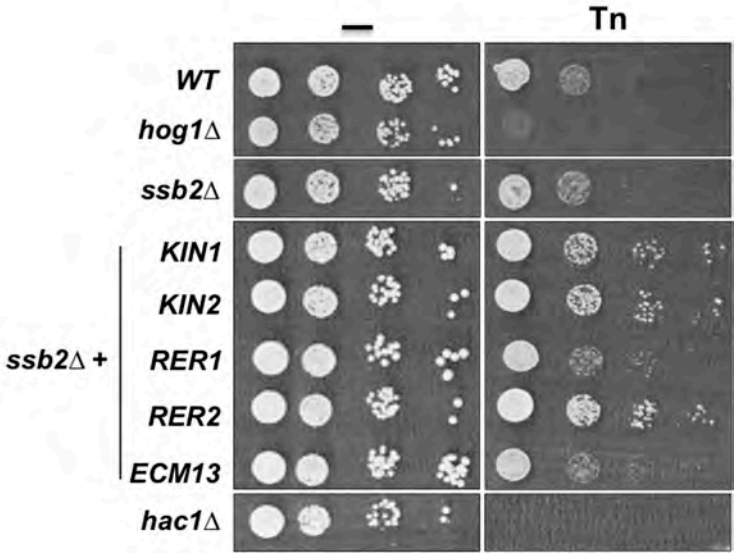

Figure 6. Effect of the inactivation of *SSB2* and overexpression of suppressor genes on Tn sensitivity. The single *ssb2*Δ mutant and transformants carrying the indicated genes were tested in 1.0 μg/mL of Tn as indicated in figure legend 2B. Overexpression was achieved by cloning the indicated genes in the multicopy plasmid YEp352 under the control of their own promoter. Serial dilution assay was performed as indicated in figure legend 2B. Plates were incubated at 30 °C for 72 h and scanned.

*3.5. The Cis-Prenyltransferase Srt1 also Suppresses the Tn Sensitivity of the Hog1*Δ *Mutant*

Tn is a protein glycosylation inhibitor that blocks the activity of the UDP-*N*-acetylglucosamine phosphate transferase (Alg7). This enzyme catalyzes the addition of *N*-acetylglucosamine to dolichol-phosphate, located in the ER membrane. Production of dolichol from farnesyl diphosphate is dependent on the activity of the *cis*-prenyltransferase Rer2 which synthesizes dolichols of 14–18 isoprene units. Yeast cells express a second *cis*-prenyltransferase known as Srt1 (Figure 7A), located mainly in lipid droplets, which synthesizes dolichols of 18–23 isoprene units [41,48]. We tested whether overexpression of *SRT1* would suppress the Tn sensitivity displayed by the *hog1*Δ mutant. We found that *hog1*Δ cells overexpressing *SRT1* grow as well as those expressing *RER2* in a medium containing 0.75 μg/mL Tn (Figure 7B). Accordingly, overexpression of *SRT1* was able to revert the sensitivity of a *pbs2*Δ mutant but not that of the *hac1*Δ mutant, indicating that the suppression process is specific to the HOG1 pathway (not shown). These results suggest that an increase in the cellular concentration of dolichol may revert the Tn sensitivity displayed by the *hog1*Δ mutant.

INFORME DE LABORES 2019

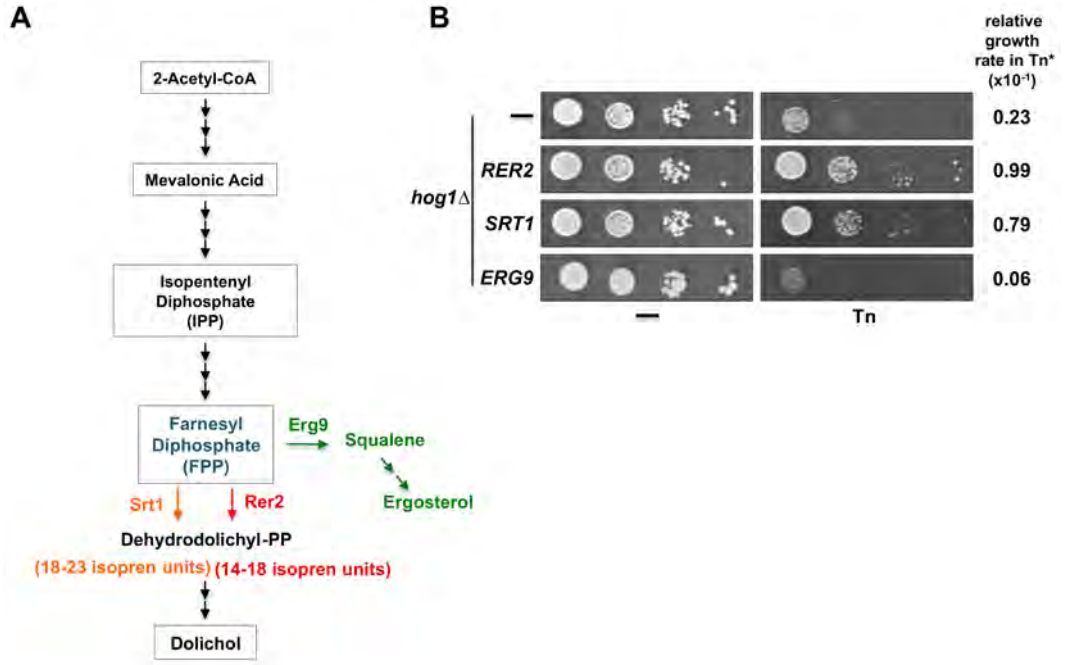

Figure 7. Effects of overexpression of proteins involved in the dolichol and ergosterol synthesis pathways on *hog1*Δ Tn sensitivity. (**A**) Schematic representation of the dolichol and ergosterol synthesis pathways. Farnesyl diphosphate (FPP) is synthesized from 2-Acetyl-CoA through the mevalonic acid pathway. FPP is a shared substrate of Rer2 (and Srt1) and Erg9 to synthesize either dolichol or ergosterol respectively. (**B**) Serial dilution assay of the *hog1*Δ strain transformed with the pYES2 vector or with pYES2 carrying *RER2*, *SRT1*, or *ERG9* genes. A spot dilution assay was performed as described above (Figure legend 2B) except that the cells were grown in SRaf medium and then spotted onto SGal or SGal containing 0.5 µg/mL Tn. Plates were incubated at 30 °C for 72 h and scanned. (*) The growth rate in Tn was measured as described in Figure legend 2C.

3.6. Hog1-Tn Sensitivity Is Enhanced by Overexpression of ERG9

Farnesyl diphosphate (FPP) is not only a precursor of dolichol but also of ergosterol through a series of reactions initiated by the farnesyl-diphosphate farnesyl transferase encoded by the essential *ERG9* gene (Figure 7A). We set out to determine whether the over-utilization of farnesyl diphosphate for the production of ergosterol would affect growth of the *hog1*Δ mutant in Tn. We found that the sensitivity to 0.5 µg/mL Tn of the *hog1*Δ mutant was enhanced when *ERG9* was overexpressed (Figure 7B). Taking this result together with the observation of the effect of *RER2* and *SRT1* overexpression indicated that the effect of Tn on the *hog1*Δ mutant may in part be dependent on the cellular concentration of dolichol.

3.7. The hog1Δ *Strain Has Reduced Polyprenols Concentration*

Based on the previous observations, we hypothesized that the deficient growth of the *hog1*Δ mutant in media containing Tn could be due to an impairment in the dolichol synthesis. We determined the polyprenol content by liquid chromatography (HPLC) in wild type, *hog1*Δ, and the *hog1*Δ overexpressing *RER2* strains treated or not treated with Tn. It was possible to detect in the three strains an enriched polyprenol that may range from 12 to 15 isopren units (Figure 8A). In the wild type strain, the Tn treatment induced approximately a two-fold increase in dolichol concentration (Figure 8B). The same treatment however was unable to induce an increment of dolichol in the *hog1*Δ strain. Overexpression of *RER2* in the *hog1*Δ mutant produced an increment of dolichol, which was statistically significant in both treatments (Figure 8B). Taking together, these results suggest that the *hog1*Δ strain has a strong defect in the polyprenol metabolism under stressful conditions and that this defect is partially compensated with the *RER2* overexpression.

INFORME DE LABORES 2019

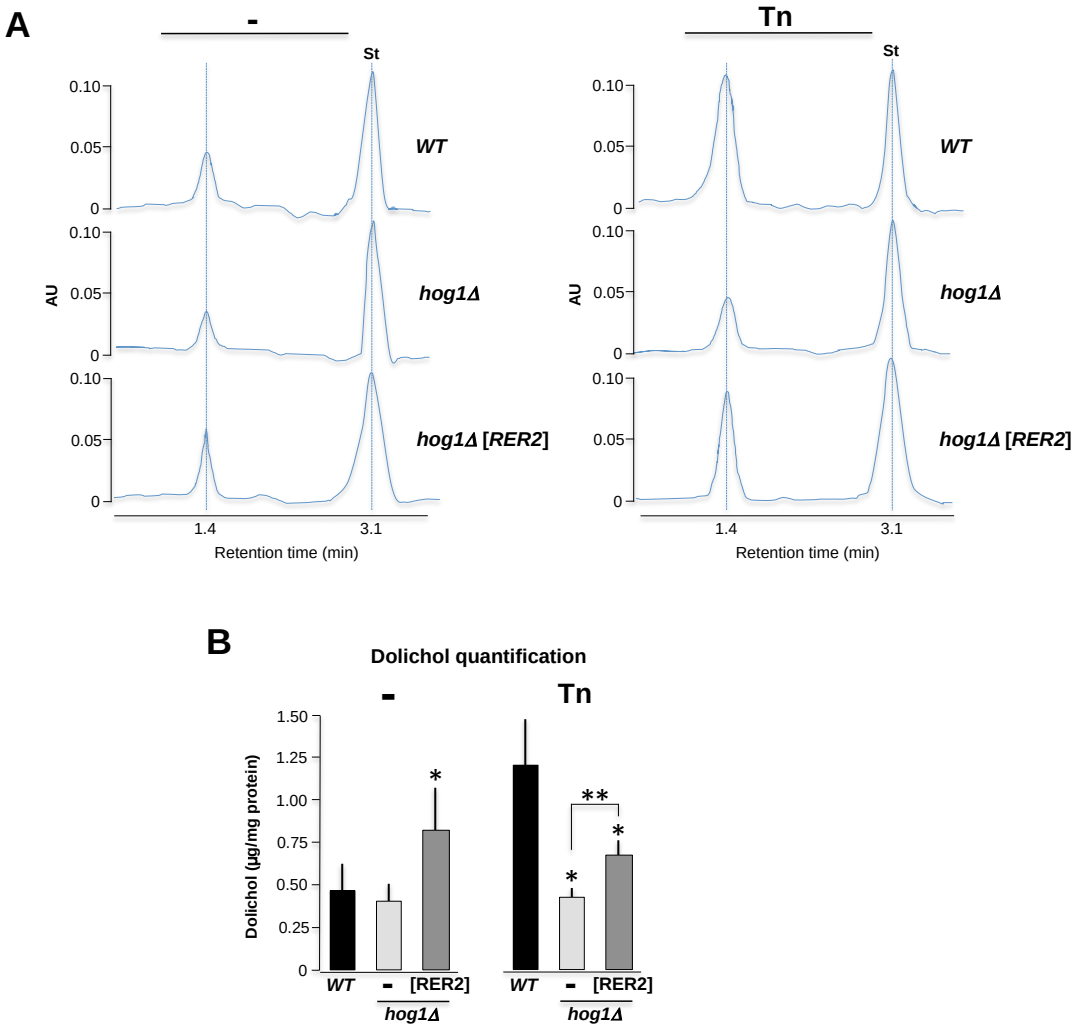

Figure 8. Effect of Hog1 inactivation and Tn treatment on the polyprenols concentration. (**A**) HPLC analysis of dolichols isolated from the wild type, *hog1*Δ and *hog1*Δ[*RER2*] strains, with or without 1 µg/mL Tn. Dolichol detection was performed by reverse phase HPLC analysis. One representative profile out of three is depicted. 1 µg/µL of standard dolichol (18 isoprene units) was included as internal control (St). (**B**) Dolichol concentration was calculated by determining the area under the curve of the dolichol peak relative to the area under the curve of the standard peak (St) and adjusted by protein concentration (See supplemental Table S4). Mean values (± SD) were calculated from three independent experiments. One asterisk indicates statistical significance regarding the WT strain. Two asterisks indicate statistical significance between *hog1*Δ and *hog1*Δ[*RER2*] strains.

4. Discussion

The isolated suppressors of Hog1 Tn sensitivity allowed us to identify genes whose products participate in a restricted number of cellular processes. According to the SGD and GO geneontology databases, these include protein glycosylation (Rer2 and Alg7); vesicle transport and exocytosis (Rer1, Rer2, Kin1, and Kin2); cell wall organization or biogenesis (Gfa1, Nab6, and Ecm13); and cell detoxification processes (Yor1). The limited number of specific suppressors that were detected indicates that the mechanisms by which Hog1 participates in a protective response to ER stress may be limited to very few pathways. It is interesting that with this screening we did not detect proven physical interactors of Hog1. This can be explained by the fact that most interaction assays with Hog1 are carried out under hyperosmotic conditions. This observation suggests that the suppressor proteins may not be phosphorylation targets of Hog1 and that Hog1 may play a regulatory role in the Tn response through one or more intermediates with the suppressor proteins. Several of these intermediates participate

INFORME DE LABORES 2019

in cellular processes related to stress conditions. However, it has been demonstrated that the kinase activity of Hog1 is essential to trigger a protective response to ER stress inducers [13,49]. Accordingly, we found putative Hog1 phosphorylation motifs (S/T-P) [50,51] in some suppressor proteins except Rer1, Rer2, and Alg7. Kin1 and Kin2 have 3 and 5 putative S/T-P phosphorylation sites respectively, while Nab6, Yor1 and Gfa1 contain one site each [52] (https://phosphogrid.org/). Although we cannot rule out that Hog1 may phosphorylate some suppressor proteins our interaction assay disregard this possibility, however a more extensive interaction study would be suitable.

It is interesting that none of the suppressors found plays a role in gene transcription and that all of them have extra-nuclear activities, which is in agreement with the observation that Hog1 is not transported into the nucleus in response to Tn stress [13,49]. Additionally, the specific suppressors found in this study were able to revert the Tn sensitivity shown by the *pbs2*Δ and the *ssk1*Δ mutants. This indicates that these suppressors may participate in one or several pathways made up of extra-nuclear proteins, including components of the phosphorelay pathway. Accordingly, a version of Hog1 that has been anchored to the plasma membrane by means of a CAAX motif was able to provide full ER stress protection [49]. All these observations support a model in which Hog1 shows regulatory cytoplasmic activity in order to counteract the stress caused by Tn.

The functions that Alg7, Gfa1 and Yor1 have in the cell make them logical candidates to provide cellular protection against Tn. In fact, they revert the Tn sensitivity not only of the *hog1*Δ mutant but also that of the *hac1* mutant. The increased concentration of Alg7, the UDP-*N*-acetylglucosamine phosphate transferase that catalyzes the addition of *N*-acetylglucosamine to dolichyl-phosphate [32], would titer the drug due to the fact that Tn and the enzyme substrate UDP-GlcNAc have a similar structure and compete for the enzyme's active site. Similarly, the overexpression of Gfa1, an amidotransferase that participates in the formation of glucosamine 6-P, which is a precursor of UDP-GlcNAc [34], would increase the concentration of UDP-GlcNAc, counteracting the inhibitory effect of Tn on Alg7. Finally, the overactivity of the ABC transporter Yor1 would help to eliminate the Tn from the cell as it does with different organic compounds and xenobiotics [36,53]. The finding of these suppressors is an indication that the screening has been performed properly since their function is related to the action mode of Tn.

Within the specific suppressors, *KIN1* and *KIN2* encode serine/threonine kinases. They are part of the Snf1 kinase family of the Ca^{2+}/calmodulin-dependent kinase II (CaMK), involved in the regulation of cell polarity and exocytosis, as well as in the regulation of the septin cytoskeleton and cell wall [39,40]. Their *hog1*Δ-suppression activity may be related to one of those functions; however, it has been recently assigned a new role for the Kin kinases. It appears that Kin1 and Kin2 may have a role in the Ire1-mediated targeting and processing of *HAC1* mRNA, thus positively regulating the UPR [54]. Interestingly, as detected by Anshu et al. [54] and in our assays, Kin1 and Kin2 are not totally redundant since a lack of Kin2 produced high sensitivity to Tn; in contrast, a lack of Kin1 barely affected the cellular response to Tn. Since the *HAC1* processing appears to be normal in a *hog1*Δ mutant [13], it is interesting to have found Kin1 and Kin2 as specific suppressors of Hog1. Our epistatic experiments suggest that Hog1 and at least Kin2 act in parallel pathways regarding ER stress. Taken together, these observations suggest that the suppression activity of Kin2 (and perhaps that of Kin1) is more closely related to its function in cell wall regulation and exocytosis, than to its role in regulating the UPR [40,54].

Rer1 and Rer2 were also found as specific Hog1-suppressors. Unlike Kin1 and Kin2, these proteins do not contain putative Hog1 phosphorylation motifs. Rer1 is localized in the early region of the Golgi apparatus and is involved in the retrieval of proteins from the Golgi and is also essential for the proper localization of proteins in the ER [42,43]. Its suppressor activity could be related to its participation in the ER localization of type II membrane proteins, including Mns1, which is the alpha-1,2-mannosidase that catalyzes the last step in glycoprotein maturation in the ER and is required for the ER-associated protein degradation [55–57]. In our assays, disruption of *RER1* moderately impaired the cell in its response to Tn and apparently it is not additive to *HOG1*. The functional relationship between the two proteins in the Tn response requires a more detailed study.

INFORME DE LABORES 2019

RER2 encodes the *cis*-prenyltransferase enzyme, which catalyzes the conversion of farnesyl diphosphate (FPP) to dehydrodolichyl diphosphate, the precursor of dolichol, which is the ER lipid where the oligosaccharide required for the *N*-glycosylation is assembled [41]. The suppression activity of Rer2 could be related mainly to its role in increasing dolichol concentration. This observation is supported by the fact that the *cis*-prenyltransferase Srt1, which catalyzes the same reaction, also suppresses the Tn sensitivity of a *hog1*Δ mutant. Rer2 is localized in dots associated with the ER and in lipid particles, while Srt1 appears to be localized only in lipid particles [48,58]. Nevertheless, Rer2 is expressed in early logarithmic phase and Srt1 is expressed in stationary phase, and the products of Srt1 are apparently not converted totally to dolichol and dolichyl phosphate; Srt1 behaves as a multicopy suppressor of *rer2*Δ mutant [48] indicating that in the absence of Rer2, Srt1 may adequately supplement the dolichol pool. The *rer2*Δ mutant has a severe growth defect while the *srt1*Δ mutant grows normally [41]. All of these characteristics imply that Rer2 and Srt1 are not redundant, and that they play different roles in the cell physiology; interestingly, they suppress the Tn sensitivity of the *hog1*Δ mutant almost to the same level. Here we found evidence that in the presence of Tn the dolichol content in a wild type strain increases significantly. This suggests that one mechanism to partially counteract the Tn effect is by overproducing dolichol. This protective mechanism is defective in the absence of Hog1 and is partially compensated by the overexpression of *RER2*. For the *hog1*Δ mutant the increased production of dolichol by *RER2* overexpression will partially suppress the Tn sensitivity. This finding is interesting since it has been observed that a *Trypanosoma brucei* mutant with defects in the *N*-glycosylation pathway accumulates larger amounts of polyprenols compared to its parental strain [59]. The involvement of Hog1 in lipid metabolism has been observed previously, for example, inhibition of sphingolipids and ergosterol biosynthesis activates the Hog1 pathway [60] and stress-mediated activation of Hog1 represses the synthesis of ergosterol [61]. An alternative approach to test that the suppression activity of Rer2 (and Srt1) is related to its function in the synthesis of dolichol was by overexpressing, in the *hog1*Δ mutant, the *ERG*9 gene, which encodes the farnesyl-diphosphate farnesyl transferase [62]. FPP is precursor of squalene, which is eventually converted to ergosterol [63,64]. Indeed, here we found that Erg9 may act as a diverter, converting FPP into squalene and enhancing the Tn sensitivity of the *hog1*Δ mutant. All these evidences indicate that the Hog1 role in the ER stress response could be related in part to its involvement in lipid metabolism including the polyprenol pathway.

The Nab6 and Ecm13 suppression mechanism is at present difficult to deduce since their function remains undefined. Nab6 appears to bind RNAs that encode proteins for the cell wall [38]. It is present in stress granules and co-purifies with Cap-binding proteins and other translation factors [38,65]. It could be that Nab6 regulates translation of this sort of mRNA in response to stress conditions since we detected that the *nab6*Δ mutant is moderately sensitive to Tn. *ECM13* encodes a protein of unknown function that is upregulated by cell wall damage and it may be involved in cell wall biosynthesis and architecture [44,45]; however the null mutant is as resistant to Tn as the wild type strain.

In summary, the screening of high dosage gene suppressors allowed us to conclude that Hog1 may be performing pleiotropic functions in order to regulate the cellular response to ER stress inducers. To counteract the effects of tunicamycin, the cell requires a number of cellular proteins to act in concert with Hog1. It is of the highest interest to study in detail the functional relationship between the suppressor proteins and Hog1. This study opens the field to the investigation of new functions of this MAP kinase in yeast.

Conservation and Variability of the AUG Initiation Codon Context in Eukaryotes

Greco Hernández,[1,*] Vincent G. Osnaya,[1] and Xochitl Pérez-Martínez[2]

Selection of the translation initiation site (TIS) is a crucial step during translation. In the 1980s Marylin Kozak performed key studies on vertebrate mRNAs to characterize the optimal TIS consensus sequence, the Kozak motif. Within this motif, conservation of nucleotides in crucial positions, namely a purine at −3 and a G at +4 (where the A of the AUG is numbered +1), is essential for TIS recognition. Ever since its characterization the Kozak motif has been regarded as the optimal sequence to initiate translation in all eukaryotes. We revisit here published *in silico* data on TIS consensus sequences, as well as experimental studies from diverse eukaryotic lineages, and propose that, while the −3A/G position is universally conserved, the remaining variability of the consensus sequences enables their classification as optimal, strong, and moderate TIS sequences.

Highlights

The Kozak sequence has been characterized as a conserved TIS in eukaryotes.

Sequencing of mRNAs from diverse species coupled to functional studies will continue to contribute to understanding the impact of sequence context on TISs with cognate or non-cognate initiation codons.

The 3D resolution of both translational initiation factors and ribosomes on mRNA will enable better understanding of their conservation, as well as the conservation of the TIS sequences.

Ongoing sequencing projects, such as the Earth BioGenome Project, will help to determine the conservation of the Kozak sequence between eukaryotes such as vertebrates, plants, and fungi.

Conservation and Variability of the Kozak Motif

Translation, namely the synthesis of proteins by the ribosome and translation factors using mRNA as the template, is a fundamental process for all forms of life because proteins catalyze the vast majority of reactions sustaining life and play structural, transport, and regulatory roles in all living organisms. In eukaryotes, regulating gene expression at the level of translation is crucial for tissues or developmental stages where transcription is quiescent or limited, as well as for the differential spatial distribution of proteins in cells and tissues [1]. Regulating translation also gives cells the potential to elicit rapid and reversible responses to sudden environmental changes and stresses without invoking mRNA transcription, processing, or transport [1]. Thus, translational control plays a significant role in determining both protein abundance and proteome composition, and, accordingly, a myriad of mechanisms to regulate translation have evolved throughout eukaryotic evolution [2,3]. Recognition of the mRNA AUG **codon** (see Glossary) that initiates translation, termed the **translation initiation site** (TIS), is subject to tight control because this step establishes the correct open reading frame for mRNA decoding (Box 1).

In the decades following 1980, Marylin Kozak analyzed the frequency of nucleotides around the TIS of vertebrate **coding sequences** (CDSs) in mRNAs [4–6]. She established that the sequence GCC*R*CCAUG*G* (where R at −3, in italic font, is A or G; and the AUG **initiation codon** is underlined) is both the consensus sequence flanking the TIS and the one most optimal for translation in vertebrate lineages; this sequence is termed the **Kozak motif** [7]. Interestingly, many new TIS sequences of phylogenetically distant, non-vertebrate phyla have been analyzed with the advent of the genomic era and high-throughput technologies, as well as with the development of different systems in which to study translation (discussed below). Even so, there is a lack of a comprehensive view of TIS consensus sequences across eukaryotes. We revisit here published data with a primary focus on vertebrates, unicellular fungi, insects, flowering land plants, and some protists to explore these data and evaluate whether the Kozak motif is also the TIS consensus sequence in different taxa. Remarkably, we observe that the −3R position is universally conserved among all eukaryotes scrutinized here, but that there is variation in the +4 position, particularly in single-celled fungi and some protists. Surprisingly, we observed that A/C at the −2 position is universally conserved as well. We also noticed that there are differences between eukaryotic lineages, and therefore propose that TIS consensus sequences can be categorized as Kozak optimal, strong, and moderate motifs.

The Kozak Motif: Optimal, Strong, and Moderate Beginnings

During translation initiation, the small (40S) ribosomal subunit binds to the mRNA at the **5′-untranslated region** (5′-UTR) and **scans** in the 5′ to 3′ direction to reach the CDS start codon, most usually an

Box 1. Translation Initiation in Eukaryotes

Translational control primarily occurs at the initiation step in which mRNA is recruited to the ribosome (reviewed in [1,25,92,93] and references therein). Translation begins with the recognition of the cap structure (m^7GpppN, where N is any nucleotide) located at the 5′ end of the mRNA by eIF4E. A 40S ribosomal subunit bound to eIF1, eIF1A, eIF3, and eIF5 then promotes recruitment of a **ternary complex** (TC), consisting of eIF2 attached to GTP and an initiator Met-tRNA$_i^{Met}$, to form a 43S **preinitiation complex** (PIC). This step positions the initiator Met-tRNA$_i^{Met}$ in the peptidyl (P) site of the ribosome. In a parallel set of interactions, the scaffold protein eIF4G interacts with the poly(A)-binding protein (PABP), the RNA helicase eIF4A, the ribosome-bound eIF3, and the cap-bound eIF4E to coordinate recruitment of the 43S PIC to the mRNA 5′-UTR. eIF4A unwinds secondary structures of 5′-UTR, allowing the 43S PIC to scan base-by-base the 5′-UTR in the search for an AUG initiation codon to start translation [1,25,92,93].

eIF1 and eIF1A drive selection of the correct start codon. They cooperatively promote the adoption of an **open conformation** of the 43S PIC that is compatible with scanning. Such conformation features the Met-tRNA$_i^{Met}$ loosely engaged in the P-site, and allows eIF1 and eIF1A to discriminate against codon–**anticodon** mismatches. 5′-UTR scanning proceeds until an authentic initiator codon, most often an AUG codon, is reached and establishes correct codon–anticodon basepairing. This event arrests scanning and promotes transition of the 43S PIC to a **closed conformation** in which Met-tRNA$_i^{Met}$ and eIF1A become tightly positioned within the P-site. Together, these actions result in the formation of a 48S PIC. Then, GTP–eIF5B promotes the release of eIF1 and eIF5B, facilitating binding of a 60S subunit to the 48S PIC to assemble an 80S initiation complex [1,25,92,93].

AUG [8,9]. The scanning model predicts that translation initiates at the AUG codon closest to the 5′ end of the mRNA, which is termed the 'first-AUG rule' [8,9]. Landmark studies to understand the role of the flanking sequence in TIS recognition by the ribosome led Kozak to analyze 153 cellular and viral mRNAs from vertebrates, observing that 'the sequences flanking the TIS are not random' [4]. She initially found that *R*NNAUG*G* (where N is any base) is the consensus sequence surrounding the AUG initiator codon, and that the two positions which show the most significant conservation, −3R and +4G, function to generate the most efficient initiation signal [4]. She later analyzed 211 cellular mRNAs, mostly from vertebrates but also from some insects, sea urchins, and flowering land plants, and observed that CC*R*CCAUG*G* was the consensus sequence around the TIS [5]. Kozak then analyzed 699 vertebrate mRNAs, and from this study an expanded consensus for the TIS context emerged, namely (GCC)GCC*R*CCAUG*G* in which 97% of mRNAs have a purine, most often an A (61%), at the −3 position [6].

Site-directed mutagenesis experiments to analyze the functional contribution of every nucleotide at positions −1 to −10 and the G at +4 position showed that translation decreases five to tenfold when either −3A or the +4G is replaced by C or U, and 20-fold when pyrimidines are substituted at both of those positions ([4,7,8] and references therein, [10]). These studies also demonstrated that the −3R position plays a key role in TIS recognition and that, in its absence, the +4G position also significantly contributes to promoting translation [7,10,11]. Lütcke *et al*. also demonstrated that, in a vertebrate system, the translational efficiency of an mRNA was 100, 85, 61, and 38% for A, G, U, and C at position −3, respectively [12]. By contrast, positions −1C, −2C, −4C, −5C, and −6G slightly contributed to promoting translation only in the absence of both −3R and +4G. Nucleotides in positions −7 to −10 showed essentially no influence on translation [7,10,11]. Likewise, the +5 and +6 positions also had no impact on translation [11].

Additional experiments showed that changing −3R and/or +4G caused some 40S ribosomal subunits to bypass the first AUG and instead initiate at the next AUG [7,13] in a mechanism termed 'leaky scanning' [8,14]. However, because recognizing the TIS position is crucial, ribosomes may initiate at AUG codons even if they lie in a weak context (i.e., lacking the −3R and/or +4G). Indeed, a −3A is usually sufficient for ribosomes to recognize the first AUG irrespective of the other nucleotides in the context [8,14]. It has also been shown that stem-loop structures ~14 nt downstream of a suboptimal AUG context improve its recognition by the 40S ribosome, possibly by slowing the scanning process. This facilitation is most significant when the ribosome stalls directly over the AUG [15].

Glossary

Aminoacyl (A) site: the site on the 40S ribosomal subunit that holds the incoming aminoacyl-tRNA.
Anticodon: the triplet of a tRNA that is complementary to an mRNA codon.
Biosphere: layer of Earth where life exists. The biosphere is one of the four layers that surround the Earth, together with the lithosphere (soil and rock), hydrosphere (water), and atmosphere (air), and the biosphere is the sum of all the ecosystems and communities on a global scale.
Coding sequences (CDSs): usually start with an AUG codon and end with any of the stop codons. In a few examples, non-cognate codons such as GUG, CUG, ACG, or AUU are used to start the coding sequences.
Closed conformation: a ribosomal state of codon–anticodon base pairing that results in displacement of eIF1s from the P-site; also called the 'in' conformation.
Codon: a sequence of three RNA nucleotides that encodes a specific amino acid (or stop signal) during protein synthesis.
Eukaryotic initiation factors (eIFs): soluble proteins that drive the initiation phase of eukaryotic translation, in other words the mRNA recruitment to the ribosome and the further formation of a ribosomal preinitiation complex at an initiation codon.
Initiation codon: mRNA triplet that opens a reading frame for protein synthesis. The majority of peptides initiate with an AUG codon which encodes methionine. Some open reading frames start with non-AUG codons (also termed 'near-cognate'), which may be GUG, CUG, ACG, and, very rarely, AUU.
Kozak motif: a consensus sequence surrounding the mRNA translation initiation site (TIS, usually the codon AUG) that was discovered by Marilyn Kozak in the 1980s in vertebrate mRNAs.
Microbial dark matter: microbial world composed of genes, genomes, bacteria, archaea, protists, and viruses of unknown identity, as well as their processes and communities. The term is by analogy to the dark matter of the cosmos studied by astronomers.

Table 1. Interactions between Factors, Ribosome, and mRNA during TIS Recognition

Species	Protein	Amino acid	Contacts	Refs
Saccharomyces cerevisiae (budding yeast)	eIF1	Arg36	Codon/anticodon duplex	[19]
Yeast	eIF1	Asp71, Glu73, Glu76	D stem backbone of Met-tRNA$_i$	[19]
Tetrahymena thermophila	eIF1	Arg26, Arg27, Gly28, Arg29, and Lys30	Codon/anticodon duplex	[20]
Oryctolagus cuniculus (Rabbit)	eIF1	Arg38–Lys42	+4 of mRNA, codon/anticodon duplex	[21]
Rabbit	eIF1	Pro77–Gly80	D stem of tRNA$_i^{Met}$	[21]
Tetrahymena thermophila	eIF1A	Asn43, Arg45, Trp69, Lys87	rRNA	[22]
Yeast	eIF1A	Gly8, Gly9, Lys10	Codon/anticodon duplex	[19]
Yeast	eIF1A	Lys16	+5 of mRNA	[19]
Yeast	eIF1A	Trp70	AUG and +4 of mRNA	[19]
Rabbit	eIF1A	Amino terminal	+4 and antisense loop of tRNA$_i$	[21]
Yeast	eIF2α	Arg55	−3 of mRNA	[18,19]
Yeast	eIF2α	Arg57	−2 of mRNA	[18,19]
Rabbit	eIF2α		−3 of mRNA	[17,24]
Rabbit	rpS26e	Val83	−3 of mRNA	[21]
Rabbit	rpS5		−3 and −4 of mRNA	[17,24]
Rabbit	rpS15		+4 and +5 of mRNA	[17,24,26]

Overall, these experiments showed that the context sequence strongly influences TIS recognition by the ribosome in vertebrate mRNAs. Mainly, positions −3R (most often A) and +4G are both the most conserved nucleotides and exert the most critical influence on translational efficiency. Thus, the Kozak motif GCC*R*CCAUG*G* was established as the optimal context for TIS recognition in vertebrate mRNAs [8]. Further, depending on the presence of the two crucial nucleotides (i.e., −3*R* and +4*G*), sequences surrounding the TIS have been classified as 'optimal', GCC*R*CCAUG*G*; 'strong', NNN*R*NNAUG*G* (only the two important nucleotides are present); 'adequate', NNN*R*NNAUG(A/C/U) or NNN(C/U)NNAUG*G* (only one of these nucleotides is present); and 'weak', NNN(C/U)NNAUG(A/C/U) (any sequence lacking both key nucleotides) Kozak motifs [16].

Consistent with the importance of a purine at the −3 and +4 positions, Pisarev *et al.* showed an interaction between these nucleotides and the translational machinery [17]. They observed interactions between −3A and the **eukaryotic initiation factor** (eIF) 2α subunit, and of +4G with ribosomal protein S9 (rpS9) and 18S ribosomal RNA (rRNA). Further biochemical, genetic, and structural studies in yeast, rabbit, and *Tetrahymena thermophila* have recently led to a full understanding of the mRNA TIS recognition by the 40S ribosome **peptidyl (P) site**, eIF1, eIF1A, eIF2α, and rpS26e at the atomic level (Table 1 and Box 2) [18–27].

Open conformation: a complete ribosomal complex in which initiation factors eIF1, eIF1A, eIF2, and eIF4F, together with the 40S subunit, establish a state that promotes scanning; also called the 'out' conformation.
Peptidyl (P) site: ribosomal tRNA-binding site that holds the peptidyl-tRNA.
Preinitiation complex (PIC): a macromolecular complex containing the 40S small ribosomal subunit (bound to eIF1A, eIF1, and eIF3) and the ternary complex. This complex requires the cooperative action of eIF4F to attach to the mRNA.
Scanning: ribosomal movement in a 5′ to 3′ direction along the 5′-UTR of an mRNA to unwind secondary structures (promoted by RNA helicases) to reach an initiation codon.
Ternary complex (TC): molecular complex comprising eIF2, a molecule of GTP, and an initiator Met-tRNA (Met-tRNA$_i$). It binds the 40S ribosomal subunit to promote 43S complex formation during translation initiation.
Translation initiation site (TIS): mRNA triplet that opens the reading frame for protein synthesis. TIS triplets are most frequently AUG (encoding methionine), but other non-cognate codons such as GUG (encoding valine) and CUG (encoding leucine) may sometimes act as a TIS.
5′-Untranslated region (5′-UTR): the mRNA 5′-UTR is located upstream of the AUG start codon. It does not contain a protein coding sequence but is crucial for regulating translation by a variety of mechanisms.

The TIS Consensus Context in Disparate Lineages

Sequence Analyses of TIS Consensus Sequences

More recently, the TIS context of CDSs from many species belonging to phylogenetically distant taxa, namely single-celled fungi, insects, vertebrate, flowering land plants, and some protists, have been analyzed *in silico* by different research groups to identify TIS consensus sequences (Tables S1–S5 in the supplemental information online). The universe of published consensus motifs prompted us to determine their distribution across the tree of life [28,29], and to ask whether or not the optimal vertebrate Kozak motif GCC*R*CCAUG*G* is also the TIS consensus sequence in non-vertebrate species.

In analyzing these data, different authors have used various criteria to select a 'consensus' sequence. Many of them used the most common procedure in the field, namely the Cavener consensus rule [30,31]. According to this rule, a particular nucleotide at a specific position is given a consensus status indicated by a capital letter if its frequency is greater than 50% and greater than twice the frequency of the second most frequent nucleotide at that position. When no single nucleotide satisfies these criteria, a pair of bases are assigned co-consensus status and indicated by capital letters if the sum of their frequencies is greater than 75%. If no single nucleotide or pair of nucleotides meet these criteria, the most frequent nucleotide is denoted by a lower-case letter.

Thus, by using the Cavener consensus rule, we recalculated the published consensus sequences of those reports that did not use it. We observed only slight variations between the recalculated sequences and the original sequences (Tables S1–S5). We then categorized all consensus sequences according to the Kozak motifs defined above [16]. We choose to use the term 'moderate' instead of 'adequate' for those TIS contexts that possess only one of the key nucleotides. We did not recalculate the sequences of Nakagawa *at al.* [32], Pesole *et al.* [33], and Acevedo *et al.* [34] because the raw data were not provided. Figure 1 (Key Figure) depicts a global view of the distribution of the consensus sequences surrounding the CDSs TIS across the tree of life, according to the current classification of eukaryotes [28,29].

Over the years, many studies have corroborated that the optimal Kozak motif GCC*R*CCAUG*G*, or a slight variation of it, GCM*R*NCAUG*G* (where M is an A or C), is actually the consensus sequences around the TIS in vertebrate (phylum Chordata) mRNAs, demonstrating the highly predictive power of Kozak's findings (Table S1) [31,32,35–37]. However, some of the species analyzed, such as cattle, pig, red junglefowl, and the fish *Danio rerio*, possess strong motifs NNN*R*NCAUG*G* as the consensus

Box 2. Recognition of the AUG Start Codon

To date, recognition of the correct AUG start codon by initiation factors in eukaryotes is well known at the ultrastructural level (Figure I) [9,18–22,92]. During the initiation of translation, eIF1 and eIF1A attach to the 40S subunit near the P-site and the **aminoacyl (A) site**, respectively. For mRNA scanning to proceed, eIF1 and the eIF1A C-terminal tail (CTT) act together to discriminate against non-AUG codons. When non-AUG codons are detected, the Arg38–Lys42 stretch of rabbit eIF1 spatially interferes with the anticodon stem-loop of $tRNA_i^{Met}$ and nucleotide +4 of mRNA [21]. The Pro77–Gly80 region of rabbit eIF1 also obstructs interaction with the D stem of $tRNA_i^{Met}$ [21]. These steric clashes destabilize mismatches between codon–anticodon duplexes and result in the open conformation that promotes scanning (Figure IA). In brief, the open conformation does not allow full accommodation of $tRNA_i^{Met}$ in the P-site owing to clashes with eIF1 and eIF1A-CTT [18–25,92].

Upon recognition of an AUG codon by correct basepairing with the anticodon of Met-$tRNA_i^{Met}$, yeast eIF1A N-terminal tail (NTT) residues Gly8, Gly9, and Lys10 interact with the codon–anticodon duplex and stabilize it, while yeast eIF1A Lys16 and Trp70 contact nucleotides +4 and +5 of the mRNA [19,21]. These interactions inhibit scanning, stabilize codon–anticodon duplex formation, and promote a transition to the closed conformation that displays tight accommodation of $tRNA_i^{Met}$ within the P-site. AUG recognition also drives conversion of GTP–eIF2 to GDP–eIF2, liberating phosphate (Pi), as well as dissociation of eIF1, GDP–eIF2, and eIF1A-CTT from the P-site. Transition to the closed conformation (Figure IB) brings rabbit Arg55 and Arg57 of eIF2α D1 loop in contact with mRNA nucleotides −2 and −3, and Val83 of rabbit rpS26e to contact nucleotide −3. These interactions promote the initiation of translation from an AUG in an appropriate context [18–25,92].

(A) Ribosome open conformation during scanning. (B) Once a TIS is recognized, that ribosome changes to a closed conformation that is incompatible with the scanning process.

context instead of an optimal motif [32,37]. Indeed, the −6G, −5C, and −1C positions are relatively well conserved across vertebrate consensus sequences (Table S1 and Table 2). Further, tunicates (phylum Chordata), the closest living relatives of vertebrates, occupy the most basal position in the chordate phylogeny and have been extensively studied to understand the evolutionary origin of vertebrates [38]. Within this lineage, the sea squirt *Ciona intestinalis* possesses a moderate Kozak motif with a K at the +4 position (where K is a G or U) as the preferred TIS consensus sequence [32] (Table S1). This observation could suggest that the optimal Kozak motif for vertebrates appeared at the emergence of the chordates. It would be exiting to study whether or not this motif is also the TIS consensus motif in other tunicate species. We also noticed that the –2M position is highly conserved among the consensus sequences of the vertebrates and the tunicate studied (Table 2).

Key Figure

The Consensus Translation Initiation Site (TIS) Kozak Motif Varies among Different Eukaryotes

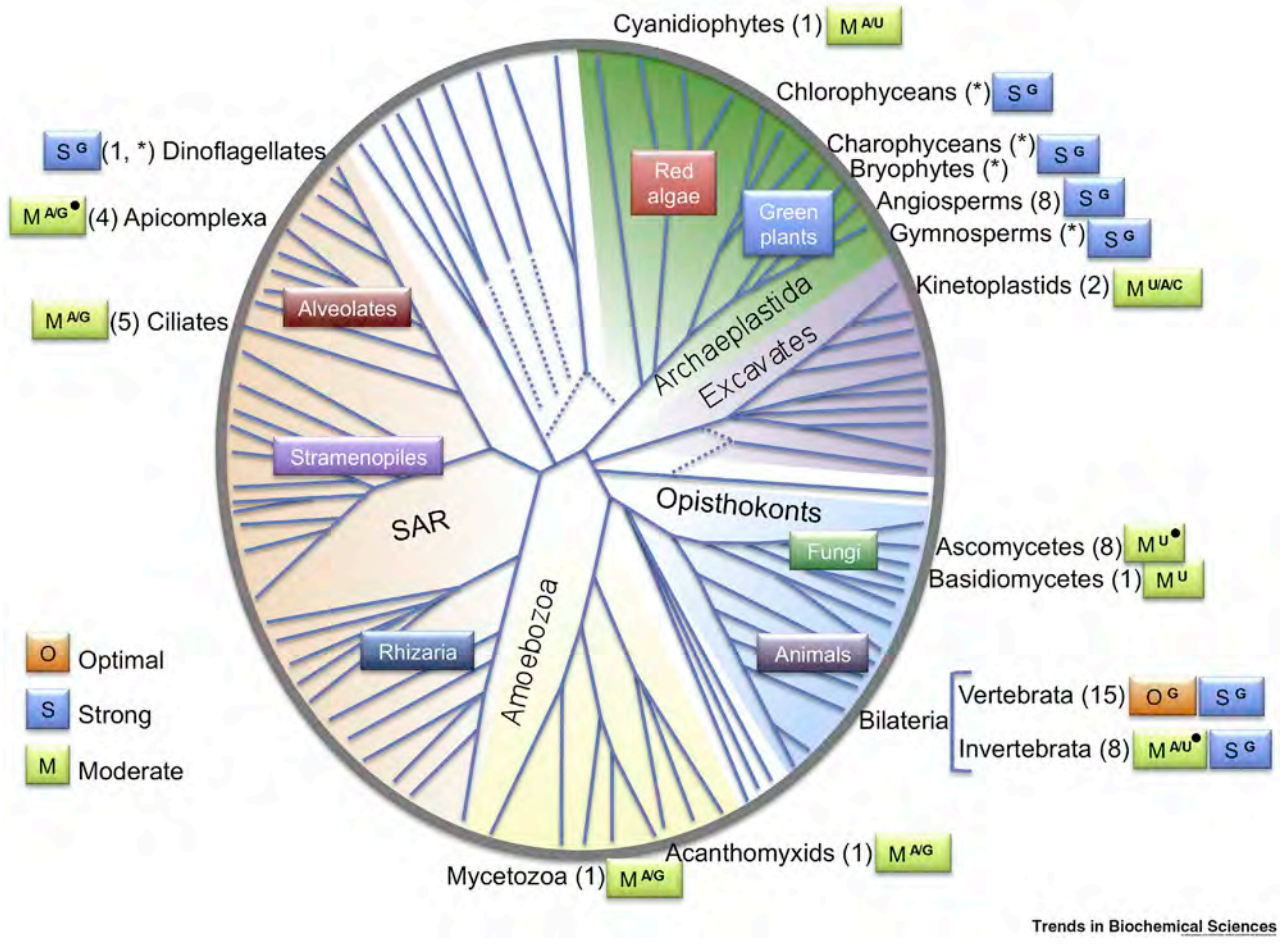

Figure 1. The A or G at the −3 position is conserved in all lineages studied. Other positions (including the functionally key +4 nucleotide) of the consensus Kozak motif vary among different eukaryotes. As a preferred sequence, the optimal Kozak motif is restricted to vertebrates and some angiosperm (monocotyledon) plants. Strong Kozak motifs are present in some vertebrates, flowering land plants (supergroup Archaeoplastida), and Dinoflagellates (supergroup Alveolates). Moderate Kozak motifs are the prevalent TIS consensus in fungi, invertebrates, apicomplexans, ciliates, mycetozoans, and acanthomyxidans. Numbers in brackets indicate the number of species analyzed in each lineage, an asterisk (*) indicates cases where the number was not specified by the authors. (●) Indicates lineages that generally use moderate Kozak motifs but contain a few species that use strong Kozak motifs (Tables S1–S5 for details). The preferentially used nucleotide(s) at the +4 position are indicated as superscripts. Classification of eukaryotes is according to [28,29]. Kozak motifs are defined according to [16]: O, optimal GCC*R*CCAUG*G*; S, strong NNN*R*NNAUG*G*; M, moderate NNN*R*NNAUG(A/C/U) or NNN(C/U)NNAUG*G*. Abbreviations: N, any nucleotide; R, purine (A or G); SAR, stramenopiles, alveolates, and rhizaria. Scheme adapted from Burky [28] with permission from Cold Spring Harbor Laboratory Press.

Among invertebrate species, several insects (phylum Arthropoda) have been analyzed (Table S2) [31,32,34,37,39]. Whereas the fruit fly *Drosophila melanogaster* possesses a strong motif [31,34,37], species from different orders, including *Apis mellifera*, *Bombyx mori*, and *Tribolium castaneum* on the one hand, and *Anopheles gambiae* on the other, contain moderate consensus motifs of the type NNM*R*MMAUGK and NNN*R*NNAUGW (where W is A or U), respectively [32,39]. Further,

invertebrate from other phyla, such as the roundworm *Caenorhabditis elegans* (phylum Nematoda) and the blood fluke *Schistosoma japonicum* (phylum Platyhelminthes), also possess moderate motifs as TIS consensus flanking sequences [31,32]. More specifically, *A. mellifera*, *B. mori*, *T. castaneum*, and *S. japonicum* have moderate consensus motifs with a K at the +4 position [31,32,39]. Interestingly, the −4M and −2M positions appear to be relatively well conserved in the consensus sequences of the invertebrates mentioned here (Table 2).

Within the supergroup Archaeplastida (Plantae), several species of green plants (land plants and green algae) have been analyzed (Table S3). They possess strong Kozak motifs as the consensus TIS context [31–33,36,40–43]. The frequencies of TISs containing guanine at positions −3 and +4 were observed to be different between monocotyledon and dicotyledon mRNAs. Whereas monocot mRNAs contain higher frequencies of −3G/+4G nucleotides, −3A/+4G are more frequent in dicot mRNAs. It should be pointed out that the 5′-UTRs of monocot mRNAs are GC-rich, whereas those of dicots are AU-rich sequences [31–33,40,41,43]. Moreover, we have noticed that, among the consensus sequences of the plant species here scrutinized, the −2M position is well conserved (Table 2). A single species of red algae has also been analyzed, namely *Cyanidioschyzn merolae* [32], which possesses a moderate consensus motif.

All fungi (supergroup Opisthokonts) analyzed have been unicellular species, including *Saccharomyces cerevisiae*, *Aspergillus fumigatus*, *Deberyomyces hansenii*, *Yarrowia lipolytica*, *Eremothecium gossypii*, *Kluyveromyces lacti*, *Candida glabrata*, *Schizosaccharomyces pombe* (phylum Ascomycetes), and *Cryptococcus neoformans* (phylum Basidiomycetes) (Table S4). In contrast to the animals and plants mentioned above, these unicellular fungi mainly have moderate Kozak motifs with a bias towards U at the +4 position [31–33,44,45] (Figure 1). Moreover, the −2M and −4M positions also appear to be relatively well conserved (Table 2). It would be interesting to analyze whether or not this is also the case in multicellular fungi.

Table S5 shows protist species from diverse phyla of the supergroups Amebozoa and Excavates, and the group Alveolates. Among them, different species of dinoflagellates (Alveolates), such as *Symbiodinium kawatii*, use strong Kozak motifs as TIS consensus sequences [46,47]. By contrast,

Table 2. Most Conserved Positions among TIS Consensus Sequences from Coding Sequences in Different Groups of Eukaryotes[a]

Group	Sequence[b]							
	−6	−5	−4	−3	−2	−1	AUG	+4
Vertebrates	G	C		*R*	M	C	———	*G*
Tunicata			M	*A*	M		———	G/U
Invertebrates			M	*R*	M		———	G/A/U
Green plants				*R*	M		———	*G*
Red algae				*A*	M	C	———	A/U
Fungi			M	*R*	M		———	U
Amoebozoa (Mycetozoa, Acanthomyxids)				*R*	M		———	R
Alveolates (Dinoflagellates, Apicomplexa, and Ciliates)								
Excavata (Kinetoplastids)				*R*	M		———	C/A/U
Universally conserved				*R*	M		———	

[a]Owing to its key functional importance, the +4 position is also shown despite its lack of conservation.
[b]Key: ———, AUG; M is A or C; R is A or G.

apicomplexan species (Alveolates) such as *Theileria* spp., *Cryptosporidim parvum*, and *Plasmodium falciparum* [32,48], the kinetoplastids (Excavata) *Leishmania major* and *Trypanosome brucei* [32], the mycetozoan (Amebozoa) *Dictyostelium* spp. and *Acanthamoeba castellanii* [31,32,49], and the ciliates *Paramecium* spp., *Tetrahymena* spp., *Euplotes* spp., *Oxytricha* spp., and *Stylonyclia lemnae* [49], prefer moderate Kozak motifs with different nucleotides (namely G, A, U, or C) at the +4 position as the consensus TIS context. Interestingly, although the −2M position is well conserved in all protist consensus sequences included here, M at the −4 position is also conserved among apicomplexan, dinoflagellate, and mycetozoan species (Table 2).

Recently, a myriad of giant, novel viruses have been discovered that contain substantial sets of translational factors, including eIF1 and eIF2α [50,51]. It would be exciting to investigate whether or not those factors are involved in the host TIS context recognition.

Experimentally Tested TIS Consensus Sequences

Despite the high value of *in silico* analyses, the functional importance of most TIS consensus sequences remains to be experimentally evaluated. Indeed, only some sequences from a few species have been tested in the laboratory (Table S6). As mentioned, the optimal Kozak motif has experimentally been shown *in vitro* to be the best sequence for promoting translation in vertebrates, in particular, rat and rabbit [7,10,11]. Despite these findings, for other vertebrates such as the model organism zebrafish (*Danio rerio*), the optimal Kozak sequence was found to be a poor predictor of translation efficiency [37]. In this case, the investigators found that, although the optimal Kozak sequence efficiently promoted translation *in vivo*, it is neither the most frequent nor the most efficient sequence for initiating translation. Instead, the most frequent sequence is almost twice as efficient at promoting translation as the optimal Kozak motif [37]. Thus, the capacity of the sequences to promote translation may vary among different species, and therefore should be experimentally tested in the specific organism of interest.

Experimental studies of invertebrate species are scarce. Only two insects have been analyzed, namely *D. melanogaster* [34] and *B. mori* [39]. According to what has been observed *in silico*, strong Kozak motifs have the most influence on promoting translation in *Drosophila* [34]. In the case of *B. mori*, a difference was observed between the *in silico*-obtained consensus TIS sequence [32,39] and the most efficient sequence determined experimentally [39]. In particular, the +4 position appears to be different. This apparent discrepancy might be explained by the significant dissimilarity between the number of analyzed sequences in both approaches, namely 14 sequences *in vitro* [39] versus 50 [39] and 875 sequences [32] *in silico*.

Regarding plants, the influence of the TIS context on translation initiation has been experimentally examined in some flowering species (Table S6). *In vitro* translation assays observed no differences in translation efficiency in the wheat system when −3A was changed for G, U, or C [12]. Other *in vitro* assays with 21 sequences did find that −3A/G and +4G are the most efficient nucleotides for translation initiation [4]. Later, *in vivo* experiments in tobacco (16 sequences) [43], *Arabidopsis thaliana* and *Oryza sativa* (64 sequences) [52], and *Picea abies* and *Zea mays* (both 16 sequences) [43] have shown that −3A/G and +4G indeed confer the best translational efficiency.

Among fungi, only *S. cerevisiae* has been experimentally studied, although some discrepancies have been observed. Early studies by Looman and Kuivenhoven (1993) of 47 sequences showed that this yeast prefers the moderate Kozak motif AAUUANNAUGUCU for optimal mRNA translation [53], in agreement with different *in silico* analyses of genomic sequences that also established a moderate sequence with a +4U as the TIS consensus context [31,32,44,45]. Among these studies, Nakagawa *et al.* [32] analyzed 5980 CDSs. By contrast, Pesole *et al.* inspected 1378 CDSs *in silico* [33], obtaining the strong Kozak motif CAMMAUGG as the TIS consensus context. In agreement with this result, ribosome profiling experiments (also termed Ribo-Seq) enabled the analysis of 1735 mRNAs and observed that both core nucleotides (−3A and +4G) are widely used in yeast [54]. The different results between the genomic and the Ribo-Seq observations might reflect incorrect annotation of the main

Trends in Biochemical Sciences

CellPress REVIEWS

CDS AUGs in the earliest studies because we now know that there may be considerable use of upstream AUGs or non-AUG codons of CDSs. We could also explain these differences by the fact that the genomic studies analyzed all annotated genes, whereas the second approach investigated the set of mRNAs being translated at a specific moment under specific growth conditions. More studies will be necessary to better understand the optimal TIS Kozak motif in *S. cerevisiae*. So far, apart from *S. cerevisiae*, no other unicellular organisms have been experimentally analyzed in this regard.

Conservation and Variability among Eukaryotes

Overall, the *in silico* and experimental studies show that, across taxa, the most highly conserved position in the consensus TIS context and the nucleotide that influences translation the most is the purine at position −3 (most frequently A). The conservation of the initiation factors involved in TIS recognition, together with the fact that all taxa here examined possess identical preferences for the crucial −3 position, is an indication of the mechanistic similarities in translation initiation.

Interestingly, the −2A/C position appeared to be the second most conserved position in those lineages scrutinized here (Table 2). This observation is in agreement with early studies by Nakagawa *et al.* who reported a strong bias towards A/C at position −2 in 47 genomes of diverse species of animals, fungi, plants, and protists [32]. They found that genes with higher expression levels showed stronger signals, suggesting that nucleotides at these positions are involved in the regulation of translation initiation [32]. Accordingly, a contact between yeast eIF2α and the −2 position has been observed during TIS recognition by the translation machinery [18,19]. Position −2A/C is present in chordates, the invertebrate, plants, single-celled fungi, and protist TIS consensus sequences. This observation means that the translation machinery that recognizes the start codon is highly conserved. In the line with this idea, sequence comparisons of the translational machinery factors driving recognition of the TIS consensus sequence, namely eIF1, eIF1A, eIF2α, and ribosomal protein S26 (rpS26), showed no significant differences in the amino acids involved in TIS and Kozak motif recognition among the species reviewed here (Figures S1–S4). Indeed, the percentage of identity among these factors is in the same range of identity of other initiation factors such as eIF4E and eIF4A from the same lineages (Figure S5), suggesting that the variations in those factors causing a context preference are subtle, or that more mechanistic details of context recognition remain to be uncovered.

Early studies of genomic sequences of 47 species from different taxa by Nakagawa *et al.* [32] showed that the diversity of TIS consensus motifs can be arranged into two distinct general patterns, namely GCCGCCAUG and AAAAAAAUG. By reviewing a much broader spectrum of species from different taxa, we have observed significant variability of Kozak motifs among different species (Figure 1 and Table 2). The experimental and *in silico* studies described here agree with *in silico* analyses that optimal and strong Kozak motifs (i.e., with a +4G) appear to be the best sequences to promote translation in vertebrates [5,6,31–33,35]. In *Drosophila*, land plants, and dinoflagellates, strong Kozak motifs (with a +4G) are also the preferred sequence surrounding the CDS TIS [31–34,36,40–43,46,47]. Interestingly, the consensus sequence flanking the AUG initiator codon appears to have diverged in other eukaryotes. In particularly, nucleotides at positions −6, −5, −4, and −1, as well as the key position +4, in single-celled fungi (Ascomycetes) [31–33,44,45] and some protists (for instance some ciliates, kinetoplastids, apicomplexans, and mycetozoans [31,32,48,49] show a preference for moderate Kozak motifs with a bias towards a +4U (Ascomycetes) and +4A/C/U for the aforementioned protists. Thus, the optimal Kozak motif does not appear to be the optimal sequence to initiate translation in all lineages. Finally, we noticed that –3U/C and –2U/G are universally absent nucleotides in the consensus TIS motif for CDSs. Because 18S rRNA is also involved in TIS recognition, differences in this rRNA among species might also contribute to differential TIS context recognition. It would be interesting to experimentally study the sequences flanking the TISs in a larger number of species of different phyla to better understand the distribution of Kozak motifs across the tree of eukaryotes.

Strong Initiation at Non-AUG Initiator Codons

Despite the predominant use of the AUG codon to start CDS translation across eukaryotic lineages, decoding in some mRNAs initiates at codons different from AUG. Although translation starting at non-AUG codons is much less efficient than canonical initiation, CUG, GUG, ACG, and UUG are the most commonly used near-cognate codons [55]; codons AUU, AUC, AUA, and AGG may also be used, albeit very rarely [55].

Recent advances in ribosome profiling aiming to precisely map TISs genome-wide in different systems, particularly human, mouse, and *S. saccharomyces*, have revealed thousands of alternative translation initiation events at non-AUG codons [56,57]. These approaches are based on the action of antibiotics such as lactimidomycin, harringtonine, puromycin, and cycloheximide which block ribosome activity at different steps of translation. However, there is ongoing debate on the value of some of these data because it remains unknown what proportion of these ribosomal footprints are due to experimental artifacts and how many represent actual translation initiation events [55,58,59]. It is noteworthy that a computational analysis found a weak correlation between context strength and TIS efficiency for the non-AUGs codons obtained in several Ribo-Seq datasets [60]. By contrast, the use of genetically engineered reporters in mammals indicates that translation from non-AUGs is more dependent on their TIS context than is translation from AUG codons, although sequence context affects each non-AUG start codon differently [61].

We reviewed studies that experimentally addressed the translation of non-AUG codons in their natural contexts (Table S7). In vertebrate mRNAs (*H. sapiens*, *M. musculus*, *O. cuniculus*, *Ratus norvegicus*, and the monkey *Chlorocebus aethiops*) there is a sharp bias to use either strong or moderate Kozak motifs around non-AUG TISs to achieve the most efficient translation [13,62–77]. This context usage contrasts with the AUG TIS of vertebrate CDSs which prevalently prefers an optimal Kozak motif as the consensus context [5,6,32,33,36]. The flowering land plants *N. plumbaginifolia*, *Orychophragmus violaceus* [69], wheat [70], and *A. thaliana* [71], as well as the fungi *N. crassa* [78] and *S. cerevisiae* [72,74], also prefer either optimal or strong Kozak motifs flanking non-AUGs TISs in different transcripts. In the case of the ascomycetes *S. cerevisiae* [73] and *Candida albicans* [75], the galactokinase and CARP2A mRNAs, respectively, possess moderate contexts with an A at the +4 position. Among protists, *P. falciparum* uses the moderate Kozak context and start codon UUUUUUUUAGG in aldolase mRNA (interestingly, UAG is a stop codon in the canonical genetic code) [76].

In Table S8 we have reviewed the influence of context on the translation of non-AUG TISs in experimentally tested human [79] and *S. cerevisiae* [80–82] transcripts. Although human non-AUGs prefer strong Kozak motifs (NNN*R*NNAUG*G*) for most efficient translation, *S. cerevisiae* may prefer moderate (NNN*A*NNAUGA or NNN*A*NNAUGR) Kozak motifs for efficient translation. Again, more sequences and species should be tested to understand in more depth the influence of context on non-AUG TIS recognition.

Concluding Remarks

The evolution of eukaryotes towards a myriad of different lineages has resulted in large-scale changes and significant innovations at many levels. At the molecular level, this includes the translation process. Emerging evidence suggests that the fundamental mechanisms of translation are well conserved in all eukaryotes, even though the initiation step has undergone substantial increases in sophistication upon the emergence of eukaryotes [2,83,84]. Likewise, the studies reviewed here show that the TIS consensus context also has diverged to some extent during eukaryotic evolution, and that this diversity includes the crucial nucleotide at the +4 position; thus, some lineages appear to possess optimal Kozak consensus sequences, some have moderate to strong TIS consensus sequences, and others may utilize various TIS consensus sequences. Near-cognate start codon TISs from the few species analyzed to date, including vertebrates, show a strong preference for a strong, but not optimal, TIS consensus context. It is remarkable that, despite these changes, for both AUG and non-AUG initiator codons, A or G (most frequently A) at the −3 position is a universal feature of all taxa analyzed so

far. The second most conserved position across the lineages scrutinized here appears to be A/C at the −2 position, and U/C and U/G at the –3 and –2 positions are universally absent in the consensus Kozak motif for CDSs.

In the near future we believe that several recently launched and highly ambitious global sequencing initiatives will unlock a wealth of highly valuable novel information on the **biosphere**. These projects include the Earth BioGenome Project that aims to sequence the genomes of all of eukaryotic species on Earth over a period of 10 years [85], metagenomics projects that plan to publish the genomes of over 100 000 species of the **microbial dark matter** within the next 5 years [86–89], and projects that will extensively study the spectrum of viruses in thousands of geographically diverse samples to uncover the so-called 'virome of Earth' [90,91]. Undoubtedly, the field of translation will benefit from these ground-breaking projects (see Outstanding Questions).

Outstanding Questions

Is the Kozak motif of monophyletic origin, meaning that it appeared in the last ancestor of all eukaryotes, or it did appear several times during eukaryotic evolution?

From the data discussed herein, the −3 position is the most conserved base in the TIS sequence. Is the purine at the −3 position conserved across all eukaryotes?

After the publication of global sequencing initiatives such as the Earth BioGenome Project, will we find further diversity in TIS consensus sequences across eukaryotes?

It is well documented that translational control plays a key role in cancer onset and progression. Is the prevalence of translation of mRNAs containing specific Kozak motifs (i.e., weak, moderate, strong, or optimal) altered during cancer development?

ABSTRACT

Phosphorylation of the human α_{1B}-adrenergic receptor (fused with the green fluorescent protein) was studied employing the inducible Flp-In HEK293 T-Rex system for expression. Serine/alanine substitutions were performed in five sites corresponding to those previously identified as phosphorylation targets in the hamster ortholog. Desensitization was decreased in these mutants but receptor phosphorylation was still clearly detected. The protein phosphorylation of the wild-type receptor (fused to the green fluorescent protein) was studied, using mass spectrometry, under baseline and stimulated conditions (noradrenaline or phorbol myristate acetate). Basal phosphorylation was detected at sites located at the intracellular loop 3 and carboxyl terminus, and the number of sites detected increased under agonist activation and stimulation of protein kinase C. The phosphorylation patterns differed under the distinct conditions. Three of the phosphorylation sites detected in this work corresponded to those observed in the hamster receptor. The phosphorylation sites detected included the following: a) at the intracellular loop 3: serines 246, 248, 257, 267, and 277; and threonines 252, 264, and 268, and b) at the carboxyl terminus: serines 396, 400, 402, 406, 423, 425, 427, 455, and 470, and threonines 387, 392, 420, and 475. Our data indicate that complex phosphorylation patterns exist and suggest the possibility that such differences could be relevant in receptor function and subcellular localization.

1. Introduction

G protein-coupled receptors (GPCR) are involved in a plethora of actions that maintain homeostasis, mediating the physiological action of a large variety of hormones, local hormones (autacoids), neurotransmitters and growth factors and also participate in the pathogenesis of many diseases. As indicated by their name, GPCR interact with G proteins, which modulate the activity of enzymes and ionic channels to exert their actions [1,2]. These receptors exhibit a characteristic structure constituted of an extracellular amino terminus, an intracellular carboxyl terminus (Ctail), and seven transmembrane domains joined by intracellular and extracellular loops [1,2].

GPCR phosphorylation appears to be a very early event that regulates the function of this large family of receptors and it is associated with the attenuation of receptor activity (desensitization) and internalization [3–5]. However, there is evidence of desensitization in the absence of receptor phosphorylation [3,6], and recent data indicate a role of GPCR phosphorylation in membrane targeting/localization [7,8]. In addition, there is clear evidence indicating that desensitization is not limited to a decrease in GPCR signaling through a particular pathway but that in fact it represents a “switch” in which a pathway is attenuated while another (others) is (are) activated [4,9]. Frequently, such a switch involves the decrease of G protein-mediated signaling and the triggering of additional molecular events including, in addition to post-translational modifications of receptors and the resulting conformational changes, interaction with other molecular entities, such as β-arrestins [9,10].

Current data also indicate that the sites at which the phosphorylation of GPCR takes place is of great importance, since these might vary depending on the cell type in which they are expressed or on the agents that lead to a such covalent modification and, more importantly, that phosphorylation at different sites can lead to distinct functional outcomes and receptor localizations [11,12]. These general proposals have been denominated the “phosphorylation barcode hypothesis” [11,12].

INFORME DE LABORES 2019

In many cases, this involves receptor's phosphorylation at both Ctail and intracellular loop 3 (IL3) residues (see for example [7,13–21]).

α_1-Adrenergic receptors (α_1-AR) constitute a subfamily of GPCR composed of three members, the α_{1A}-, the α_{1B}-, and the α_{1D}-AR [22–24]. All of these couple to Gq and exert their actions mainly through the inositol trisphosphate/diacylglycerol/calcium signaling pathway [22,23], although other signaling processes also appear to participate in their actions [25]. It is well-known that the three receptor subtypes are phosphorylated in response to agonists and the pharmacological or physiological activation of protein kinase C (PKC) [7,19,20,23,26–33]. The α_{1B}-AR subtype was the first receptor of this subfamily to be cloned [34] and it has been extensively studied. Pioneer contributions by Cotecchia and coworkers, using receptor mutants with deletions and mutagenesis of specific sites, together with functional studies, identified that relevant phosphorylation sites for hamster α_{1B}-AR are located in a cluster at the Ctail, which seem to be targeted by G protein-coupled receptor kinases (GRK) and PKC [30,32]. In addition, the group of Toews [35,36] has observed that, in the hamster receptor, two domains play key roles in receptor internalization/down regulation. Using deletions and site-directed mutagenesis, these authors observed that some mutated receptors internalize but do not down-regulate, other mutants that down-regulate without internalization, and that there are also receptors defective in both internalization and down-regulation [35].

Using mass spectrometry of purified receptors, we recently reported phosphorylation sites detected in human α_{1A}- [19] and α_{1D}-AR [7,20]. Interestingly, we observed differential phosphorylation of these receptor subtypes under distinct conditions (baseline, agonist stimulation, and activation of PKC) and detected that phosphorylation sites were present both at the Ctail and at the intracellular loop 3 (IL3) [7,19,20]. In the present work, again utilizing mass spectrometry, we examined the phosphorylation sites of the α_{1B}-AR subtype human ortholog and observed the following: 1) a large amount of phosphorylation sites located at both the Ctail and IL3 and 2) that the phosphorylation pattern varies under the different conditions employed. Our data suggest that the regulation of this receptor subtype is likely more complex than anticipated.

2. Materials and methods

2.1. Materials

(−)-Noradrenaline (NA), phorbol 12-myristate 13-acetate (PMA), phentolamine, and propranolol were obtained from Sigma-Aldrich Chemical. [^{32}P]Pi (8500–9120 Ci/mmol) was obtained from Perkin-Elmer Life Sciences. Dulbecco's modified Eagle's medium, fetal bovine serum, trypsin, streptomycin, penicillin, amphotericin B, blasticidin, hygromycin B, doxycycline hyclate and Fura-2AM were purchased from Invitrogen-Life Technologies. Polyethyleneimine was obtained from PolyScience and GenJet was obtained from SignaGen Laboratories. Nitrocellulose membranes were from BioRad, and SuperSignal West Pico Chemiluminescence kits were from Thermo Fisher Scientific. Agarose-coupled protein A was obtained from Merck-Millipore. Anti-phospho-ERK 1/2 (Thre202/Tyr204) (catalog number 9101S, lot: 30) and anti-total ERK (p42/44) antibodies (catalog number 4695S, lot: 21) were obtained from Cell Signaling Technology; monoclonal anti-GFP was from Clontech (catalog number 632381, lot A5033481) and polyclonal anti-GFP was generated in our laboratory [37]. Secondary antibodies were purchased from Zymed (Thermo Fisher Scientific) or Jackson ImmunoResearch, including the peroxidase affiniPure Goat anti-mouse IgG light chain antibody. Antibody dilutions were 1:1000 for primary antibodies and 1:10,000 for secondary antibodies. Parental Flp-In T-Rex HEK293 cells and the plasmid, pOG44, were obtained from Invitrogen.

2.2. Receptor mutants, cells, and transfections

The plasmid for the expression of the human α_{1B}-AR fused at the Ctail with the enhanced green fluorescent protein (eGFP) was previously described [38]. The receptor construct was subcloned into pCDNA5/FRT/TO to employ the inducible Flp-ln T-Rex expression system (Invitrogen), and the construct is referred as wild-type α_{1B}-AR. This was used as a template to generate the different mutants used; mutagenesis was commercially performed by Mutagenex, Inc. and proper changes were confirmed by sequencing (Mutagenex, Inc.).

To generate inducible receptor-expressing cells, parental Flp-In T-Rex HEK293 cells were transfected with pCDNA5/FRT/TO, containing the cDNA coding for the desired mutant, and pOG44 using GenJet following the manufacturer's instructions. Transfected cells were subjected to selection with 5 μg/ml blasticidin and 100 μg/ml hygromycin B, as previously described [39,40]. Experiments were performed after inducing receptor expression with 1 μg/ml doxycycline hyclate for 14–24 h. Cells were routinely grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum, 100 μg/ml streptomycin, 100 U/ml penicillin, and 0.25 μg/ml amphotericin B. In all experiments using NA, 1 μM propranolol was also added to avoid any β-adrenergic action; the β-blocker did not alter baseline parameters by itself (data not shown).

2.3. Intracellular calcium determinations

Intracellular calcium concentrations were assessed as previously described [41,42]. Briefly, cells were serum-starved for 2 h, and then loaded with 2.5 μM Fura-2/AM for 1 h at 37 °C, and cells were washed to eliminate unincorporated dye. Fluorescence measurements were performed at 340- and 380-nm excitation wavelengths and at a 510-nm emission wavelength, with a chopper interval set to 0.5 s, using an Aminco-Bowman Series 2 Luminescence Spectrometer. Intracellular calcium levels were calculated as described by Grynkiewicz et al. [43].

2.4. Receptor phosphorylation

Receptor phosphorylation was performed as previously described [42]. In brief, cells cultured in six-well plates were incubated for 3 h in phosphate-free Dulbecco's Modified Eagle's media supplemented with 50 μCi/ml [^{32}P]Pi. Labeled cells were stimulated as indicated, washed with ice-cold phosphate-buffered saline (137.9 mM NaCl, 2.7 mM KCl, Na_2HPO_4 10 mM; pH 7.4) (PBS) and solubilized for 1 h in the lysis buffer described previously. The extracts were centrifuged and supernatants were incubated overnight with protein A-agarose and anti-eGFP antiserum generated in our laboratory [37]. Samples were subjected to SDS-PAGE, transferred onto nitrocellulose membranes, and exposed for 18–24 h. The amount of phosphorylated receptor was assessed by PhosphorImager analysis, using the ImageQuant program. The average of the baseline values obtained in these experiments was considered as 100% and the error bar of the baselines corresponds to the dispersion of these values. Western blotting for loading controls was performed using a commercial monoclonal anti-eGFP antibody.

2.5. ERK 1/2 phosphorylation

Cells were serum-starved for 2 h. After stimulation with the indicated agents, cells were washed with ice-cold phosphate-buffered saline and lysed with Laemmli sample buffer [44]. Lysates were centrifuged at 12,700 × *g* for 5 min, and proteins in supernatants were separated by SDS-PAGE. Proteins were electrotransferred onto nitrocellulose membranes and immunoblotting was performed. Duplicate samples were run in parallel to determine total- and phospho-ERK 1/2 levels. For data normalization, maximal response was considered as 100%.

INFORME DE LABORES 2019

2.6. α_{1B}-AR purification and mass spectrometry analysis

The procedure employed was similar to those employed for α_{1A}- and α_{1D}-AR [7,19,20]. Ten 10 cm-diameter dishes (90% confluence) of HEK 293 cells expressing the wild-type α_{1B}-AR-eGFP construct, per condition, were used in each experiment. Control experiments employing non-induced HEK 293 cells were also performed. Cells were stimulated as indicated, washed twice with ice-cold PBS and solubilized for 1 h at 4 °C with ice-cold lysis buffer (10 mM Tris HCl, 150 mM NaCl, 1% sodium cholate, 1% Nonidet P40, 10% SDS, 5 mM EDTA, pH 7.4, 10 mM NaF, 10 mM sodium pyrophosphate, leupeptin 20 mg/ml, phenylmethylsulfonyl fluoride 100 mg/ml, bacitracin 500 mg/ml, soybean trypsin inhibitor 50 mg/ml, 1 mM p-serine, 1 mM p-threonine, and 1 mM p-tyrosine). The solubilized extracts were centrifuged at 12,700 ×*g* for 15 min. Pre-cleaning of the supernatants was performed using 100 µl of protein A-agarose with constant agitation for 1 h at 4 °C. After 5000 ×*g* centrifugation, the supernatants were incubated overnight under constant agitation with 30 µl anti-GFP serum and 30 µl of protein A-agarose. Pellets were washed five times with lysis buffer and solubilized with Laemmli sample buffer [44] containing 20 mg/ml dithiothreitol, 10% SDS, and 8 M urea. The samples were resolved by SDS-PAGE by running two 10% gels in parallel, one containing > 95% of the sample and the other with the remaining amount. The first gel was stained with colloidal Coomassie Blue and the bands of interest were excised and sent for mass spectrometry analysis to the Taplin Mass Spectrometry Facility (Harvard Medical School. Cambridge, MA, USA). The second gel was used to confirm the presence of eGFP-tagged receptors by Western blotting. Four different purification-mass spectrometry experiments were performed. Ascore [45], a probability-based score, was employed. The program measures the probability of correct phosphorylation site localization, based on the presence and intensity of site-determining ions in the mass spectrometry spectra. Two considerations were made: a) Ascore values > 19 were considered as the limit for reliable phosphorylation sites, and b) when two sites were detected in the same peptide, the different Ascore values were considered [45].

2.7. In silico analysis

Receptor sequences were obtained from the UniProt Knowledgebase [46]. Sequence alignments were performed using the blast-protein suite (protein-protein BLAST (http://www.uniprot.org/blast/). The possible phosphorylation sites were obtained from analysis performed using NetPhos 3.0 (http://www.cbs.dtu.dk/services/NetPhos) [47] and the Group-based Prediction System, GPS 2.1 (http://gps.biocuckoo.org/) [48] on-line services, employing cut-off values of 0.75 and 4, respectively. Prediction of the probable protein kinases involved was obtained using GPS 2.1 [48].

2.8. Statistical analysis

Statistical comparisons between groups were performed employing a parametric analysis of variance with Bonferroni's post-test, assuming Gaussian data distribution (http://www.graphpad.com/guides/prism/7/statistics/index.htm). We used the software included in the GraphPad Prism 6 software to perform these analyses. A p value of < 0.05 was considered statistically significant.

3. Results and discussion

As previously indicated, in the experiments of Cottechia and coworkers [30,32] the hamster α_{1B}-AR was studied. We centered our work on the human ortholog, mainly for its medical interest and also in order to compare the findings with what has been observed in the phosphorylation of human α_{1A}- and α_{1D}-AR [7,19,20]. Human α_{1B}-AR are phosphorylated in response to agonists and activation of PKC in a comparable way to what has been observed with the hamster receptor, and the functional consequences of such phosphorylations are also alike [26]. This is hardly surprising considering that these orthologs are remarkably similar; i.e. overall identity is ~94.6%, with the human ortholog five amino acids larger than that of the hamster (520 amino acids vs. 515 in the hamster receptor). Amino acids 1–351, which comprise the main cores of these receptors (amino termini, the seven transmembrane domains, and the intracellular and extracellular loops) show notable similarity, exhibiting only three conservative and two semi-conservative substitutions (Supplementary Fig. S1). The Ctail domains of these receptors have more differences: i.e., five additional residues are present in the human ortholog as compared to the hamster, and conservative (10), semi-conservative (3) and non-conservative (5) substitutions are present (Supplementary Fig. S2; please note that alternative alignments are possible). However, the phosphorylation sites detected in the hamster receptor [30] are all conserved in the human ortholog (S396, 402,406, 410, and 412) (Supplementary Fig. S2).

As an initial step in our work, we examined the possible roles of the sites of the human α_{1B}-AR, equivalent to those observed as phosphorylated in the hamster ortholog [30]. To achieve this goal, mutations of the putative phosphorylation sites were performed to the wild-type human α_{1B}-AR, as depicted in Supplementary Fig. S3, as well as receptor phosphorylation and functional studies (intracellular calcium determination and ERK 1/2 phosphorylation). The following receptors were generated: a) wild-type (no modification other than fusion to the eGFP). b) S396,402A (altering putative PKC sites, named PKC-m), c) S406,410,412A (altering putative GRK sites; named GRK-m), and d) S396,402,406,410,412A, altering these five sites (named PKC + GRK-m). Receptor expression was similar as reflected by fluorescence confocal microscopy (Supplementary Fig. S4) and Western blotting (see later).

β_2-AR are known to be endogenously expressed in HEK 293 cells and their activation mobilizes intracellular calcium [49]; therefore, in all experiments in which NA was employed, the cells were also incubated in the presence of 10 µM propranolol. As shown in Fig. 1A, cells expressing the wild-type receptor or any of the mutants studied increased intracellular calcium in response to NA in concentration-dependent fashion. This effect was blocked by 10 µM phentolamine, as anticipated (data not shown; prazosin was not used due to its intrinsic fluorescence). The efficacy of the different receptors was similar (i.e., an increase in intracellular calcium of ~150–200 nM was observed), with the exception of the PKC + GRK-m mutant, which was in some of the experiments less responsive to NA (statistically insignificant); the potencies of NA were also similar (EC_{50} ~ 20–60 nM). In Fig. 1B, calcium transients in response to 10 µM NA are presented. As can be observed the calcium response peaks were very similar (see also Fig. 1C); however, return to baseline was considerably slower in mutants with the putative GRK sites mutated, which resulted in significantly higher residual intracellular calcium values (determined at 100 s after agonist addition) (Fig. 1, panels B and C). These data are consistent with the idea that the receptor mutants are less susceptible to desensitization than the wild-type; i.e., the mutant receptors did not appear to desensitize as fast as the wild-type, which is in accordance with the data of Diviani et al. [30]. It has been suggested that α_{1B}-AR internalization diminish calcium signaling [50]. To what extent this plays a role in our experiments is unknown; however, vanishing of the NA-induced free calcium increases occurs within seconds, and changes in receptor internalization are hard to detect in this time frame.

The ability of PKC activation with PMA to desensitize α_{1B}-AR action was also tested with the different mutants. As shown in Fig. 2A, NA-induced increase in intracellular calcium was reduced (~50%) by preincubation for 5, 10, or 15 min with 1 µM PMA in cells expressing the wild-type receptor. A similar effect was observed in the receptor mutant in which the putative sites for this kinase family were mutated to alanine (PKC-m) but the effect of PMA decreased with the incubation time (Fig. 2B). Interestingly, cells expressing receptors in which the

Cells expressing the different α_{1B}-AR-eGFP constructs were stimulated with the indicated concentrations of NA (in the presence of propranolol) and intracellular free calcium concentration was quantified. Wild-type (WT) receptor and the following mutants with the indicated substitutions in parenthesis: (S396,402A), PKC-m; (S406,410,412A), GRK-m; and (S396,402,406,410,412A), PKC-GRK-m. Plotted are the maximal increases as the means ± S.E.M. of 7–9 experiments using different cell preparations (where no error bar is shown, it is within the symbol). Panel B. Representative free calcium tracings using the different mutants. Panel C. Bars indicate the maximal increases (PEAK, open bars) and the remaining increase over baseline observed 100 s after NA addition (RESIDUAL, dashed bars). Plotted are the means ± S.E.M. of 7–9 experiments using different cell preparations. ***$p < 0.001$ vs. Residual WT; **$p < 0.005$ vs. Residual WT.

putative GRK sites were changed to alanine (GRK-m and PKC + GRK-m) were not significantly affected by the treatment with PMA (Fig. 2, panels C and D). Attempts to study NA-induced desensitization (intracellular calcium response or inositol phosphate production) were unsuccessful due to that the action of the catecholamine decreased the general response of the cells even after extensive washing. This might involve depletion of calcium stores and/or changes in the metabolic pools of the phosphoinositides.

We examined receptor phosphorylation and observed that all of the receptors studied (wild-type α_{1B}-AR and the different mutants) were phosphorylated under baseline conditions and that this estate increased in response to NA (Fig. 3) and PMA (Fig. 4). Western blotting of the immunoprecipitated receptors was performed and, in all cases, two bands were identified; a major band of ~110 kD and another of ~100 kD. Phosphorylation was mainly detected in the band with the higher Mr, although some radioactivity was also present in the lower Mr band. Signal in both bands was quantified together (the lower Mr band might represent the receptor being processed (glycosylated) or partially degraded). In cells expressing the wild-type receptor, 1 μM NA rapidly increased receptor phosphorylation (at 2 and 5 min), which decreased at longer incubation times (15–60 min). The different mutants also augmented their phosphorylation state rapidly in response to

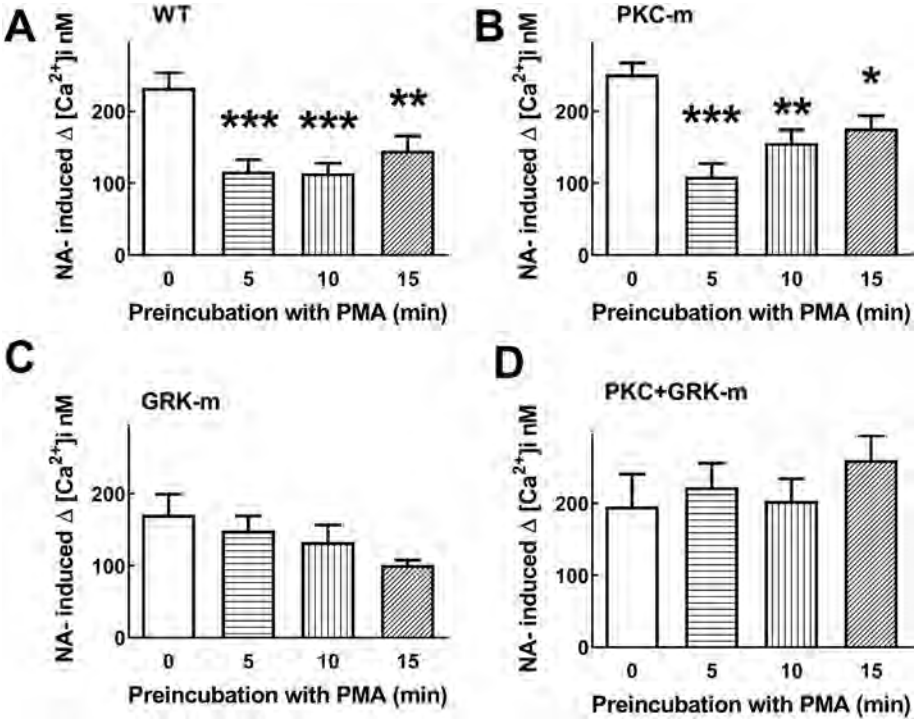

Fig. 2. Effect of PMA on NA-induced calcium response in cells expressing α_{1B}-AR mutants. Cells were preincubated for the times indicated in the presence of 1 μM PMA and then they were challenged with 10 μM NA (in the presence of propranolol). Plotted are the maximal increases in free calcium concentration as the means ± S.E.M. of 6–7 experiments using different cell preparations. ***$p < 0.001$ vs. respective time 0; **$p < 0.005$ vs. respective time 0; *$p < 0.05$ vs. respective time 0. Other indications as in Fig. 1.

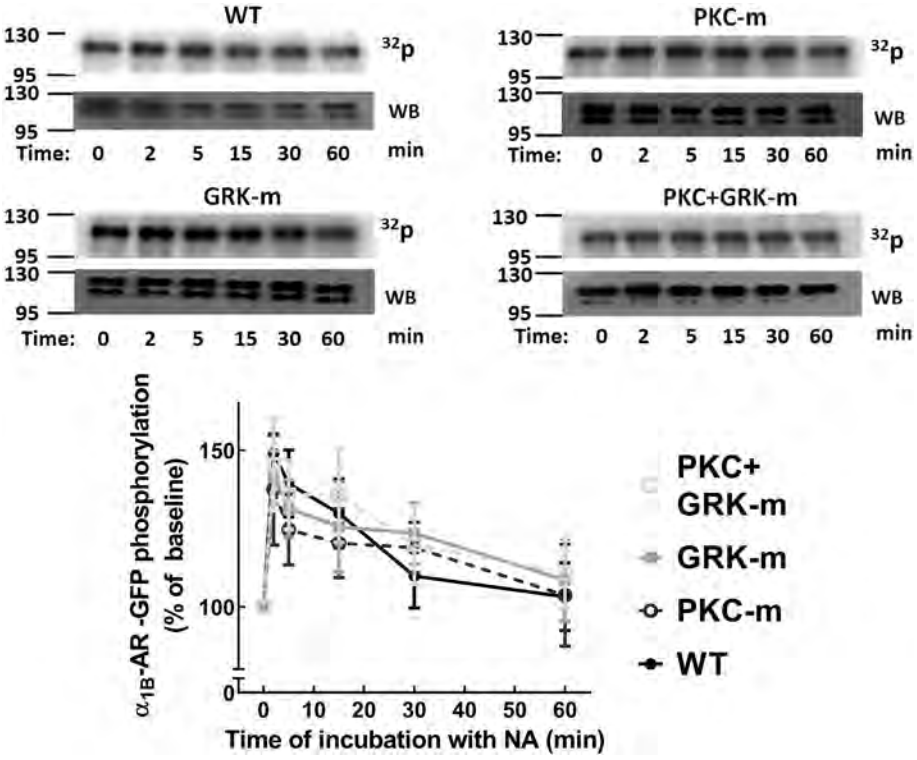

Fig. 3. Effect of NA on α_{1B}-AR phosphorylation. Cells were challenged with 10 μM NA (in the presence of propranolol) for the times indicated and receptor phosphorylation was determined. Plotted are the means ± S.E.M. of 6–9 experiments using different cell preparations. Above the graph, representative autoradiographs (^{32}P) and Western blots (WB) are shown. Other indications as in Fig. 1.

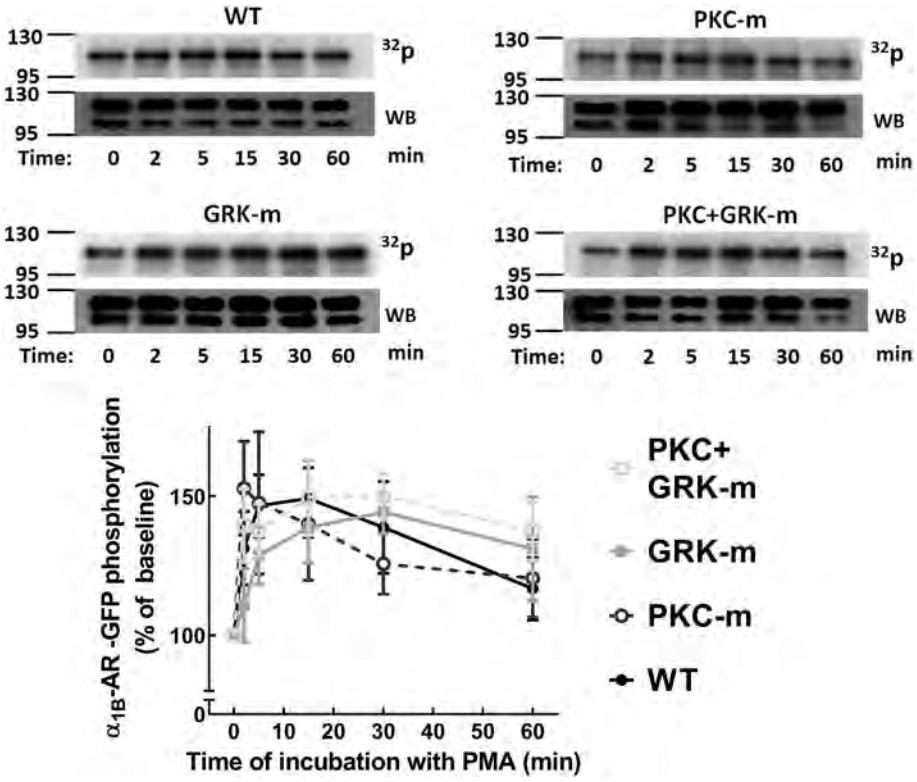

Fig. 4. Effect of PMA on α_{1B}-AR phosphorylation. Cells were challenged with 1 μM PMA for the times indicated and receptor phosphorylation was determined. Plotted are the means ± S.E.M. of 6–9 experiments using different cell preparations. Above the graph, representative autoradiographs (^{32}P) and Western blots (WB) are shown. Other indications as in Fig. 1.

NA and the effect diminished similarly (Fig. 3). In the presence of 1 μM PMA, the receptors studied, increased their phosphorylation state at 2 and 5 min, which was maintained up to 30 min, decreasing slightly afterward (60 min); when the wild-type receptor and the different mutants were compared, no statistically significant difference, was observed (Fig. 4). Nevertheless, it should be emphasized that, in these experiments, data were always normalized to the baseline phosphorylation of the receptor studied. In order to obtain a direct comparative view of the actions, cells expressing the different receptors were cultured and treated simultaneously, and samples were run using the same gels and analyzed using the baseline of the wild-type receptor as a reference (Fig. 5). These experiments evidenced that baseline phosphorylation was reduced in cells expressing the mutant receptors as compared to the wild-type even considering the relative expression,

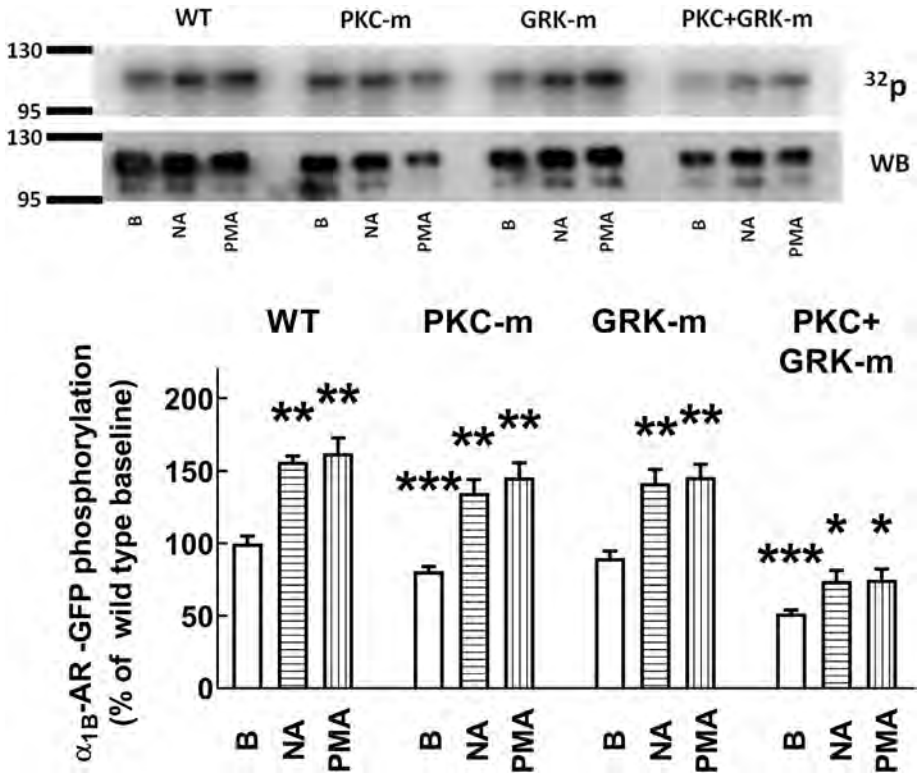

Fig. 5. Comparative α_{1B}-AR phosphorylation of the different mutants. Cells were challenged with no agent (B, baseline), 10 μM NA (plus propranolol) for 2 min, or 1 μM PMA for 15 min and receptor phosphorylation was determined. Data were normalized to the baseline phosphorylation observed in cell expressing the wild-type receptor. Plotted are the means ± S.E.M. of 10–12 experiments using different cell preparations. ***$p < 0.001$ vs. wild-type baseline (B); **$p < 0.001$ vs. respective baseline (B); *$p < 0.05$ vs. respective baseline (B). Above the graph, representative autoradiographs (^{32}P) and Western blots (WB) are shown. Other indications as in Fig. 1.

as evidenced by Western blotting, i.e., the PKC-m receptor to ~80%, the GRK-m to ~90%, and the PCK-GRK-m to ~50% of the wild-type receptor phosphorylation. These differences were reproducible and statistically significant. Similarly, decreases in phosphorylation were observed by Diviani et al. [30], which reported diminutions of 13–30% as compared to the wild-type receptor. In addition, our experiments showed that baseline and both NA- and PMA-induced phosphorylation, was present in these receptors. i.e. these mutations reduced but did not completely blocked receptor phosphorylation. Nevertheless, it should be emphasized that the phosphorylation state of the PKC + GRK-m receptor was markedly decreased, as compared to the wild-type, and that the effects of NA and PMA were reduced and were only marginally statistically significant. Work by Cotecchia and coworkers has shown that truncation of the hamster α_{1B}-AR Ctail (i.e., lacking the last 147 amino acids) nearly abolished NA- or PMA-induced receptor phosphorylation [32] as did truncation of the domain where the phosphorylation sites were detected (sites 393–414 of the hamster ortholog) [30]. The differences between our present work and those of Cottechia and coworkers [30,32] could be due to the receptor orthologs studied or to differences in the experimental conditions employed including, but not limited to, the cellular models in which the receptors were expressed, the receptor densities, and/or the conformational changes induced by the receptor modifications performed.

The effect of NA on ERK 1/2 phosphorylation was also studied. It can be observed in Fig. 6, that when cells expressing the wild-type human α_{1B}-AR were stimulated by the agonist, ERK phosphorylation increased very rapidly (i.e., maximal phosphorylation was observed at 2 min; the earliest time of determination), which progressively decreased after 15, 30 and 60 min of incubation with the agonist (Fig. 6). Interestingly, the initial response was nearly identical in cells expressing the different receptors; however, ERK 1/2 phosphorylation decreased at a much slower rate in cells with the different mutants as compared to those expressing the wild-type receptor (Fig. 6). This difference was statistically significant (at 30 and 60 min), when the response of cells with the distinct mutants were compared to those expressing the wild-type receptor. These flatter decreases are consistent with the idea that the different mutants reduce receptor turn off. It is possible that such differences could be related to changes in receptor trafficking/internalization [50]. A similar pattern was observed in cell expressing α_{1D}-AR mutants; i.e., NA-induced ERK phosphorylation decreased at a slower rate in cells expressing receptors with Ctail S/A substitutions than in those with unmodified carboxyl terminus [7,20].

The former data revealed that the modifications made to the human α_{1B}-AR mimicked some of the functional effects observed with the mutated hamster ortholog [30], but that remaining baseline, NA- and PMA-stimulated human α_{1B}-AR phosphorylation continued to be observed. Some remaining phosphorylation was also detected in the experiments using the hamster receptor [30]. Therefore, as a second step in our research, we decided to directly explore the phosphorylation sites directly present in human α_{1B}-AR under three different conditions: baseline, activation with 10 μM NA (in the presence of propranolol), or 1 μM PMA; cells were stimulated for 15 min on the basis of the previous experiments. To accomplish this, we performed receptor immunopurification experiments using a protocol similar to those employed previously to study the α_{1A}- and α_{1D}-AR [7,19,20], as described in Materials and Methods. In immunopurification studies for mass spectrometry analysis, two bands in the 110–100 kDa region were present in the Coomassie blue-stained gels which were identified as the α_{1B}-AR-eGFP construct by Western blotting using a primary antibody against the eGFP (Fig. 7). This is consistent with what was observed in the receptor phosphorylation experiments, using metabolic labeling with [^{32}P]Pi.

Mass spectrometry analysis of the immunopurified bands, obtained from four independent experiments, revealed peptides corresponding to 67% of the IL3 and 74% of the Ctail α_{1B}-AR sequences (Supplementary Fig. S5). The detected α_{1B}-AR phosphorylation sites present, under the different experimental conditions, are shown in Fig. 8, which includes the following: prediction in silico, amino acid number and peptide sequence in which it was detected, and domain localization. α_{1B}-AR phosphorylation is quite strong under baseline conditions [23,29–32,51–53] and a large number of amino acid residues present at the IL3 and also at the Ctail were phosphorylated under baseline/

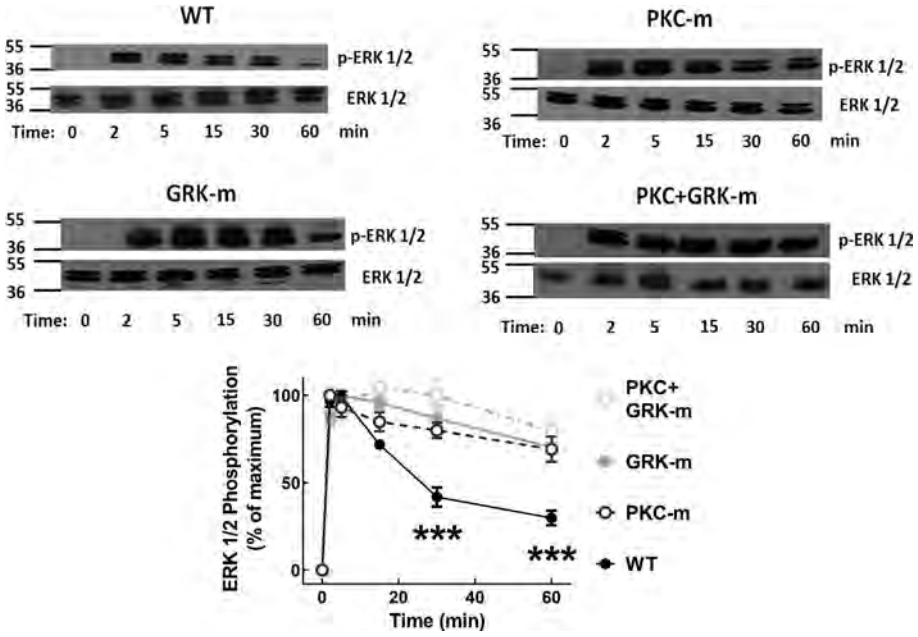

Fig. 6. Effect of NA on ERK 1/2 phosphorylation. Cells were challenged with 10 μM NA (in the presence of propranolol) for the times indicated and ERK 1/2 phosphorylation was determined. Plotted are the means ± S.E.M. of 6–8 experiments using different cell preparations. Above the graph, representative phospho-ERK 1/2 (p-ERK 1/2) and total ERK 1/2 (ERK 1/2) Western blots are shown. ***$p < 0.001$ vs. the different mutants. Other indications as in Fig. 1.

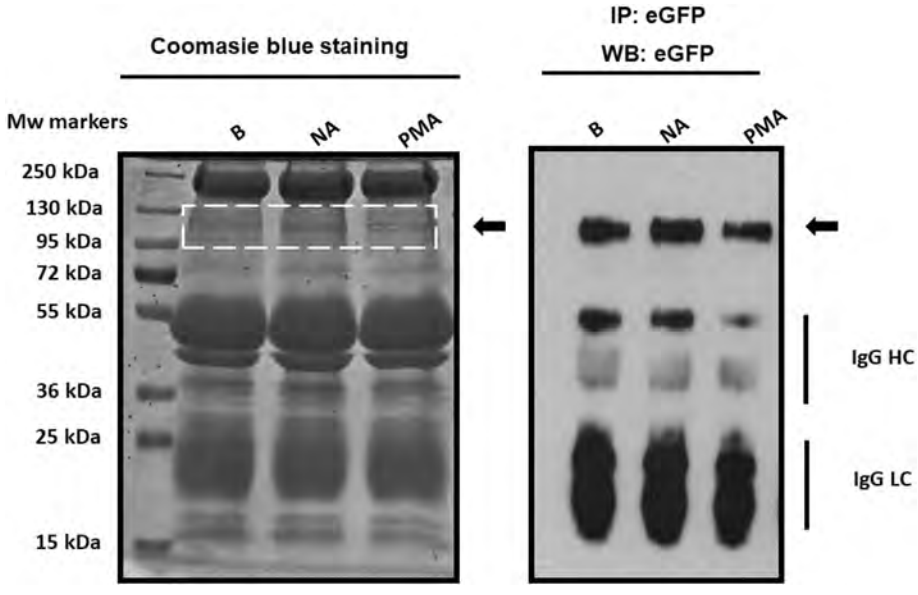
unstimulated conditions (Fig. 8, panels A and B). Interestingly, some of these residues were not found phosphorylated under stimulation by NA or PMA; these include S248, S268, T420, and T475 (Fig. 8, panels A and B). Some amino acids were detected phosphorylated only in response to NA and include: S246, S277, S396, S400, S402, and S406. Residues phosphorylated in response to PMA include T387 and T392 whereas S267 and S425 were found phosphorylated under both baseline and PMA-stimulated conditions (Fig. 8, panels A and B). Other residues were detected phosphorylated under all studied conditions (baseline, NA- and PMA-stimulated) including: T252, S257, T264, S423, S427, S455, and S470 (Fig. 8, panel A and B). Other phosphorylation sites were detected but their Ascore value [45] was low. It should be mentioned, that the mass spectrometry method employed in this study is only qualitative and therefore, we cannot estimate the proportion/relative magnitude of receptors phosphorylated in a given residue. Phospho-amino acid analysis of experiment using the hamster ortholog have not detected p-tyrosine and either only p-serine (COS-7 cells) [30] or marked signal of phospho-serine with clear traces of p-threonine (Rat-1 fibroblasts) [29]. This latter finding is consistent with our present data, in which some threonine residues were detected phosphorylated. This difference could be due to the cell system model employed for receptor expression, as this has been shown with muscarinic receptors and which seems to be of great importance in defining the so-called phosphorylation bar-code and its functional consequences [12].

The putative protein kinases involved in these phosphorylations were explored using the Group-based Prediction System, GPS 2.0. As it could have been anticipated on the bases of the previous work on this receptor [30,31], in many cases, several kinases, including members of the GRK and PKC families, were able to phosphorylate these sites (Supplementary Table 1); other protein kinases, such as PKA, AKT, GSK3, PDK-1, and p38, were also identified in the protein kinase prediction analysis (Supplementary Table S1).

Sequence alignment of the IL3 and Ctail domains of the α_{1B}-ARs of different species was subsequently performed (Supplementary Fig. S6). All of the phosphorylation sites were conserved among these orthologs. In contrast, when these domains of human α_{1A}-, α_{1B}- and α_{1D}-AR subtypes, were aligned, none of the identified phosphorylation sites were conserved among these three different subtypes and only a few



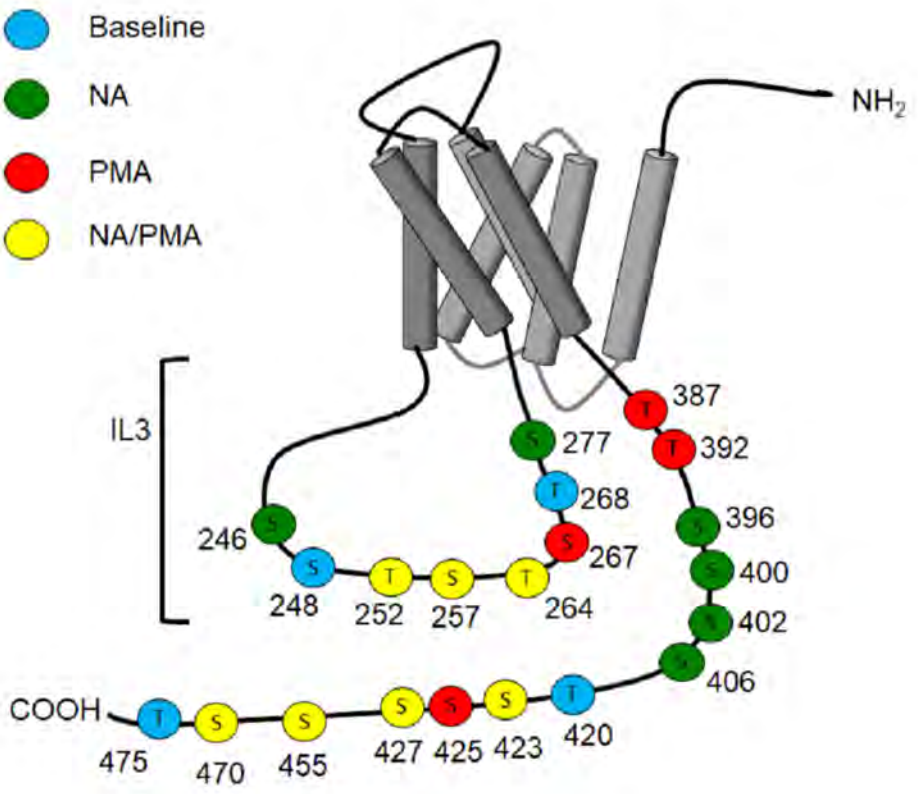


Fig. 7. Representative α_{1B}-AR immunopurification samples employed for the mass spectrometry studies. Cells expressing the α_{1B}-AR-eGFP construct were treated with: no agent (baseline, B), 10 μM NA (and propranolol), or 1 μM PMA, for 15 min; subsequently were lysed and subjected to immunopurification as described under Material and Methods. Samples were separated by SDS-polyacrylamide gel electrophoresis and stained with Coomassie blue (left image); molecular weight markers are shown in the first lane and their Mr is indicated. A small aliquot was also subjected to electrophoresis, and the gel was electrotransferred onto a nitrocellulose membrane. Western blotting was performed using anti-GPF antibodies. The arrows indicate α_{1B}-AR-eGFP localization. Bands corresponding to IgG HC (heavy chains) and LC (light chains) are also indicated.

INFORME DE LABORES 2019

Fig. 8. Phosphorylation sites detected by mass spectrometry in samples of the wild-type α_{1B}-AR-eGFP construct. Panel A. Diagram of the wild-type α_{1B}-AR indicating the observed phosphorylation sites under the different conditions employed. Numbers indicate the residue sequence position, and letters identify the amino acid. Blue (B, baseline); green (NA + propranolol) sites only observed phosphorylated in samples from cells incubated with noradrenaline; red (PMA) sites only observed in samples from cells incubated with phorbol myristate acetate; and yellow (NA/PMA) sites observed phosphorylated in cells incubated with either NA or PMA. IL3, intracellular loop 3. Panel B, α_{1B}-AR phosphorylated peptides detected by mass spectrometry. The first column indicates whether the site phosphorylated was or was not predicted by in silico analysis. The second and third columns indicate the amino acid detected and its position in the receptor's sequence. The next columns show the phosphopeptides detected and their domain location. The last column shows the cell-incubation conditions under which the modifications were detected, marked with the same color code employed in panel A.

were conserved between two of them (Supplementary Fig. S7).

Supplementary Fig. S8 presents comparative models of the human α_{1B}-AR putative phosphorylation sites (extrapolated from the mutational/functional data obtained with the human ortholog [30]) and the actual phosphorylation sites detected by mass spectroscopy. As can be observed, three of the sites were confirmed by the present data and a much more complex phosphorylation pattern was detected. Supplementary Fig. S9, presents models of the three human α_1-AR with the phosphorylation patterns observed by mass spectrometry; these were obtained using the same cell-expression model and similar receptor constructions (i.e., receptors fused at the Ctail with the eGFP).

The pioneer work of Diviani, Lattion and Cotecchia [30] performed > 20 years ago, using mutagenesis and deletions in parallel with functional studies, defined a cluster of five serines as the major phosphorylation sites of the hamster α_{1B}-AR. Methodological advances over the past years allow now direct identification of phosphorylated sites. In the present work, we detected S396, S402 and S406 as phosphorylated, which correspond to three of the sites detected in the hamster receptor (Supplementary Fig. S8). The former two correspond to residues assigned as targets for PKC [30] and the kinase prediction performed is consistent with such an assignment (Supplementary Table S1). The third site, S406, was assigned as a GRK target [30]; however, kinase prediction failed to detect it as such, despite its being surrounded by acidic residues, suggesting the possible roles of other kinases (Supplementary Table S1). The remaining two serines, defined for hamster α_{1B}-AR (i.e., S410 and S412 in the human receptor), were covered by the mass spectrometry analysis (Supplementary Fig. S5) but no phosphorylation was detected. A series of possibilities might explain this, as follows: it could due to the conformation of the human receptor ortholog, as due to availability or accessibility to GRK (namely GRK2 and GRK3 [30]); restrictions imposed by the eGFP tag, and/or the possibility that those (phospho)-ester bonds could be unstable during the mass spectrometry analysis, among others. In any case, the data obtained with the hamster receptor and the present findings define S396, S402, and S406 as major phosphorylation targets in the α_{1B}-AR of humans, hamsters, and likely, other species (Supplementary Fig. S6).

It is noteworthy that it has been observed that at least two domains at the hamster α_{1B}-AR Ctail of the, one including amino acids 403–425 and another in the 367–380 region, appear to play roles in internalization/down-regulation [35]. No phosphorylation was detected in the region corresponding to amino acids 367–380 of hamster α_{1B}-AR. However, in the region corresponding to the first domain, we detected phosphorylated S406, T420, S423, and S425. We have previously observed that human α_{1B}-AR internalize through different processes, i.e., processes involving interaction with different Rab proteins when stimulated by NA, or through the physiological or pharmacological activation of PKC [54,55]. It is possible that the phosphorylated sites might play a role in internalization/down-regulation, but this remains to be experimentally tested.

Detection of phosphorylated residues at the human α_{1B}-AR IL3 was unexpected, because it has been observed that deletion of the hamster Ctail or of the serine cluster (Δ 393–413) in this domain, nearly abolished receptor phosphorylation [30]. Consistent with this, work from our laboratory has shown, using Rat-1 fibroblast as expression model, that hamster α_{1B}-AR are markedly phosphorylated under baseline, NA- or PMA-stimulated conditions, whereas bovine α_{1A}-AR is also phosphorylated, but to a much lesser degree [53]. Swapping the Ctail of these receptors demonstrated that this domain of the α_{1B}-AR comprises the main phosphorylation target, and that the intense phosphorylation pattern can be transplanted to the α_{1A}-AR [53,56] (although little correlation between receptor phosphorylation and function was detected [56]). It is possible that the three phosphorylated sites detected are those predominantly phosphorylated but that overexpression and strong stimulation, required to obtain significant signal in the mass spectrometry experiments, might permit detection of residues that under other conditions might be phosphorylated to a much lesser extent. However, significant α_{1B}-AR phosphorylation was observed in mutants with S/A substitutions (Figs. 3–6). It is also of interest that our studies on the three human α_1-AR ([7,19,20] and the present work) showed phosphorylation at both the IL3 and Ctail domains (Supplementary Fig. S9), although such sites were poorly conserved (Supplementary Fig. S7).

The complexity of the phosphorylation patterns of the human α_1-AR hampers the possibility of studying the functional significance of the different sites. Recently we obtained evidence that sites at the human α_{1D}-AR Ctail might control the plasma membrane location of this receptor subtype [7]. Similarly, in a recent and elegant study, Strakova and coworkers [8] reported that casein kinase 1-mediated phosphorylation of the Frizzled 6 receptor is required for its plasma membrane localization and that this contributes to its asymmetric distribution in epithelial cells. Our present work provides further evidence that three serine residues are important in human α_{1B}-AR phosphorylation and suggests that phosphorylation patterns are much more complex than previously anticipated. Receptor phosphorylation is an intricate process that takes place within space-temporal dimensions and, very likely, our phosphorylation data represent just a “frame” within the large “picture”. The fact that some sites were detected phosphorylated under baseline conditions, but not when stimulated (Fig. 8), suggest to us that, during cell activation, the action of different protein kinases and phosphatases might take place, and this could occur in a very dynamic manner, with different receptor phosphorylation patterns, coexisting at distinct times and receptor's cellular localizations. In addition, there is evidence showing that phosphorylated β_2-adrenoceptor subpopulations (i.e., receptors phosphorylated at different sites) could be present simultaneously in a single cell; these might be present in different subcellular compartments and subserve in different functions [57]. It is likely, therefore, that the phosphorylation pattern we observed might be the addition of a series of different states present in the cells.

Declaration of Competing Interest

All authors declare no conflict of interest.

Acknowledgments

The authors thank Dr. Myron L. Toews for reading and commenting on the manuscript. They also thank Drs. Steven C. Prinster and Myron L. Toews for allowing us access to unpublished data on internalization and down-regulation of α_{1B}-AR. The advice of Ross Tomaino, Associate Director of the Taplin Mass Spectrometry Facility (Harvard Medical School, USA) was very important for the development of this work, and it is gratefully acknowledged. The authors express their gratitude for advice and technical support to Dr. Maria Teresa Romero-Ávila from our laboratory and the following members of the indicated Service Units of our Institute: Dr. Héctor Malagón and Dr. Claudia Rivera (Bioterio); Juan Barbosa and Gerardo Coello (Cómputo); and Aurey Hernández and Manuel Ortín (Taller) for their advice and technical support. David A. Hernández-Espinosa is a doctoral student from Programa de Doctorado en Ciencias Bioquímicas, Universidad Nacional Autónoma de México, and was the recipient of a doctoral fellowship (CVU: 706381) from Consejo Nacional de Ciencia y Tecnología (CONACyT).

Appendix A. Supplementary data

Role of NADPH oxidase-2 in the progression of the inflammatory response secondary to striatum excitotoxic damage

Diego Rolando Hernández-Espinosa, Lourdes Massieu, Teresa Montiel and Julio Morán*

Abstract

Background: During excitotoxic damage, neuronal death results from the increase in intracellular calcium, the induction of oxidative stress, and a subsequent inflammatory response. NADPH oxidases (NOX) are relevant sources of reactive oxygen species (ROS) during excitotoxic damage. NADPH oxidase-2 (NOX-2) has been particularly related to neuronal damage and death, as well as to the resolution of the subsequent inflammatory response. As ROS are crucial components of the regulation of inflammatory response, in this work, we evaluated the role of NOX-2 in the progression of inflammation resulting from glutamate-induced excitotoxic damage of the striatum in an in vivo model.

Methods: The striata of wild-type C57BL/6 J and NOX-2 KO mice (gp91$^{Cybbtm1Din/J}$) were stereotactically injected with monosodium glutamate either alone or in combination with IL-4 or IL-10. The damage was evaluated in histological sections stained with cresyl violet and Fluoro-Jade B. The enzymatic activity of caspase-3 and NOX were also measured. Additionally, the cytokine profile was identified by ELISA and motor activity was verified by the tests of the cylinder, the adhesive tape removal, and the inverted grid.

Results: Our results show a neuroprotective effect in mice with a genetic inhibition of NOX-2, which is partially due to a differential response to excitotoxic damage, characterized by the production of anti-inflammatory cytokines. In NOX-2 KO animals, the excitotoxic condition increased the production of interleukin-4, which could contribute to the production of interleukin-10 that decreased neuronal apoptotic death and the magnitude of striatal injury. Treatment with interleukin-4 and interleukin-10 protected from excitotoxic damage in wild-type animals.

Conclusions: The release of proinflammatory cytokines during the excitotoxic event promotes an additional apoptotic death of neurons that survived the initial damage. During the subsequent inflammatory response to excitotoxic damage, ROS generated by NOX-2 play a decisive role in the extension of the lesion and consequently in the severity of the functional compromise, probably by regulating the anti-inflammatory cytokines production.

Background

During excitotoxic damage, neuronal death produced by the overstimulation of the glutamate receptors is determined by several factors, including the increase of intracellular calcium [1], reactive oxygen species (ROS) production [2], microglia activation, and inflammatory responses [3]. Among these factors, the increase in ROS contributes significantly to the subsequent inflammatory process [4]. This condition has implications not only at the onset of damage, but also during the progression of the neuronal death [5].

Although the mitochondria have been classically considered as the main source of ROS [6], the relevance of other sources of ROS such as the NADPH oxidases family (NOX), which are widely distributed in all the studied species and are present in basically all the cell types evaluated, has gained great importance as mediators of excitotoxic damage [7]. In this regard, the genetic or pharmacological inhibition of NOX activity constitutes a neuroprotective condition in several pathologies involving excitotoxicity, such as hypoxia, hypoglycemia, and neuroinflammation [8–10]. Among the homologs of the NOX family, NOX-2 seems to be the main responsible for the observed neuronal death in numerous models of excitotoxic damage [11, 12]. The specific inhibition of NOX-2 in neurons, astrocytes, and microglia prevents neuronal death in different experimental conditions [13, 14]. In a previous study, we observed in genetically deficient NOX-2 mice and wild-type animals treated with a NOX inhibitor that ROS production, lesion size, and microglial reactivity were markedly decreased during excitotoxic damage [13].

A large body of evidence points to neuroinflammation as a main component of most of the central nervous system (CNS) disorders, including those involving excitotoxic damage [15]. Local immune cells orchestrate a series of events in order to stimulate tissue reparation in response to cell damage [16]. Microglia activation constitutes the first line of defense against brain tissue injury [17], through the induction of a range of phenotypes from resting ramified cells to motile amoeboid microglial cells [18]. At the molecular level, a variety of pro- and anti-inflammatory mediators, including interleukins, as well as ROS, nitric oxide, and eicosanoids are produced [19]. In contrast to proinflammatory mediators that participate in neuronal death, the anti-inflammatory mediators can contribute to neuroprotective actions [20, 21].

Cytokines are pleiotropic molecules that define the characteristics and the resolution of the immune response [22]. The characteristics of the response are subordinated to the sum of the proinflammatory and anti-inflammatory stimuli in the microenvironment. TNF-α, IL-1β, IL-6, IL-8, and IL-12, among others, are considered as classic proinflammatory molecules [23–25], while TGF-β, IL-4, and IL-10 are classified as anti-inflammatory cytokines [26, 27].

A simplified classification of the polarization of microglia has been developed, and two phenotypes were proposed based on functional characteristics, the type of cytokines released, and the presence of some molecular markers [28]. The M1 phenotype refers to the classically activated macrophages, which is characterized by the expression of proinflammatory cytokines [29] and the M2 phenotype designates the alternatively activated macrophages that are related to the production of anti-inflammatory cytokines and the resolution of the process [30–32].

Although the M1/M2 concept is widely accepted, it should be noted that the new technologies and the recent data in the field have led to reconsider this classification. For example, both “M1” and “M2” markers can be simultaneously expressed in the same microglial cells or macrophages [33] and M2 cells show a wide range of functional and biochemical features [34]. Thus, the microglial/macrophage polarization seems to be a more complex process than originally described and the M1/M2 phenotypic classification has been reviewed [35, 36], and different intermediate phenotypes have been described on the basis of their functionality and the molecular markers expressed under different physiological states [35, 37].

The mechanisms mediating the inflammatory response of macrophages/microglia are not completely understood, but evidence has provided a framework to propose that ROS may shape the inflammatory response [38, 39], as well as the regulation of microglial activation [40, 41]. This is in line with the association between ROS and several microglia-driven neuropathologies [38]. On the other hand, experimental evidence suggests that microglial NOX2 is involved in neurotoxicity by both producing extracellular ROS [41] and by participating in the redox signal involved in the inflammatory response [42, 43]. For example, NOX activation by interferon and LPS results in microglial expression of iNOS and cytokines mediated by the activation of MAP kinases, NFκB, and STAT1 phosphorylation [44, 45].

It has been suggested that NOX2 plays a key role in the expression of the M1 phenotype by a mechanism mediated by IL10 and STAT3 [37, 46]. Furthermore, the lack of NOX2 leads to a M2 phenotype mediated by a downregulation of NFκB nuclear translocation in a model of TBI and diabetes [46, 47]. Thus, ROS derived from glial cells and from different sources, including NOX2, participate in the microglial activation and play a key action by defining the microglial phenotype, which may have a central role in neurotoxicity and neurodegenerative diseases [43, 45].

In this study, we evaluated the time course of cell damage, NOX activity, and production of cytokines, as well as the functional sequelae, resulting from the excitotoxic damage in an in vivo model. We also tested the

protective action of two exogenous anti-inflammatory cytokines in this model. We propose that NOX-2, besides participating in the neuronal excitotoxic damage, also regulate the production of pro- and anti-inflammatory cytokines, which results critical for the progression of the cell death.

Methods

Animals

All animals were handled according to the National Institutes of Health Guide for the Care and Use of laboratory animals (NIH Publication No. 8023, revised 1978) and the local Committee for the Care and Use of Laboratory Animals (CICUAL protocol JMA72-15). All efforts were made to minimize pain, as well as the number of animals used. Wild-type (WT) adult mice C57BL/6 (8 weeks old) were obtained from the bioterium of the Instituto de Fisiología Celular, Universidad Nacional Autónoma de México. The NOX-2 KO (gp91$^{Cybbtm1Din/J}$) adult mice generated on a C57BL/6 background were purchased from the Jackson Laboratory (Bar Harbor, ME), and the colony was established at the vivarium of the Instituto de Fisiología Celular, Universidad Nacional Autónoma de México. Mice were housed and kept under controlled temperature (20–22 °C) with a regulated 12-h light-dark cycle, with water and food ad libitum. The mice used for this study were divided as follows: 40 animals were used for histological analyses, 30 for immunoblot and enzyme activity determinations (NOX and caspase-3), and 30 for cytokine analysis.

Intrastriatal glutamate injection

C57BL/6 WT and NOX-2 KO mice were anesthetized with 3% isoflurane in a 95% O2/5% CO2 mixture and placed on a stereotaxic frame (David Kopf Instruments, Tujunga, CA). A stainless steel needle was positioned in the right striatum according to the following coordinates: anterior-posterior + 0.8 mm from bregma, lateral + 2.2 mm from midline, and vertical 3.2 mm from dura [35]. With the aid of an injection pump (model 55; Harvard, South Natick, MA), 0.5 μL of a solution of monosodium glutamate (1 M) or saline solution (0.9%) was injected (0.175 μL/min). A second (25 WT animals) and a third group (25 WT animals) of mice were treated with 0.7 ng/mL of interleukin-4 (cell signaling #5208) or 0.4 ng/mL of interleukin-10 (cell signaling #5261), respectively, in the same monosodium glutamate solution (Fig. 1). Five minutes after the injection, the needle was gently withdrawn, and the skin was sutured with nylon [48]. Mice recovered from anesthesia in a temperature-controlled chamber and were placed in individual cages with water and food ad libitum.

At different times after the surgery, animals received a lethal dose of sodium pentobarbital to subsequently extract the brain. For biochemical analyses, some animals were killed by cervical dislocation at different times (1, 6, 12, and 24 h) and striata were dissected and homogenized. To that, the olfactory bulb and cerebellum were removed from the brain and a sagittal section was made on the midline to separate the hemispheres and dissect the striate, which can be delimited as tissue slightly more transparent than the surrounding cortex [49]. The tissue obtained (15–20 mg) was homogenized in lysis buffer and protease inhibitors at 4 °C (OMNI TC homogenizer). The homogenate was centrifuged at 5000 g for 5 min to remove the cellular debris and subsequently the amount of protein was quantified [50].

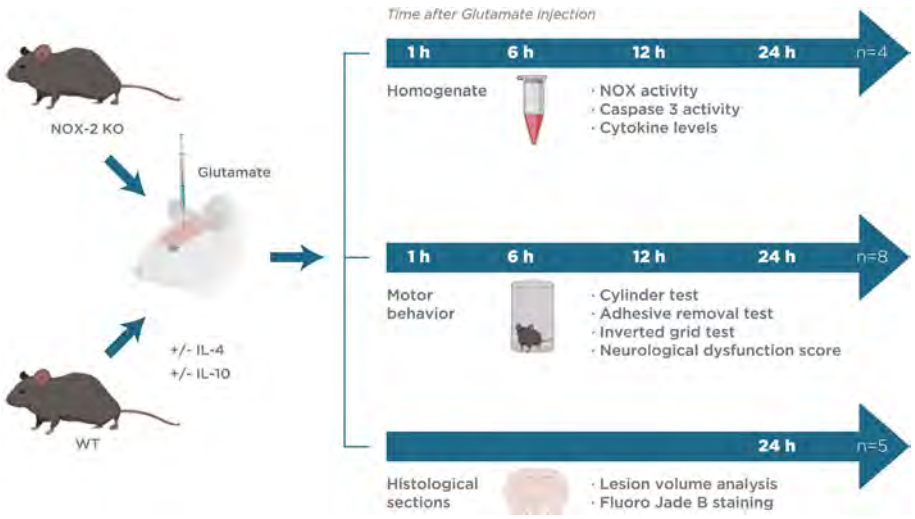

Fig. 1 Illustration of the timeline experimental design. Wild mice (WT, without treatment and treated with interleukins 4 or 10) and NOX-2 KO were administered with monosodium glutamate (1 M). Subsequently, they were sacrificed at 24 h to obtain histological sections ($n = 5$). Some animals were sacrificed at 1, 6, 12, and 24 h to obtain striatum homogenate ($n = 4$). Motor behavior tests were performed at 1, 6, 12, and 24 h in animals of both groups ($n = 8$)

Lesion volume analysis

Glutamate-induced lesions were evaluated 24 h after the surgery (Fig. 1). Mice were deeply anesthetized with sodium pentobarbital and were transcardially perfused with 30 mL of 0.9% saline solution followed by 35 mL of 4% paraformaldehyde solution in 0.1 mM phosphate buffer at pH 7.4. Brains were removed and placed in the same fixative solution at 4 °C. Consecutive series of striatal coronal sections (40 μm thick) for cresyl violet and Fluoro-Jade B (FJB; Chemicon, Temecula, CA) staining were obtained in a cryostat (1510s, Leica, Microsystems Nussloch GmbH, Heidelberger Nussloch, Germany). After staining with cresyl violet, all sections where a lesion was visible (pale cresyl violet stain) were selected for quantification of the lesion volume. The damaged areas were delineated manually and measured using an image analyzer (ImageJ 1.48v analyzer program; Wayne Rasband, NIH, USA) by an experimenter blinded to the treatments. Total lesion volume was obtained from the sum of all damaged areas multiplied by the width of the sections (40 μm).

Fluoro-Jade B staining

Briefly, one drop of 1% NaOH solution diluted in 80% ethanol was added to coronal sections mounted on slides, and after 2 min, it was replaced by a 70% ethanol solution. Slides were covered with 0.06% potassium permanganate for 10 min, and then brain sections were washed and incubated for 10 min with a 0.0004% Fluoro-Jade B (FJB) solution prepared in 0.1% acetic acid. Finally, the sections were washed, dried at 50 °C, dehydrated with xylol, and covered with Permount (Fisher Scientific, Fair Lawn, NJ). Slices were observed under an epi-fluorescence microscope (Eclipse Ti-S, Nikon instruments Inc.) using a U-MNB2 filter (395–590 nm). Total FJB-positive cells were counted as previously described using the ImageJ.1.48v analyzer program (Wayne Rasband, NIH, USA) in the entire striatum in three sections per mouse, namely, the section containing the needle tract (middle section) and the adjacent anterior and posterior sections located 160 μm away from the middle section [48].

NOX activity

NOX activity was determined in striatal homogenates at different times (0.5, 1, 3, 6, 12, and 24 h) after glutamate administration (Fig. 1). NOX activity was estimated as the oxidation of dihydroethidium (DHE) to ethidium (Et) [48]. Briefly, tissue homogenates were incubated with 0.02 mM DHE, 0.5 mg/mL salmon DNA, and 0.2 mM NADPH as substrate. Et fluorescence was measured during 30 min at an excitation wavelength of 480 nm and emission of 610 nm using a Synergy HT Multi-Detection fluorescence microplate reader (Biotek Instruments, Colchester, VT). Duplicate samples were prepared, and NOX activity was expressed as the change in Et fluorescence per milligram protein per minute versus control (saline). Some samples were incubated in the presence of 1 μM of the NOX inhibitor diphenyleneiodonium (DPI; Sigma) or 15 UI of superoxide dismutase (SOD, Sigma) to corroborate the specificity of the assay.

Immunoblot

Tissue homogenates (50 μg protein per lane) were subjected to SDS–PAGE. The resolved proteins were transferred to PVDF membranes at 120 V for 1 h. The membranes were blocked overnight with 5% nonfat dry milk in TBS and treated, overnight at 4 °C, with anti-NOX2/gp91phox (1:500; ab80508, Abcam, USA) and anti-GAPDH (1:3000; 14C10, Cell signaling, USA) antibodies. After further washing, the blots were incubated with alkaline phosphatase-conjugated secondary antibody (1:10000) for 1 h at room temperature. Bands were visualized by using the enhanced chemiluminescence system according to the manufacturer's recommendations (Bio-Rad Laboratories, Hercules, CA) and exposed to Kodak XAR-5 film.

Caspase-3 activity

Caspase-3 activity was determined in striatal homogenates at different times (1, 3, 6, 12, and 24 h) after glutamate administration (Fig. 1). Caspase-3 activity was assayed by a fluorogenic technique [51] in a luminescence spectrometer (Shimadzu, RF-5301PC), using the peptide Ac-VDVAD-AMC as a substrate to detect the proteolytic activity. Caspase activity was followed 30 min after addition of substrate (80 μM) and tissue homogenate (50 μg/mL) in a standard solution. Results depicting caspase activity were calculated as the change in fluorescence intensity per milligram protein per minute and expressed as fold change versus control (saline).

Cytokine levels

Cytokine levels were measured using the mouse ultrasensitive ELISA kit assay for IL-1β (ab100704), IL-4 (ab100710), IL-6 (Abcam, ab100712), IL-10 (ab46103), IL-12 p40/70 (100699), TNF-α (100747), and TGF-β (119557). The tissue samples, corresponding to 100 μg of striatal protein (diluted 1:10), were obtained after different times (1, 3, 6, 12, and 24 h) of glutamate administration (Fig. 1) and were used for cytokines measurement according to the manufacturer's protocol (Abcam, MA, USA). Assays were carried out in a colorimetric spectrometer (Shimadzu, RF-5301PC). The results were calculated based on a concentration curve provided by the manufacturer and were expressed as picograms of cytokine per milligrams of protein.

Cylinder test of forelimb asymmetry

Animals were examined for preferential use of the unilateral forelimb during upright postural support before and after glutamate administration (Fig. 1). Briefly, mice were placed in a pyro-glass cylinder (10 cm in diameter) on a tabletop and video-recorded for 3 min. The number of unilateral and bilateral wall contacts was recorded. The percentage of bilateral contacts was assessed on each test using the formula 100 × bilateral contacts/total forelimb wall contacts, whereas the percentage of unilateral contacts was assessed using the formula 100 × unilateral contacts/total forelimb wall contacts. The results are expressed as the percent of unilateral exploration [52].

Adhesive removal test

The animal cage was placed in the testing room at least 30 min before starting the experiment to allow habituation to the new environment. Animals were gently removed from the testing box and an adhesive tape strip (0.2-in. square) was placed on the snout (dorsal portion). Animals were returned to the testing cage and a timer was set. Conduct was observed and recorded for 60 s or until the piece of tape was removed with the forelimb. Training consisted of five trials (one per day), and testing after glutamate administration at different times (1, 3, 6, 12, and 24 h) was carried out (Fig. 1). Result indicated the latency to adhesive tape removal in seconds [53].

Inverted grid test

The inverted grid test was used to assess coordination and limbs muscular strength, especially related to distal musculature and digit manipulations. Mice were placed in the center of a horizontal square (15 cm^2) grid consisting of a wire mesh (0.5 cm^2) surrounded by wooden walls. The grid was placed 20 cm above a tabletop and was rotated upside down allowing mice to move freely. Each mouse was recorded for 60 s. The time the mice remained and moved upside down was recorded. If a mouse fell from the mesh grid within 10 s, additional trials were allowed (max three trials) within an interval of 1 min, in this case, latencies before falling were measured. The means ± standard error of the mean (SEM) of three trials were calculated. No pretraining was performed, but a pretest of 30 s before the day of the experiment was carried out for habituation [53].

Neurological dysfunction score

All behavioral tests were conducted by the same experimenter in a quiet and low-lit room with white noise background. Pretests were conducted to exclude abnormally behaving animals. A combination score from a battery of three behavioral tests (adhesive test, inverted grip test, and cylinder test) was used to measure the neurological functional deficits (ND). We determined the grand NDs score (NDS) by combining all the tests, assuming an equal weight of each of the tests and assigning a value of 15 points to the maximum performance [53, 54].

Statistical analysis

Data were analyzed as means ± SEM. The data were evaluated statistically by the two-way analysis of variance (ANOVA) for biochemical and histological tests and repeated measures ANOVA for behavioral tests, followed by Tukey's test for pairwise comparisons by using GraphPad Prism v6.0 and SigmaPlot 12.3 software. In the case of significance, a further ad hoc two-tailed Student's t test was applied. Significance was considered when $p < 0.05$.

Results

Striatal excitotoxic lesion and neuronal degeneration are minor in NOX-2 KO mice

To determine the impact of excitotoxic damage, both lesion volume and neuronal degeneration were evaluated in WT and NOX-2 KO mice as detailed in the "Methods" section. Representative tissue sections from WT and NOX-2 KO animals stained with cresyl violet are shown in Fig. 2a. WT and NOX2 KO mice treatment with saline, as a control of the procedure, developed a small lesion similar in both groups (0.05 ± 0.02 mm^3 and 0.03 ± 0.01 mm^3, respectively). As it was expected, in the groups treated with glutamate, NOX-2 KO mice showed only 38% of the lesion observed in WT mice (WT, 1.2 ± 0.14 mm^3 vs NOX-2 KO, 0.45 ± 0.10 mm^3 $p < 0.05$; Fig. 2b).

The FJB-positive cells were counted in tissue sections 24 h after glutamate injection (Fig. 2c). Again, a higher number of degenerated cells were found in WT mice injected with glutamate (82.3 ± 11.1 cells/mm^2) than in saline-injected animals (3.06 ± 0.6 cells/mm^2; $p < 0.05$). In accordance to the tissue lesion measurements, the number of FJB-positive cells in NOX-2 KO mice (35.9 ± 7.5 cells/mm^2; $p < 0.05$) were about half of that observed in WT mice treated with glutamate. Representative tissue sections from WT and NOX-2 KO animals showing FJB-labeled cells are shown in Fig. 2a. Together, these results confirm that NOX-2 participates in the tissue injury and neuronal degeneration induced by glutamate.

NOX-2 activity increases during excitotoxic damage

In the present study, we measured NOX activity in striatal homogenates of WT and NOX-2 KO mice at different times after glutamate injection (0.5, 1, 3, 6, 12, and 24 h). An increase in the enzyme activity over saline (control) levels was detected at 1 h after glutamate administration in WT mice (225 ± 27% vs control, $p < 0.05$;

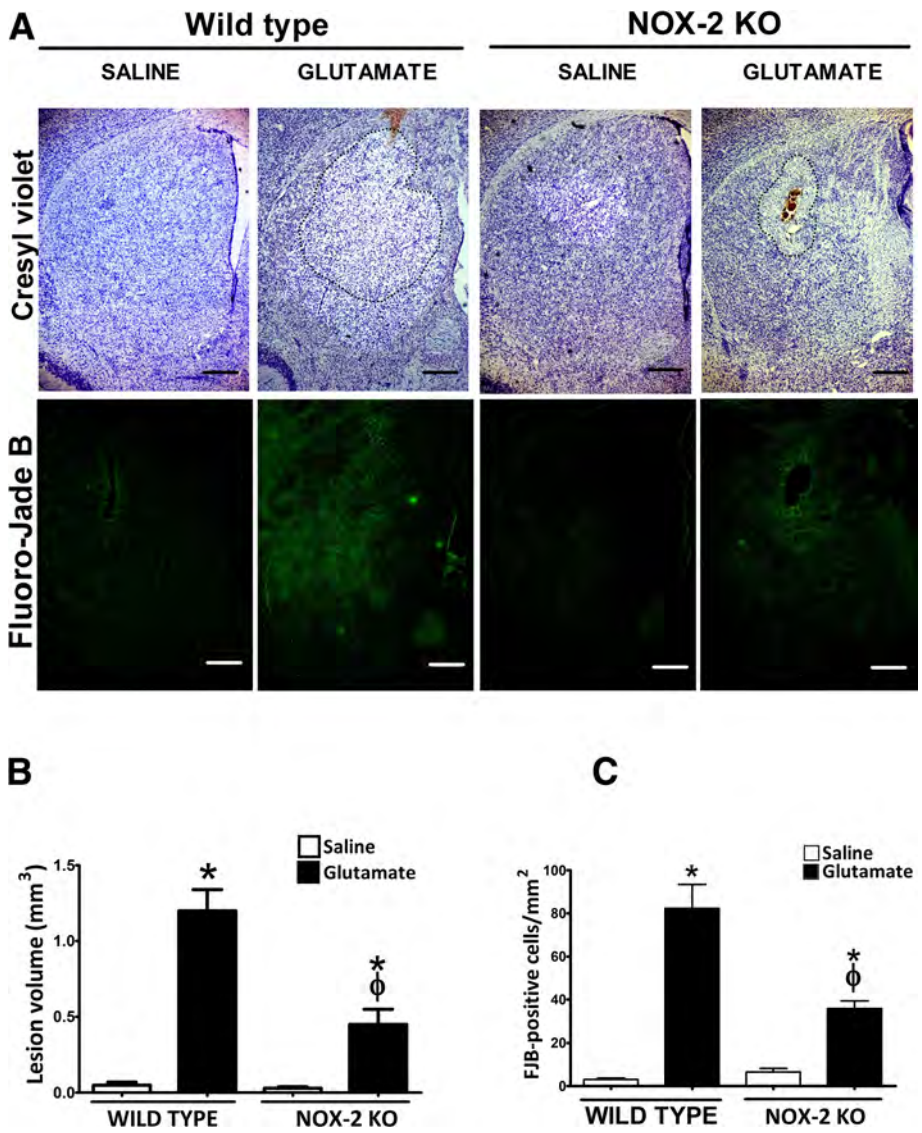

Fig. 2 Lesion area and neuronal degeneration in wild-type and NOX-2 KO mice injected with glutamate in the striatum. Histological sections were obtained after 24 h of intracerebral administration of saline (NaCl 0.9%) or glutamate (1 M) as detailed in the "Methods" section. **a** Representative micrographs of coronal striatal sections showing striatal lesions stained with cresyl violet and damaged cells positive to Fluoro-Jade B. The dotted line delimits the area of lesion of mice treated with glutamate. The scale bars represent 200 μm. **b** Quantification of the lesion volume 24 h after saline or glutamate injection is expressed in cubic millimeters. **c** Total number of FJB-positive cells counted in three slices per mice. Data are expressed as means ± SEM of five independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\varphi}p < 0.05$ vs wild-type mouse (WT) treated with glutamate

Fig. 3). Although the NOX activity remained increased during 24 h, we observed two peaks of activation, the first 1 h after glutamate injection (130 ± 15% vs control) and the second after 12 h (195 ± 10% vs control). The increase of NOX activity in NOX-2 KO mice after glutamate administration was more discrete and about half of that in WT mice at 12 and 24 h ($p < 0.05$). These results indicate that the administration of glutamate leads to an early and a late activation of NOX during the excitotoxic damage and that this activation is attenuated in NOX-2 KO animals.

We found that NOX2 protein was upregulated by glutamate treatment in a time-dependent manner. The protein levels increased from 6 h and continued increasing after 12 and 24 h (Additional file 1: Figure S1). The observed changes in protein levels did not correlate with the observed changes in NOX activity. For example, at 1 h no change in the protein was observed, while a large increase in NOX activity occurred (Fig. 3 and Additional file 1: Figure S1). This suggests that the observed changes in NOX activity are regulated by other conditions than protein enrichment.

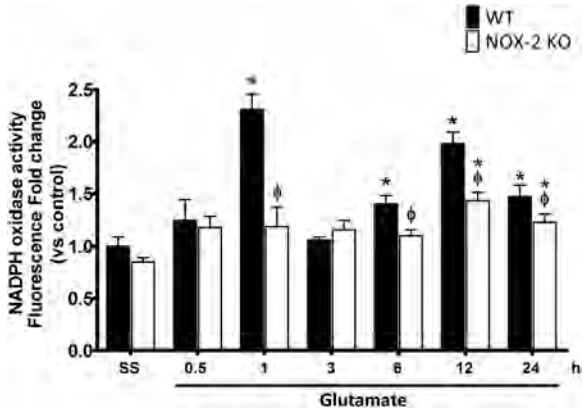

Fig. 3 NOX-2 activity during excitotoxic damage in wild-type and NOX-2 KO mice. NOX activity was evaluated as the change of fluorescence intensity resulting from dihydroethidium (DHE) oxidation to ethidium (Et) in striatum homogenates of WT and NOX-2 KO mice treated with glutamate (1 M) 0.5, 1, 3, 6, 12, and 24 h after glutamate administration. Data are expressed as fold change of Et fluorescence relative to WT saline. Values are means ± SEM of four independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\varphi}p < 0.05$ vs the corresponding wild-type mouse (WT) treated with glutamate

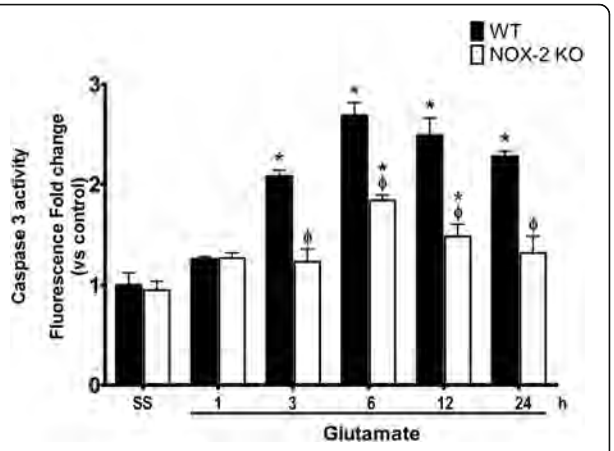

Fig. 4 Caspase-3 activity in wild-type mice and NOX-2 KO after administration of glutamate. Active caspase-3 was measured in striatum homogenates after 1, 3, 6, 12, and 24 h of glutamate (1 M) administration in WT and NOX-2 KO mice. Fluorescence produced by the cleavage of the specific substrate for caspase-3 was quantified in relative units of fluorescence (FRU) and the results are expressed as the fluorescence fold change relative to WT saline. Values are mean ± SEM of three independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\varphi}p < 0.05$ vs corresponding wild-type mouse (WT) treated with glutamate

NOX-2 KO mice resistance to excitotoxic damage involves a decrease in caspase-3 activation

Intrastriatal injection of glutamate causes an increase of caspase-3 activation at 3 h after glutamate administration in WT (208 ± 9% vs control) and after 6 h in NOX-2 KO mice (197 ± 16% vs control). We found that after 6 h, caspase-3 activation was lower in NOX-2 KO ($p < 0.05$) as compared to WT mice (NOX-2 KO 180 ± 10% vs WT 280 ± 25%, $p < 0.05$), and the same effect is observed during the following 24 h (NOX-2 KO 57 ± 15% vs WT 128 ± 9%, $p < 0.05$; Fig. 4). Thus, NOX-2 KO mice exhibit a lower activation of caspase-3 during excitotoxic injury induced by the administration of glutamate.

NOX-2 KO mice exhibit better motor recovery than wild-type mice after excitotoxic damage

Striatum lesions lead to alterations in the control of voluntary movements and muscle tone, predominantly in the forelimbs [53]. We therefore explored the degree of functional compromise resulting from the excitotoxic damage as an index of striatal injury. To assign a neurological deficit score (NDS), we evaluated three tests in WT and NOX-2 KO mice to obtain a motor score (Fig. 5).

The cylinder test indicates the latency of forelimb asymmetry (Fig. 5a). Prior to glutamate administration, WT and NOX-2 KO mice tended to preferentially make bilateral wall contacts in the cylinder before glutamate administration (WT 10 ± 3% and NOX-2 KO 8 ± 2% of unilateral contacts). Excitotoxic damage in WT mice resulted in an early and sustained decrease in bilateral contacts from 1 h (90 ± 5% unilateral contacts) to 24 h (50 ± 4% unilateral contacts). NOX-2 KO mice show a similar compromised motor function that WT mice at 1 h (78 ± 6% unilateral contacts; $p < 0.05$), but despite the fact that they exhibited a severe decline at short time, they managed to recover at 24 h (18 ± 8% unilateral contacts), unlike the WT, which do not reach control levels ($p > 0.05$; Fig. 5a).

The adhesive removal test evaluates the control of voluntary movements (Fig. 5b). Prior to administration of glutamate, both WT and NOX-2 KO mice took a maximum of 14 s to remove the adhesive (WT 12 ± 2 s and NOX-2 KO 10 ± 2 s). After 1 h of glutamate administration, WT mice were unable to remove the label before 60 s. After 24 h, WT mice showed an improvement in the ability to remove the label; however, the time to removal was markedly higher than that shown by the saline controls (WT + GLU 37 ± 5 s vs WT + SS 11 ± 3 s, $p < 0.05$). NOX-2 KO mice had a similar performance to that shown by the WT mice after 1 h (WT 55 ± 5 s vs NOX-2 KO 50 ± 7 s, $p > 0.05$). However, at 6 h, the NOX-2 KO mice showed a marked recovery as compared to WT mice (WT 44 ± 5 s vs NOX-2 KO 22 ± 4 s; $p < 0.05$). It reaches control levels after 12 h, a situation that did not occur in WT mice (WT 37 ± 5 s vs NOX-2 KO 12 ± 3 s, $p < 0.05$; Fig. 5b).

Finally, the inverted grid test indirectly allows evaluation of the muscle tone of the mice extremities (Fig. 5c).

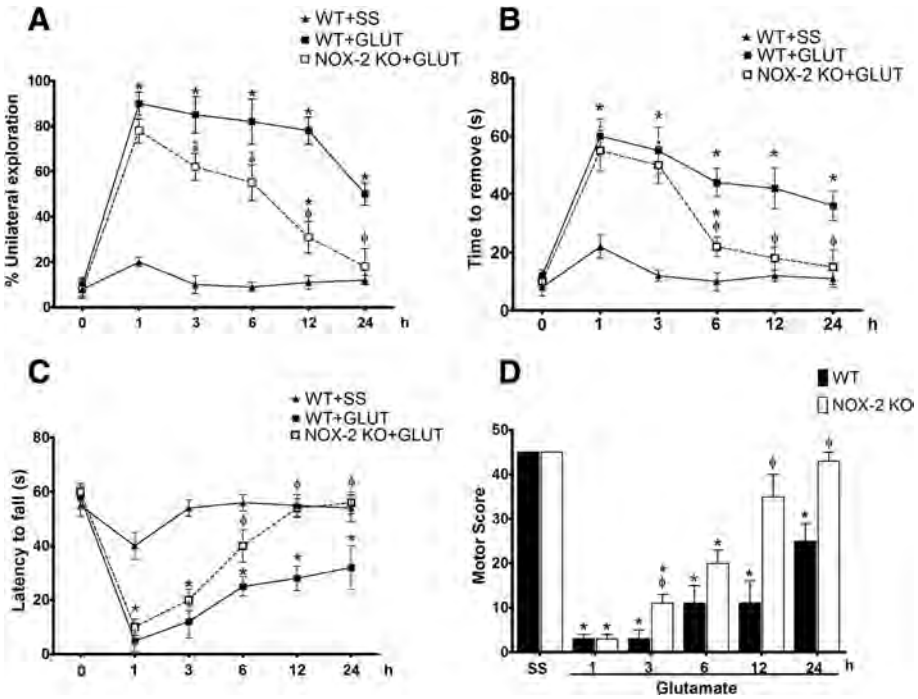

Fig. 5 Motor activity recovery after glutamate administration in NOX-2 KO mice. Performance of wild-type (WT + SS) animals and WT or NOX-2 KO mice injected with glutamate (WT + GLUT; NOX-2 KO + GLUT) was evaluated in three tests of motor behavior at 1, 3, 6, 12, and 24 h after glutamate intracerebral injection. These tests were later integrated to obtain a motor score that reflects functional deterioration. **a** Cylinder test in which each mouse obtained a percentage based on the ratio of unilateral and bilateral explorations performed in three trials, of 3 min each; the percentage was expressed as mean ± SEM of eight independent tests. **b** Adhesive removal test that quantifies the time in which the animals remove a label previously placed by the examiner. The time of removal was quantified in seconds and was expressed as means ± SEM of six independent animals. **c** The tone and muscle strength of the four limbs was evaluated by exposing the mice to the inverted grid test in which the decay time was quantified for three non-consecutive opportunities of a maximum of 60 s of duration. The results are expressed as means ± SEM of the latency to fall of six independent tests. **d** To integrate the three previous tests, an arbitrary score was assigned to the performance of each animal, giving the highest score to the performance of the mice injected with saline (45 points). The results are expressed in arbitrary units of motor score as the mean ± SEM of the latency to fall of six independent tests. *$p < 0.05$ vs the corresponding saline control; $^{\Phi}p < 0.05$ vs the corresponding wild-type (WT) mouse treated with glutamate

Control mice remained attached to the inverted grid for about a minute (56 ± 4 s), which is considered an adequate performance and is established as the baseline. After 1 hour of glutamate administration, both the WT and NOX-2 KO mice were unable to remain attached for long time to the grid (WT 5 ± 4 s and NOX-2 KO 10 ± 3 s). In comparison to WT mice, the NOX-2 KO mice showed a better functional recovery from 6 h after the event (WT 25 ± 4 vs NOX-2 KO 40 ± 6 s $p < 0.05$) reaching a performance similar to control animals from 12 h, which is not observed in WT mice (WT 32 ± 8 vs NOX-2 KO 54 ± 4 s $p > 0.05$; Fig. 5c).

Motor function parameters were integrated into a NDS (Fig. 5d). To that, each test was given an equivalent weight in the score, assigning an arbitrary value of 15 points (for each test) to the control animals treated with saline solution. Therefore, a poor performance during the test corresponded to a decrease in the points awarded [55]. The WT mice treated with glutamate showed a poor score in the first 3 h (3 ± 1 points), which improved at 12 h (11 ± 5 points) and 24 h (25 ± 4 points). NOX-2 KO mice treated with glutamate obtained a poor score in the first hour (3 ± 1 points), reaching a marked improvement at 24 h with a performance similar to the control animals (43 ± 2 points, $p > 0.05$; Fig. 5d). As we observed in the previous tests, the functional recovery of the NOX-2 KO mice surpasses that observed in WT mice after 12 h of glutamate administration (WT 11 ± 5 vs NOX-2 KO 35 ± 4 s $p < 0.05$). Based on these findings, we suggest that NOX-2 activity is associated with a worst functional motor recovery after glutamate administration.

The pattern of cytokine production in response to excitotoxic damage depends on NOX-2

The resolution of the excitotoxic damage depends on the inflammatory response, which aims to remove damaged tissue and recover functions [56]. We characterized the inflammatory response to excitotoxic damage and evaluated the involvement of NOX-2 in the production

of cytokines associated with the inflammatory response in the CNS (Fig. 6a).

Regarding the inflammatory cytokines, we observed an increase of IL-1β in the WT (701 ± 30 pg/mg^{-1} protein) after 6 h of glutamate administration, when compared with the saline control (298 ± 41 pg/mg^{-1} protein). In a similar manner, the NOX-2 KO mice depicted and increased value for this interleukin (682 ± 24 pg/mg^{-1} protein). At 12 h, the IL-1β levels were markedly reduced in both conditions, but still above the control (WT + GLU 400.7 ± 22 vs. NOX-2 KO + GLU 420 ± 15 pg/mg^{-1} protein, $p < 0.05$), returning to control levels at 24 h (WT + GLU, 380 ± 58 and NOX-2 KO + GLU, 401 ± 63 pg/mg protein; Fig. 6a). No differences were found between WT mice and NOX-2 KO in the production of IL-1β.

Excitotoxic damage also caused a similar increase of the inflammatory cytokine IL-6 in both groups at 6 h and 12 h (WT + GLU, 650 ± 85 and NOX-2 KO + GLU, 553 ± 91 pg/mg^{-1} protein). Unexpectedly, after 24 h of glutamate administration, NOX-2 KO maintained high levels of IL-6 compared to WT mice (WT 381 ± 41 vs NOX-2 KO 581 ± 43 pg /mg^{-1} protein, $p < 0.05$; Fig. 6c).

IL-12 levels increased at the first hour after glutamate treatment in both WT (423 ± 52 pg /mg^{-1} protein) and NOX-2 KO (475 ± 74 pg /mg^{-1} protein) mice as compared to the saline control (WT 282 ± 28) and saline NOX-2 KO (321 ± 31 pg /mg^{-1} protein, $p < 0.05$), respectively. After 6 h, WT mice treated with glutamate showed a maximum increase, which was significantly higher than that observed in NOX-2 KO mice (WT 673 ± 39 vs NOX-2 KO 385 ± 35 pg /mg^{-1} protein, $p < 0.05$).

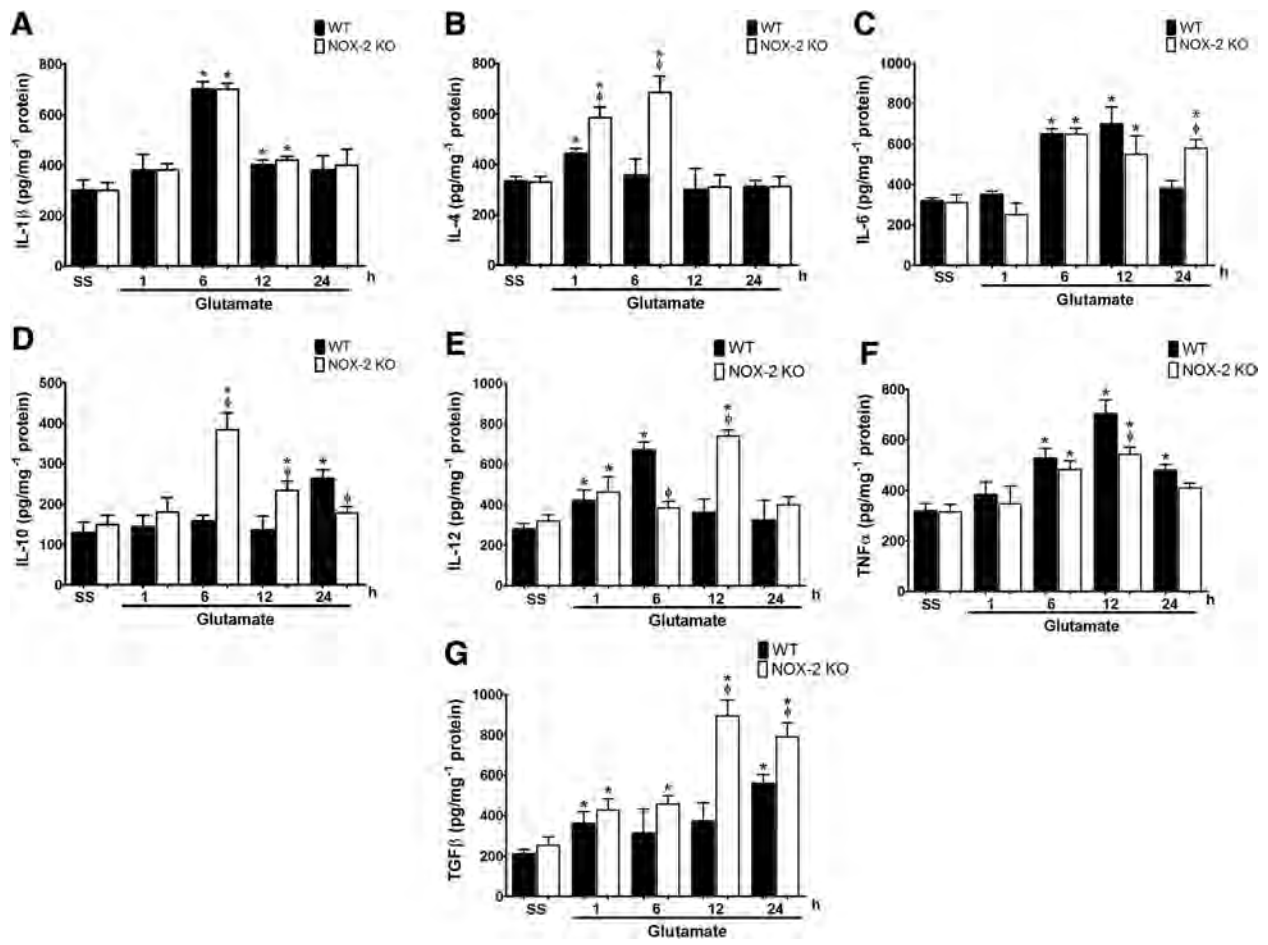

Fig. 6 Pattern of cytokine production in wild-type and NOX-2 KO mice after the striatal injection of glutamate. Characterization of the inflammatory response was carried out by determination of cytokines concentration in striatum homogenates of wild-type (WT) and NOX-2 KO mice determined by enzyme-linked immunosorbent assays (ELISA) at 1, 6, 12, and 24 h after administration of saline (SS) or glutamate (1 M) as detailed in the "Methods" section. **a** Interleukin-1β (IL-1β), **b** interleukin-4 (IL-4), **c** interleukin-6 (IL-6), **d** interleukin-10 (IL-10), **e** interleukin-12 (IL-12), **f** tumor necrosis factor α (TNF-α), and **g** transforming growth factor β (TGF-β). Data are expressed as picograms per milligram of protein and are means ± SEM of three independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\Phi}p < 0.05$ vs the corresponding WT mouse treated with glutamate

At 12 h, this pattern was inverse since IL-12 levels were much higher in NOX-2 KO than in WT mice (WT 363 ± 67 vs NOX-2 KO 743 ± 29 pg /mg^{-1} protein, $p < 0.05$; Fig. 6e).

We observed an increase of TNF-α induced by glutamate in both WT (528 ± 39 pg /mg^{-1} protein) and NOX-2 KO mice at 6 h (483 ± 35 pg /mg^{-1} protein) and 12 h (WT 704 ± 54; NOX-2 KO 542 ± 29 pg /mg^{-1} protein). The production of TNF-α in NOX-2 KO mice was always lower than in WT, particularly at 6 and 12 h. After 24 h, the observed increase was reduced in both WT (482 ± 22 pg/mg protein) and NOX-2 KO mice (410 ± 20 pg/mg^{-1} protein, $p > 0.05$; Fig. 6f).

Regarding the production of anti-inflammatory cytokines, we measured the concentration of some of the anti-inflammatory cytokines previously reported in the CNS, such as IL-4, IL-10, and TGF-β [21, 22]. One hour after glutamate administration, NOX-2 KO mice showed an almost twofold increase in the production of IL-4 as compared to control (saline) (NOX-2 KO 586 ± 42 vs NOX-2 KO + SS 330 ± 32 pg/mg^{-1} protein; $p < 0.05$), while in WT mice, glutamate induced an increase of 125% with respect to the saline control (WT + GLU 443 ± 20 vs WT + SS 335 ± 18 pg/mg^{-1} protein; $p < 0.05$). The observed difference between WT and NOX-2 KO was markedly increased at 6 h (WT 357 ± 54 vs NOX-2 KO 685 ± 65 pg/mg protein, $p < 0.05$; Fig. 6b). At 12 and 24, no difference was observed between groups and values returned to control values.

The administration of glutamate to NOX-2 KO mice caused an increase of IL-10 more than double respect to WT mice at 6 h (WT 158 ± 14 vs NOX-2 KO 384 ± 42 pg/mg^{-1} protein, $p < 0.05$) and this increase was maintained only in NOX-2 KO group until 12 h (WT 136 ± 34 vs NOX-2 KO 234 ± 24 pg/mg^{-1} protein, $p < 0.05$). However, at 24 h, we observe an increase of IL-10 in WT, while values in NOX-2 KO continued decreasing (WT 263 ± 21 vs NOX-2 KO 178 ± 18 pg/mg^{-1} protein, $p < 0.05$; Fig. 6d).

Regarding the production of TGF-β (Fig. 6g), a negative regulatory cytokine, we observed a similar increase both in WT as NOX-2 KO mice treated with glutamate at 1 h (WT 360 ± 59 vs NOX-2 KO 427 ± 56 pg/mg^{-1} protein, $p < 0.05$). This increase was maintained only in the NOX-2 KO group, until 24 h, reaching a maximum concentration at 12 h (WT 372 ± 91 vs NOX-2 KO 893 ± 79 pg/mg^{-1} protein, $p < 0.05$). At this time, it reaches more than double than that found in WT mice. In contrast, WT mice showed only a second increase at 24 h, which was lower than that observed in NOX-2 KO (WT 557 ± 45 vs NOX-2 KO 789 ± 69 pg/mg^{-1} protein, $p < 0.05$). These results suggest that the change in the cytokines profile in NOX-2 KO mice is characterized by an increase in the production of anti-inflammatory cytokines and that this increase occurs preferentially at early times during the excitotoxic event.

Administration of IL-4 partially prevents the excitotoxic lesion

One of the most evident differences in the response of the NOX-2 KO mice to the excitotoxic damage was the increase in the production of anti-inflammatory cytokines; therefore, we treated animals with exogenous IL-4 or IL-10 simultaneously to glutamate administration and evaluated neuronal degeneration and lesion volume. Representative tissue sections from WT and NOX-2 KO animals stained with cresyl violet and Fluoro-Jade B are shown in Fig. 7a. In the case of WT mice treated with IL-4, we observed a significant decrease in the lesion volume (WT 1.2 ± 0.14 vs WT + IL-4 0.72 ± 0.05 $p < 0.05$; Fig. 7b), as well as a decrease in degenerating cells (WT 82.3 ± 11.1 vs WT + IL-4 35.4 ± 4.7 cells/mm^2 $p < 0.05$) as compared to mice administered only with glutamate (Fig. 7c).

NOX activity and caspase-3 activation are regulated by IL-4 in the excitotoxic process

Since the NOX-2 KO mice showed an increased production of IL-4, we explored the possibility of reciprocal regulation through the determination of NOX activity in WT mice treated with IL-4 (Fig. 8). Under these conditions, WT mice treated with IL-4 showed a 50% reduction in NOX activity induced by glutamate only at 12 h (GLU 85 ± 12% and GLU + IL-4 vs 44 ± 12% above control $p < 0.05$; Fig. 8). Concordantly, mice treated with IL-4 also showed a significant reduction in the activation of caspase-3 after 12 h (GLU 249 ± 10% vs GLU + IL-4 187 ± 9% compared with controls, $p < 0.05$) that was maintained at 24 h (GLU 229 ± 9% vs GLU + IL-4 172 ± 10% compared with the control $p < 0.05$; Fig. 9).

The administration of IL-10 reduces the lesion induced by excitotoxic damage

After glutamate administration, we found that the lesion volume was also markedly reduced in mice treated with IL-10. Representative tissue sections from WT and NOX-2 KO animals stained with cresyl violet and Fluoro-Jade B are shown in Fig. 10a. Animals treated with IL-10 showed a decrease of more than 60% in the lesion volume as compared to the untreated mice (GLU 1.2 ± 1.14 vs GLU + L-10 0.45 ± 0.05 mm^3 $p < 0.05$; Fig. 10b). As for the degenerating cells, the administration of IL-10 also decreased the number of positive cells to Fluoro-Jade B by 60% (GLU 83.4 ± 11.3 vs GLU + IL-10 32.3 ± 4.6 mm^3 $p < 0.05$; Fig. 10c).

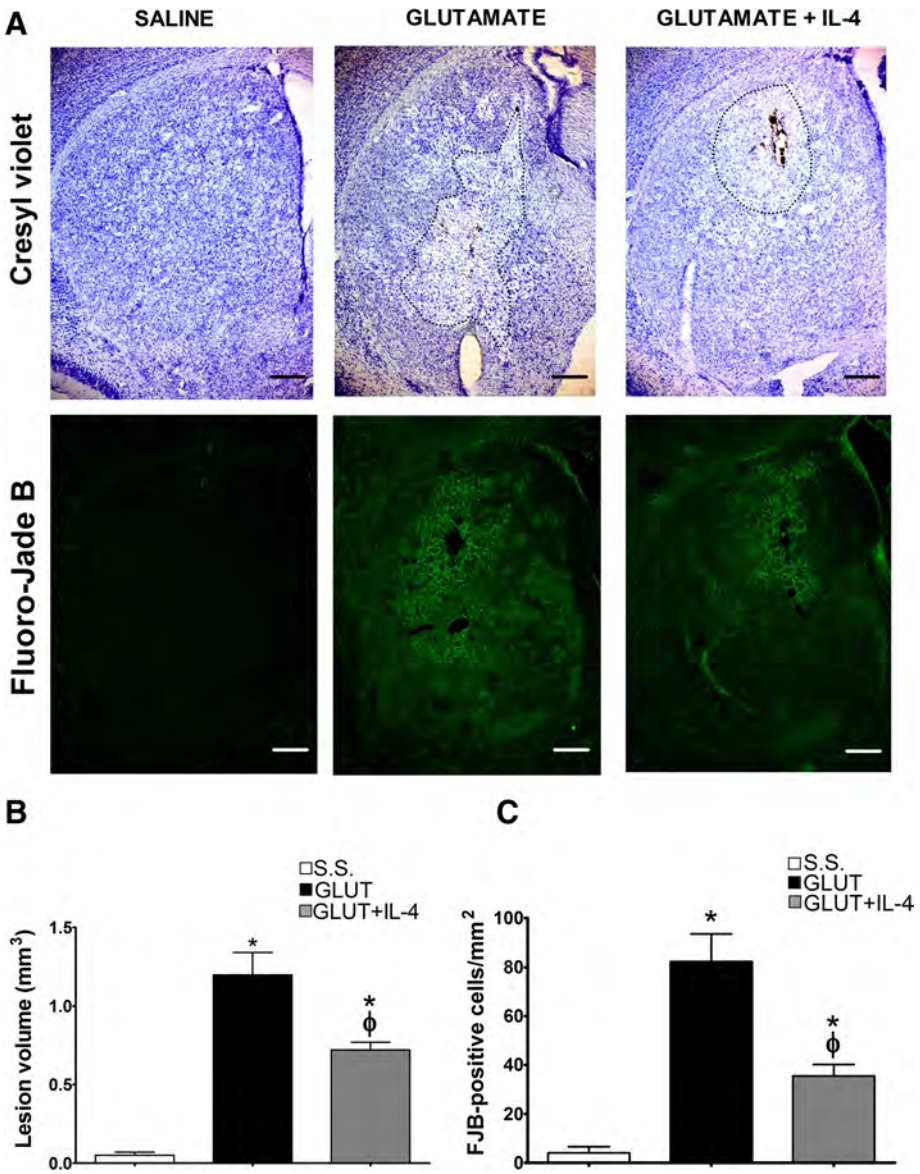

Fig. 7 Effect IL-4 on the striatal lesion and neuronal degeneration in wild-type mice treated with glutamate. Histological sections of wild-type (WT) mice were obtained after 24 h of intracerebral administration of NaCl 0.9% (S.S.), only glutamate (GLUT) or glutamate + 0.7 ng/mL of IL-4 (GLUT + IL4) as detailed in the "Methods" section. **a** Representative micrographs of coronal striatal sections showing lesions stained with cresyl violet and damaged cells positive to Fluoro-Jade B. The dotted line delimits the area of lesion of mice treated with glutamate. The scale bars represent 200 μm. **b** Quantification of the lesion volume 24 h after saline or glutamate injection is expressed in cubic millimeters. **c** Total number of FJB-positive cells were counted in three slices per mice. Data are expressed as mean ± SEM of six independent experiments. *$p < 0.05$ vs saline control (S.S.); $^{\varphi}p < 0.05$ vs the corresponding mouse treated only with glutamate (GLUT)

The NOX activity and caspase-3 activation are regulated negatively by IL-10

When WT animals were simultaneously treated with glutamate and IL-10, NOX activity was markedly reduced at 1 h (GLU 231 ± 25% vs GLU + IL-10 108 ± 7% of the control, $p < 0.05$); 6 h (GLU 141 ± 5% vs GLU + IL-10 115 ± 4% compared with controls, $p < 0.05$); and 12 h (GLU 195 ± 12% vs GLU + IL-10 132 ± 7% of the control, $p < 0.05$), as compared to mice injected only with glutamate. Nevertheless, 24 h after the excitotoxic insult, both groups showed similar levels of catalytic activity (GLU 147 ± 4% vs GLU + IL-10 134 ± 5% $p > 0.05$; Fig. 11).

Under these conditions, IL-10 also decreased the activity of caspase-3. As we showed previously, the administration of glutamate promotes the increase of active caspase-3 from 3 to up 24 h after the injection. The co-administration of IL-10 reduced caspase-3 activation

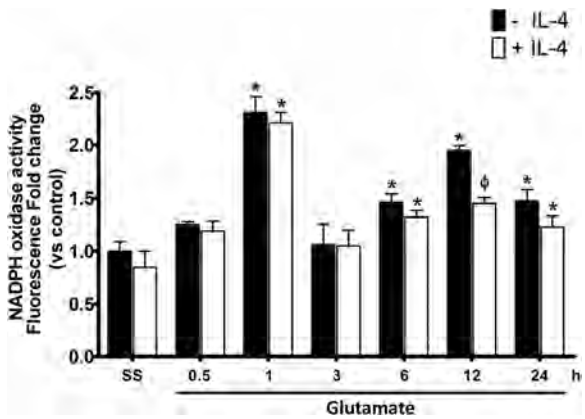

Fig. 8 NOX activity in wild type mice treated with IL-4 after glutamate administration. NOX activity was evaluated in WT mice treated with NaCl 0.9% (S.S.), only glutamate (– IL-4) or glutamate + 0.7 ng/mL of interleukin-4 (+IL4); the determination of NOX activity was measured by the fluorescence resulting from the dihydroethidium (DHE) oxidation in striatal homogenates of mice from 0.5 to 24 h (0.5, 1, 3, 6, 12, and 24 h) after glutamate administration. Data are expressed as fold change of fluorescence relative to saline without IL-4. Values are means ± SEM of three independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\Phi}p < 0.05$ vs the corresponding time of mice treated with glutamate alone

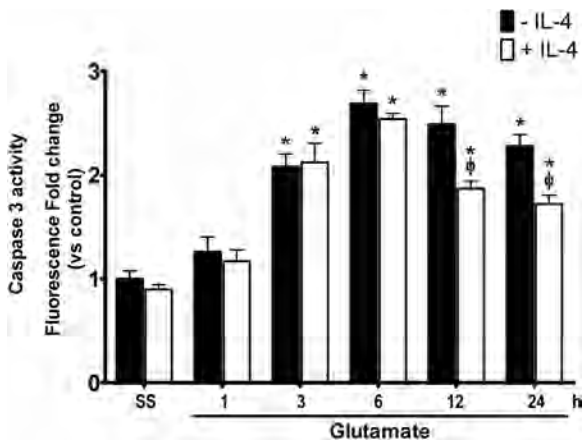

Fig. 9 Caspase-3 activity in wild-type mice treated with IL-4 after glutamate administration. Active caspase-3 was measured in striatal homogenates of wild-type (WT) mice treated with NaCl 0.9% (S.S.), only glutamate (– IL-4) or glutamate + 0.7 ng/mL of interleukin-4 (+IL4) after 1, 3, 6, 12, and 24 h. Fluorescence produced by the cleavage of the specific substrate for caspase-3 was quantified as relative units of fluorescence (FRU). Data are expressed as fold change of fluorescence relative to saline without IL-4. Values are means ± SEM of three independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\Phi}p < 0.05$ vs the corresponding time of mice treated with glutamate alone

by 90% at 3 h (GLU 201 ± 18% vs GLU + IL-10 112 ± 4% above control, $p < 0.05$) and 24 h (GLU 228 ± 27% vs GLU + IL-10 118 ± 6% above control, $p < 0.05$) after the injection. At 6 h and 12 h, it decreased approximately 50% (GLU 270 ± 30% vs GLU + IL-10 194 ± 15% of the controls, $p < 0.05$; GLU 249 ± 10% vs GLU + IL-10 177 ± 6% compared with controls, $p < 0.05$; Fig. 12).

IL-10 administration improves motor recovery in mice after excitotoxic damage

Mice treated with IL-10 had a better performance in tests of motor behavior after glutamate administration (Fig. 13). In the cylinder test, although mice treated with IL-10 showed a performance similar to those that did not receive treatment, at 1 h (GLU 10 ± 3% vs GLU + IL-10 8 ± 2 unilateral contacts $p < 0.05$) they were able to recover the control level at 6 h (GLU 82 ± 5% vs GLU + IL-10 20 ± 4% unilateral contacts, $p < 0.05$), while this did not happen in the untreated mice (Fig. 13a). In the adhesive test, mice treated with IL-10 were also able to recover baseline performance at 3 h (GLU 55 ± 8 s and GLU + IL-10 20 ± 6.5 s, $p < 0.05$), while those not treated did not reach these recovery levels in 24 h (GLU 36 ± 5 s vs GLU + IL-10 15 ± 5 s, $p < 0.05$; Fig. 13b). In the inverted grid test, mice treated with IL-10 had a better performance than the untreated mice from the first hour after glutamate treatment (GLU 5 ± 4 s vs GLU + IL-10 26 ± 3 s $p < 0.05$). In contrast to the animals treated with glutamate alone, these animals recovered to values similar to the control group after 12 h (SS 58 ± 2 s vs GLU + IL-10 50 ± 4 s, $p > 0.05$) and 24 h (Fig. 13c).

The improvements by IL-10 treatment observed in the individual tests were reflected in the NDS (Fig. 13d). We observed a significant high score in mice treated with IL-10 at 3 h (GLU 3 ± 2 points and GLU + IL-10 22 ± 4 points $p < 0.05$), which progressively improved and reached values similar to those observed in control group at 24 h (GLU 11 ± 5 points and GLU + IL-10 40 ± 3 points $p < 0.05$; Fig. 13d). Mice injected only with glutamate also showed a progressive increase in the motor score, but it was significantly lower of the control values at all times.

Discussion

In ischemia and brain trauma, neurons lose the ability to control ion homeostasis minutes after the primary injury, resulting in the accumulation of intracellular calcium, cell depolarization, release of glutamate, impaired mitochondrial function, energy failure, and elevated reactive oxygen species production [57–59]. This occurs during the first few minutes-hours after the event and will determine the course of brain damage, including neuroinflammation. For example, the use of NMDA receptor blockers in experimental models of ischemia and

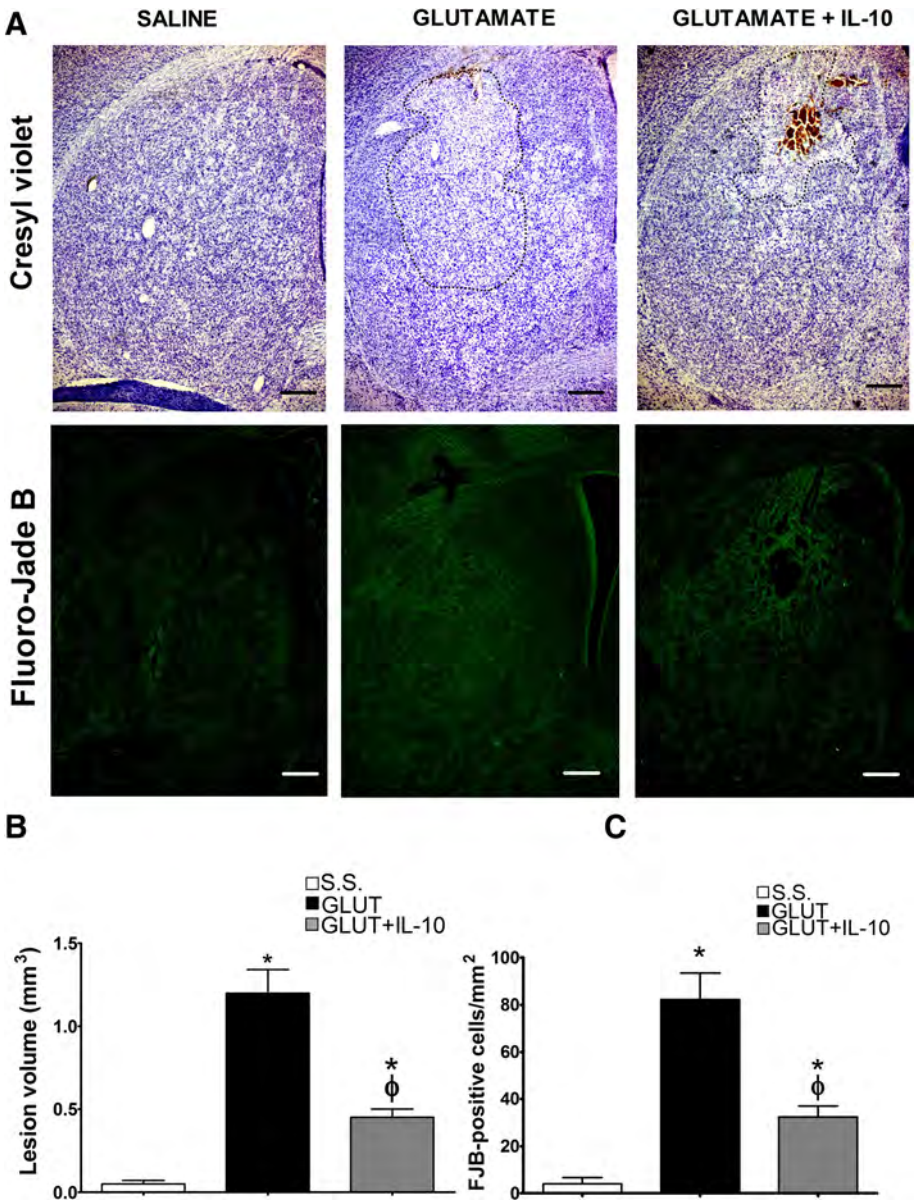

Fig. 10 Effect of IL-10 on the lesion area and neuronal degeneration in wild-type mice treated with glutamate. Histological sections of wild-type (WT) mice were obtained after 24 h of intracerebral administration of NaCl 0.9% (S.S.), only glutamate 1 M (GLUT) or glutamate + 0.4 ng/mL of interleukin-10 (GLUT+IL-10) as detailed in the "Methods" section. **a** Representative micrographs of coronal striatal sections showing lesions stained with cresyl violet and damaged cells positive for Fluoro-Jade B. The dotted line delimits the area of lesion of mice treated with glutamate. The scale bars represent 200 μm. **b** Quantification of the lesion volume 24 h after saline or glutamate injection is expressed in cubic millimeters. **c** Total number of FJB-positive cells counted in three slices per mice. trauma markedly reduces neuronal damage and neuroinflammation when administered during the first minutes-hours of insult [60, 61]. Diverse studies postulate that the magnitude of the primary response is associated with the severity of the inflammatory response that can last for months or even years [62, 63]. Therefore, it is necessary to evaluate the processes taking place during the early stages of brain injury, as we did in this study. This could help to define the early clinical intervention that can be decisive in the prognosis.

In animal models, the exogenous administration of glutamate produces an overstimulation of synaptic receptor that leads to oxidative stress and neuronal death. Besides, the excitotoxic damage is closely associated with an inflammatory response [64]. During this process, ROS are key pieces since they participate directly in

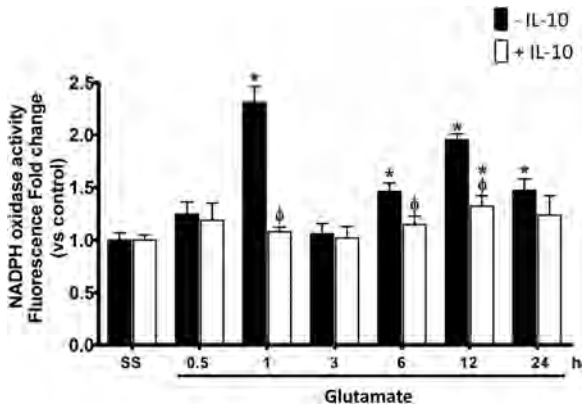

Fig. 11 NOX activity in wild-type mice treated with IL-10 after glutamate administration. NOX activity was evaluated in wild-type mice (WT) treated with NaCl 0.9%(S.S.), only glutamate 1 M (– IL-10) or glutamate + 0.4 ng/mL of IL-10 (+ IL-10) as detailed in the "Methods" section. The determination of NOX activity was measured as the change in fluorescence intensity resulting from the dihydroethidium (DHE) oxidation to ethidium (Et) in striatal homogenates after 0.5, 1, 3, 6, 12, and 24 h after glutamate administration. Data are expressed as fold change of Et fluorescence relative to saline without IL-4. Values are means ± SEM of three independent experiments. *$p < 0.05$ vs the corresponding saline control; $^{\Phi}p < 0.05$ vs the corresponding time of mice treated with glutamate alone

neuronal death and other parallel physiological processes that are also affected by the excitotoxicity [65, 66].

Several sources of cellular ROS have been involved in the excitotoxic damage; one of the most interesting is the NOX family, whose only known function is ROS production [64, 67]. The seven homologs (NOX-1 to NOX-5 and DUOX-1 and DUOX-2) have different subcellular localizations, and their activation is associated with various signaling pathways of the cell physiology [25, 48]. Particularly, NOX-2 seem to be involved in cell death, since its inhibition markedly reduces neuronal damage in several pathological processes such as ischemia, hypoglycemia, and brain trauma [8, 9, 14], where excitotoxicity is a main component.

In previous studies, we demonstrated that pharmacological inhibition of NOX in primary cultures of cerebellar granule neurons decreases apoptotic death caused by different conditions [67, 68]. Using an animal model of genetic inhibition of NOX-2 or with the administration of NOX inhibitors, we have confirmed the involvement of NOX-2 in excitotoxic neuronal death [13], which correlated with findings of other groups that report that the increase of NOX-2 activity promotes apoptotic death [69].

In the present study, we corroborated that NOX-2 KO mice are less susceptible to excitotoxic damage than WT mice, evidenced by a smaller lesion and less number of positive cells to Fluoro-Jade B in NOX-2 KO mice treated with glutamate (Fig. 2). In this model, we corroborated that NOX-2 is involved in excitotoxic damage since an increase of NOX activity was observed in response to the administration of glutamate. This increase occurred in a biphasic manner (1 and 12 h after glutamate administration). Since both peaks of NOX activity occurred within 12 h of difference (Fig. 3), we suggest that this feature is part of two separate phenomena. We hypothesize that the first increase in ROS participates in a direct response to the extracellular increase of glutamate, while the increase observed at 12 h probably corresponds to the cellular response for the recovery of homeostasis; however, more studies are required to test this possibility.

Our results indicated that the lack of NOX-2 is associated with a minor activation of caspase-3 (Fig. 4), probably resulting from a decrease in apoptotic signaling pathways. It is likely that the neuroprotective effect observed in NOX-2 KO mice results from a decrease of the initial damage and reduced activation of subsequent death signaling pathways. These findings correlate with reports in showing that the increase of NOX-2 activity is associated with the activation of caspase-3 and apoptotic death [68, 69]. It is important to emphasize that the excitotoxic damage includes other mechanisms of cell death (necrosis and autophagy) and that the lack of NOX-2 activity does not completely prevent cell death.

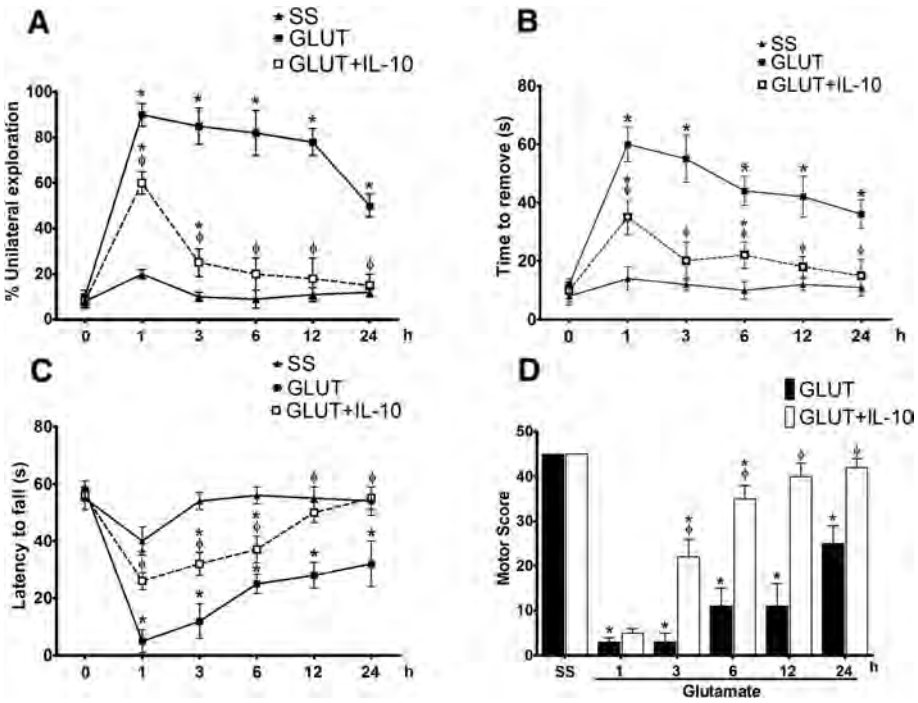

Fig. 13 IL-10 improves motor recovery in wild-type mice after glutamate administration. Motor behavior of wild-type mice injected with NaCl 0.9% (SS), 1 M glutamate (GLUT) and glutamate + 0.4 ng/mL of IL-10 (GLUT + IL-10), was evaluated in three tests of motor behavior at 1, 3, 6, 12, and 24 h after glutamate intracerebral injection. **a** Cylinder test, in which each mouse obtained a percentage based on the ratio of unilateral and bilateral explorations performed in three trials, of 3 min each; the percentage was expressed as mean ± SEM of six independent tests. **b** Adhesive removal test quantifies the time in which the animals remove a label previously placed by the examiner. The time of removal was quantified in seconds and was expressed as means ± SEM of six independent tests. **c** Inverted grid test was evaluated by exposing the mice to the inverted grid test in which the decay time was quantified for three non-consecutive opportunities of a maximum of 60 s of duration. The results are expressed as means ± SEM of the latency to fall of six independent tests. **d** Integration of behavioral performance of three previous tests was carried out by assigned an arbitrary score to the performance of each animal, giving the highest score to the performance of the mice injected with saline (45 points). The results are expressed in arbitrary units of motor score as the mean ± SEM of the latency to fall of six independent tests. *$p < 0.05$ vs the corresponding saline control; $^{\varphi}p < 0.05$ vs corresponding mouse treated with glutamate alone

Striatal injuries usually result in impaired sensorimotor function and movement execution [70]. The present results show a clear positive correlation between a reduction of the lesion size and a better recovery of motor function. In both WT and NOX-2 KO mice treated with glutamate, the initial motor function was similarly affected, probably due to the action of glutamate on striatal neuronal circuits. However, this condition improves much faster for the NOX-2 KO animals (Fig. 5) according to the damage observed in both animals (Fig. 2).

The increase in NOX-2 activity is relevant for excitotoxic damage and the inflammatory process. It has been suggested that it contributes, along with various cytokines, to the function impairment and secondary damage orchestrated by microglia [71, 72]. Persistent inflammation can promote secondary tissue injury through excess production of proinflammatory factors, such as TNF-α, IL-1β, and IL-6. These factors promote the polarization of the resident microglia to the M1 phenotype, which in turn causes neuronal death; the sum of these events results in the aggravation of the initial injury and a poor resolution of damage.

In a previous study, we observed that during the excitotoxic damage, the activated microglia in NOX-2 KO mice showed different morphological characteristics as compared to WT animals [13]. In the present work, we observed that NOX-2 mice have a different profile of cytokines production. The major change in the pattern of cytokine production corresponded to the increase in anti-inflammatory cytokines such as IL-4, IL-10, and TGF-β, just a few hours after the initiation of the injury (Fig. 6).

As expected, we observed an increase in the production of IL-1β after 6 and 12 h of glutamate treatment. However, we did not observe any differences between the WT and NOX2-KO mice at any time after glutamate treatment (Fig. 6). This contrasts with the observed results in a model of TBI, where NOX2 deficiency induced a lower expression of IL-1β after the trauma [46]. In addition to NOX2, it has been suggested that mitochondrial ROS also play a key role in the inflammatory

process through the NLRP3 inflammasome activation [73]. It is known that the production of IL-1β is regulated enzymatically by the NLRP3 inflammasome [74, 75] and a lower IL-1β secretion is observed in macrophages treated with mitochondrial ROS scavengers [42]. The NLRP3 inflammasome is stimulated by ROS [76], and NOX-derived ROS were initially suggested to be necessary for NLRP3 inflammasome activation [77]. However, in mouse macrophages deficient in NOX, IL-1β production is unaffected [78]. This observation suggests that the mechanisms involved in NLRP3 activation and IL-1β production are dependent on the source of ROS production and the type of insult. Possibly in the present experimental conditions, other sources of ROS rather than NOX are necessary for IL-1β production.

One of the most remarkable findings in this study is that in the NOX-2 KO mice, IL-4 production increases very early during the excitotoxic process, which correlates with previous reports, suggesting that IL-4 contributes to the polarization of the microglia to an M2 phenotype promoting an anti-inflammatory response. Recent evidence shows that neurons that survive a noxious stimulus (i.e., ischemia) respond by increasing the production and release of IL-4 [20]. Although the effects of IL-4 on neuronal survival have not been extensively described, it is known that its increase may promote the release of neurotrophic factors that favor axonal repair and neuronal survival.

The increase of IL-4 in NOX-2 KO mice suggests that NOX-2 participates in the negative regulation of this interleukin. This can directly influence the inflammatory response dynamics, since IL-4 contributes decisively to the acquisition of a microglial anti-inflammatory phenotype producer of IL-10. During excitotoxic damage, the increase of NOX-2 activity correlated temporarily with the decrease of anti-inflammatory cytokines and the increase in inflammatory mediators, which agrees with that reported by other groups who postulate that NOX regulates the production and release of anti-inflammatory cytokines [79, 80].

Similarly, the production of IL-10 is also markedly increased, probably induced by IL-4 [21]. The stimulation of IL-4Rα microglial receptors promotes the activation of several signaling pathways, including the activation of Janus kinase 3/transcription 6 (JAK3/STAT6) and insulin receptor substrate 2 (IRS2). This situation promotes the expression of IL-10 by the nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) and negatively regulates the production of inflammatory interleukins by the suppressor of cytokine signaling 1 (CS1) [80].

It is known that the binding of IL-10 to its neuronal receptors (IL-10R) activates the JAK2/STAT3 pathway, which reduces oxidative stress and promotes neuronal survival [81]. It is possible that part of the observed decrease in caspase-3 activation and cell death in NOX-2 KO animals could be a consequence of a decreased ROS production, by activation of IL-10R during excitotoxicity.

In our model, a single intracerebral dose of recombinant IL-10 decreased caspase-3 activation in WT mice subjected to excitotoxic damage (Fig. 12), and it is important to note that the concentration of IL-10 administered was similar to that found in the NOX-2 KO mice subjected to the excitotoxic event. Our results showed that the treatment with IL-10 negatively regulates NOX activity (Fig. 11), which could also be associated with the reduction of oxidative stress and therefore less neuronal death.

Interestingly, in contrast to what we observed in NOX-2 KO mice (Fig. 4), the administration of IL-10 did not decrease active caspase-3 induced by glutamate treatment in the initial phase (3 and 6 h), but late in the process (12 and 24 h) (Fig. 9). This suggests that IL-10 could promote neuronal survival only during the secondary phase, being the inflammatory process a probable target. This is in line with the finding that the administration of a single dose of IL-4 markedly reduced the lesion volume (Fig. 7), but the decrease in NOX activity (Fig. 8) and caspase-3 activity (Fig. 9) occurred after 12 and 24 h of glutamate administration.

Based on our findings, including the time course of the different parameters evaluated, we can delimit two phases in the progression of neuronal damage induced by glutamate administration: an initial response, from the onset of administration to the subsequent 6 h and a secondary response, from 6 h and up to 24 h post administration. In WT mice, the initial phase is characterized by an increase in NOX activity and IL-12 production, which promotes a proinflammatory state and severe motor deterioration. During the secondary response, a proinflammatory environment predominates (increased IL-1β, IL-6, and TNF-α production and NOX activity), which promotes apoptotic neuronal death. In contrast, in NOX-2 KO mice, the initial response is characterized by an increased production of IL-4 and IL-10, which probably contributes to a decreased apoptotic death and an improved functional recovery.

Interestingly, when IL-4 was administered to WT mice treated with glutamate, NOX activity and caspase-3 activation were reduced only during the secondary response, probably because its effect depends on the increase of other factors. In support of this, when IL-10 was administered to these animals, NOX activity and caspase-3 activation decreased in both the early and the late phase after glutamate administration.

Altogether, these results lead us to propose that the neuroprotection resulting from the genetic inhibition of NOX-2 could be due, at least partially, to a differential response to excitotoxic damage, which is characterized

by an early increased production of anti-inflammatory cytokines. We have shown that the inhibition of NOX-2 activity facilitates the production of anti-inflammatory cytokines, which in turn decreases the injury secondary to excitotoxic damage and improves functional recovery.

Conclusions

The release of proinflammatory cytokines during the excitotoxic cascade promotes a secondary apoptotic death of neurons that survived the damage. During the excitotoxic process and the subsequent inflammatory response, ROS generated by NOX-2 play a decisive role in the extension of the lesion and consequently in the severity of the functional compromise.

We propose that the neuroprotection resulting from a lack of NOX-2 activity could be due, at least partially, to a differential response against excitotoxic damage, characterized by an increased production of anti-inflammatory cytokines. Although it is necessary to determine the exact mechanism by which NOX-2 participates in the regulation of these cytokines, we suggest that the inhibition of NOX-2 activity facilitates the production of IL-4, which contributes to the production of IL-10.

Lipid peroxidation
Malate-aspartate shuttle

ABSTRACT

Ethanol administration is capable of inhibiting or delaying the partial hepatectomy (PH)-induced liver regeneration, probably altering liver metabolism by means of its oxidative metabolism. Since the regenerating liver has increased capacity for oxidizing ethanol, the present study was aimed to address the contribution of the ethanol-oxidizing metabolic pathways in the regenerating liver cells. Isolated hepatocytes were prepared from control livers and from animals subjected to two-thirds PH. In both preparations, ethanol oxidation was largely increased by incubation with glucose and was highly sensitive to inhibitors of ethanol-oxidizing enzymatic pathways (alcohol dehydrogenase, catalase and cytochrome P-4502E1 activities). The latter led to a total blockade of ethanol disposal by control hepatocytes, while liver cells from PH-rats only showed an early 70–75% inhibition of ethanol catabolism with the inhibitors used. In regenerating hepatocytes, the enhanced ethanol oxidation was blocked by scavengers of reactive oxygen species, an effect that correlated with enhanced cytoplasmic lipid peroxidation by-products. Both cell preparations showed similar sensitivity to inhibitors for the malate-aspartate shuttle and mitochondrial electron transport chain; the shift of the cytoplasmic redox state was also quite similar after ethanol oxidation. A more oxidized mitochondrial redox state was found in hepatocytes from PH-rats and more shifted to the reduced state during ethanol oxidation this effect was not abolished by inhibiting alcohol dehydrogenase activity. In conclusion, data clearly show that an important fraction of ethanol is metabolized through a non-enzymatic-mediated oxidative event, which could largely contribute to the deleterious effect of ethanol on the proliferating liver.

1. Introduction

The etiology of alcoholic liver disease (ALD) is highly complex involving different disease stages, such as steatosis, steatohepatitis, fibrosis, and cirrhosis, as well as disruptions in multiple liver cell types, metabolic and signaling pathways, and sub-cellular organelle function. Alcohol consumption depresses hepatic mitochondrial bioenergetics, increasing mitochondrial reactive oxygen species (ROS) production, and promotes an increased sensitivity of the mitochondrial permeability transition (MPT) pore [1]. Indeed, patients with ALD are not good candidates for replacement of their own liver by a donor organ, despite that patient and organ survival is excellent after liver transplantation in this patient's population. Interestingly, ALD patients returning to consume alcohol may consume greater amounts of ethanol [2]. This could be indicating that the transplanted organ, probably promoted to somehow proliferate, could have a distinct handling of the consumed ethanol.

In this context, although the mechanisms of its inhibitory effect are not defined, it is well known that acute and chronic ethanol treatment inhibits DNA synthesis in the regenerating rat liver after partial hepatectomy (PH), induced by a toxic injury, as well as in cultured hepatocytes [3–5]. However, evidence suggests that acute and chronic ethanol inhibits hepatocyte proliferation through different mechanisms. A single oral ethanol administration is capable of inhibiting or delaying the PH-induced liver regeneration [6,7]. Here, it is likely that liver metabolism of exogenous ethanol could alter the overall metabolism of the regenerating liver, i.e., causing disturbances in the cell redox state, energy charge, and the mitochondrial metabolism in the regenerating organ [8].

The ability of the regenerating organ to oxidize the administered ethanol could participate in the deleterious alcohol effects on liver cell proliferation. After PH, the remnant liver shows very enhanced

INFORME DE LABORES 2019

metabolism of ethanol, which constitutes the main factor affecting ethanol pharmacokinetics in hepatectomized rats [9]. Moreover, ethanol blocks the PH-induced changes in the liver cell redox state, minimizing the metabolic adjustments mediated by redox potentials and affecting preparative events that culminate in the compensatory liver growth [10]. Despite having demonstrated that the regenerating liver oxidizes ethanol faster in vivo, the underlying mechanisms remain to be elucidated.

Isolated hepatocytes have been proved to be a useful system for studying regulatory events in ethanol oxidation. Despite that isolated liver cells do not oxidize ethanol at rates comparable to those in vivo [11], rate-determining factors on ethanol oxidation have been identified [12,13]. As other metabolic pathways, there is not a single rate-determining step for the ethanol metabolism pathway, and control is shared among several steps [14]. However, factors such as liver alcohol dehydrogenase (ADH) activity, translocation of cytosolic reducing equivalents into mitochondria, and their further oxidation through the mitochondrial electron transport [15,16] could become rate-limiting for ethanol oxidation, depending on the experimental conditions.

Little is known about ethanol metabolism at the onset of liver cells proliferation; however, some interesting findings have been reported. For instance, neonatal liver cells have a higher capacity of NADH generation and, thereby, ethanol oxidation by these cells induces a more reduced cytoplasmic redox state [17]. In addition, cells from malignant hepatomas showed decreased ADH-mediated ethanol oxidation, and ADH-independent enzyme pathways are also dramatically reduced. Indeed, the content of mitochondrial protein and oxygen consumption are reduced in liver tumors; hence, cytosolic re-oxidation of NADH becomes the limiting factor during ethanol metabolism by tumoral liver cells [18]. In actively ethanol-metabolizing hepatoma cells, accumulation of acetaldehyde and increased mitochondrial NADH/NAD ratio lead to a dramatic ethanol-induced reduction in cell number [19], which strengthens the relationship between ethanol metabolism and liver cell proliferation.

Since there are no reports evaluating the main ethanol-oxidizing metabolic pathways in the rat regenerating liver, induced by PH, the present study was aimed at addressing the underlying mechanism in the stimulated ethanol oxidation, which is found in the PH-induced proliferating liver. Results clearly show that an important fraction of ethanol is metabolized through non-enzymatic mediating oxidative events that can largely contribute to the deleterious effect of ethanol on the proliferating liver.

2. Material and methods

2.1. Materials

4-Methylpyrazole (4-MP), 3-amino 1,2,4-triazole (3-AT), diallyl sulfone, amino-oxyacetate, rotenone, and other reagents were purchased from Sigma Chemical Co. (St. Louis, MO). Collagenase (type CS II) was obtained from Worthington Biochemicals (Freehold, NJ).

2.2. Animal treatments

Male Wistar rats (240–270 g, body weight, n = 70 in total) obtained from the certified bioterium of the Instituto de Fisiología Celular, UNAM, were housed under a 12:12 h light/dark cycle with free access to food (diet chow 500I, LabDiet Co.) and water. Two-thirds PH was performed according to the technique of Higgins and Anderson [20]: in rats intraperitoneally anesthetized with ketamine (40 mg • kg^{-1}), the liver central and left lateral lobes were removed in order to achieve a two-thirds hepatectomy, while controls were sham-operated rats. Abdominal wall and skin were sutured by planes and animals were allowed to recover. At indicated times post-treatment animals were euthanized by decapitation, after an overdose with sodium pentobarbital. Another set of control animals was fasted overnight before euthanasia. Animal procedures were conducted according to the Federal Regulations for Animal Experimentation (Ministry of Agriculture, SAGARPA, Mexico).

2.3. Ethanol bioavailability in rats subjected to PH and treated with 4-MP

In a set of fed animals (n = 20) grouped according to their surgical status (sham-operated or with PH), ethanol only (1.5 g • kg^{-1}b.w. in 40% w/v solution) was administered by intragastric intubation immediately after surgery, or concomitantly with a single dose of 4-MP (200 mg • kg^{-1}b.w.) intraperitoneally administered. Either, ethanol and 4-MP concentrations administered in vivo, were selected to accomplish an adequate estimation of blood ethanol clearance, as well as to achieve a maximal inhibition of liver ADH [9,21]. After treatments, animals were placed in restriction cages, without further access to water and food, and blood samples were collected from the wound of the excised tips of the tail with heparinized 50-μL capillary pipettes. Blood sampling was scheduled every 15 min during the first 2 h, every 30 min for the next 2 h, and every hour thereafter for a total of 10 h post-administration of ethanol only [9]. In the animals treated with 4-MP, sampling was done every 2 h until 12 to 16 h post-administration (not shown). Blood ethanol was quantified in neutralized acid extracts by an enzymatic method, recording reduction of NAD^+ [22]. The area under the curve (AUC) for ethanol elimination from the blood was calculated by a trapezoidal method, from the beginning of ethanol administration to the time it was no longer detected [23].

2.4. Hepatocyte incubations

In another set of animals (n = 25) and at the indicated times after surgical treatment, animals were anesthetized with ketamine (30 mg • kg^{-1}) in the morning, and liver cells were prepared essentially by the collagenase method of Berry and Friend [24], as modified by Seglen [25]. The liver was perfused with a calcium-free buffer prior to the perfusion with a collagenase (0.03%) and calcium-containing buffer (pH 7.4), previously oxygenated by bubbling carbogen (95% O_2 −5% CO_2). After separation from non-parenchymal cells by centrifugation, viability of hepatocytes was 90–95% as judged by trypan blue exclusion for all preparations. The hepatocytes were suspended in the same buffer containing 10 mmoles • L^{-1} glucose and 2.0% (w/v) fatty acid-free bovine serum albumin [26]. Typical assays were done usually with 100 mg (wet wt.) of liver cells in 2 mL of the described incubation medium plus 1 mL of buffer, containing 10 mmoles • L^{-1} of ethanol and agents, such as (in mmoles • L^{-1}, final concentration): 5.0 4-MP, 1.0 3-AT, 1.0 diallyl sulfone, 0.005 rotenone, 0.2 amino-oxyacetate, 0.5 thiourea, and 0.4 butylated hydroxytoluene; all these compounds were added 5 min before adding ethanol. Hepatocytes were incubated in rubber-stoppered 25-mL plastic flasks for 60 min at 37 °C, and the reaction was ended with 1 mL of 3 mol • L^{-1} perchloric acid.

2.5. Analytical procedures

In neutralized samples from perchloric acid-extracts, ethanol and glucose concentrations were determined enzymatically as previously described [9,22]. The cytosolic and mitochondrial fractions were obtained from whole liver by differential centrifugation, as described previously in detail [27]. The activities of alcohol dehydrogenase (ADH; EC 1.1.1.1), aldehyde dehydrogenase (ALDH; EC 1.2.1.3), and catalase (EC 1.11.1.6) were measured as described elsewhere [4]. The “supplemented” activities of the malate-aspartate and of the α-glycerophosphate shuttles were essentially determined using the assay previously described by Hernández-Muñoz et al. [28]. Mitochondrial and cytosolic activities of aspartate aminotransferase (AST; EC 2.6.1.1), as well as that of malate dehydrogenase (MDH; EC 1.1.1.27), were determined as described elsewhere [28]. In the same acid extracts, neutralized with 4 mol • L^{-1} K2CO3, the redox-pair metabolites: lactate,

pyruvate, α-glycerophosphate, dihydroxyacetone phosphate, β-hydroxybutyrate, and acetoacetate, were enzymatically determined, as described before [29,30]. The amount of aldehydic products generated by lipid peroxidation was quantified in the cytosolic fraction through the technique using the thiobarbituric acid reaction (TBARS), as previously modified [31].

2.6. Calculations and Statistics

Cytoplasmic and mitochondrial NAD/NADH ratios were calculated as follows: NAD/NADH = [oxidized substrate]/[reduced substrate] × $1/K_{eq}$, taking into account equilibrium constants for lactate, α-glycerophosphate, and β-hydroxybutyrate dehydrogenases [32]. Areas under curves were calculated by a trapezoidal method. All data were analyzed with the GraphPad Prism software, using an ordinary one-way ANOVA and a post hoc Newman-Keuls analysis, considering $p < 0.01$ as significant.

3. Results

3.1. Blood ethanol clearance in rats subjected to PH and treated with 4-MP

After intragastric administration of a single ethanol dose (1.5 g/kg b.w.), sham-operated rats reached a maximum blood alcohol concentration (BAC) of 21.2 ± 3.9 mM, associated with an area under the curve (AUC) of 11.7 ± 1.1 mM • h^{-1} (Fig. 1A). As previously found [9], animals subjected to PH (24 h after surgery) showed a much lower peak during the first 4 h after ethanol administration (BAC = 12.6 ± 2.5 mM, $p < 0.01$ against controls) without significantly modifying the AUC (15.8 ± 2.2 mM • h^{-1}; Fig. 1A). These data indicate that the regenerating liver has a very enhanced ethanol metabolism, particularly at 24 h post-surgery (Fig. 1A). Under conditions of inhibiting in vivo liver ADH activity, such as the main ethanol-metabolizing enzyme in the liver, 4-MP administration significantly changed AUCs and BACs in both sham operated and animals subjected to PH (Fig. 1B). Whereas in vivo 4-MP administration did not significantly change maximal BAC in control animals (22.6 ± 3.9 mM), and an expected prolongation of the AUC was noted (39.4 ± 4.1 mM • h^{-1}; Fig. 1B).

Also expected, rats undergoing PH and administered ethanol plus 4-MP showed a delayed maximal BAC of 30.8 ± 2.8 mM, significantly higher than that in controls ($p < 0.01$), and the AUC was largely increased (51.8 ± 5.6 vs. 39.4 ± 4.1 mM • h^{-1} in controls, $p < 0.01$; Fig. 1B). Hence, in vivo treatment with 4-MP readily delayed blood ethanol clearance in both experimental groups; however, since the magnitude of the inhibitory effect of 4-MP was differential (Fig. 1B), data suggest that ADH activity in the regenerating rat liver could have a lower participation in ethanol oxidation.

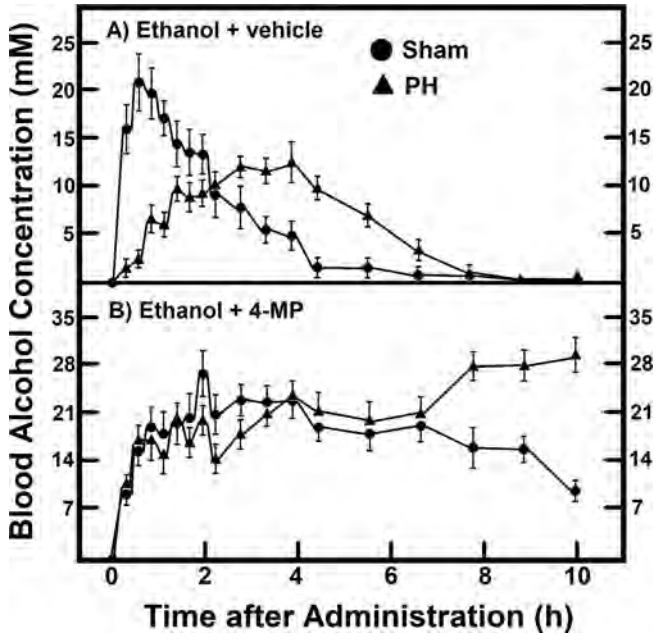

Fig. 1. Effect of in vivo 4-MP administration on blood alcohol concentrations in sham-operated and rats subjected to PH. Results are expressed as mean ± SE of 5 animals per experimental group. Panel A shows BACs and AUCs for ethanol metabolism in control and PH-rats (24 h after surgery) after intra-gastric alcohol administration (1.5 g • kg^{-1}b.w.). Panel B, control and partially hepatectomized rats additionally treated with 200 mg • kg^{-1}b.w. of 4-MP. Note the participation of first-pass metabolism of ethanol (panel A) without 4-MP treatment. Symbols for the experimental groups at the top of panel A.

3.2. Glucose utilization and ethanol oxidation by hepatocytes isolated from normal animals and from regenerating livers

To test the participation of possible metabolic pathways involved in ethanol oxidation, we used fresh isolated liver cells. Firstly, since ethanol oxidation largely depends on the metabolic status of isolated hepatocytes, the rates of glucose and ethanol utilization in liver cells obtained from normal fed or fasted animals were determined. Hepatocytes obtained from overnight fasted rats consumed more actively glucose than those from fed animals, an effect found to be constant up to 60 min of cell incubation (Fig. 2A). Despite that ethanol did not significantly modify glucose utilization in both cell preparations (fasted and fed animals) its oxidation was practically doubled in hepatocytes also incubated with glucose (Fig. 2B). Once tested the metabolic conditions for glucose utilization and ethanol oxidation in the hepatocyte's preparations, ethanol oxidation by hepatocytes obtained at different times post-surgery was measured (Fig. 2C). In the presence

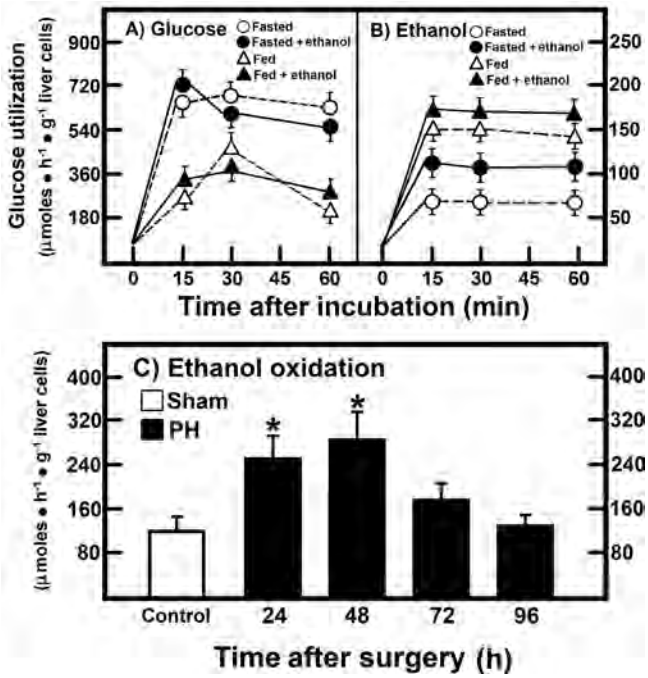

Fig. 2. Glucose and ethanol consumption by hepatocytes isolated from normal starved or fed rats, and the increased ethanol oxidation after PH. Results are the mean ± SE of five individual determinations made in duplicate per each experimental group. Panel A, glucose (10 mmoles • L^{-1}) consumption and, in panel B, ethanol (10 mmoles • L^{-1}) clearance by control hepatocytes from fed and starved rats. Panel C depicts the rate of ethanol oxidation by control hepatocytes and those isolated from PH-rats after several times post-surgery. Symbols at the top of each panel. Statistics as follows: *$p < 0.01$ against the control group.

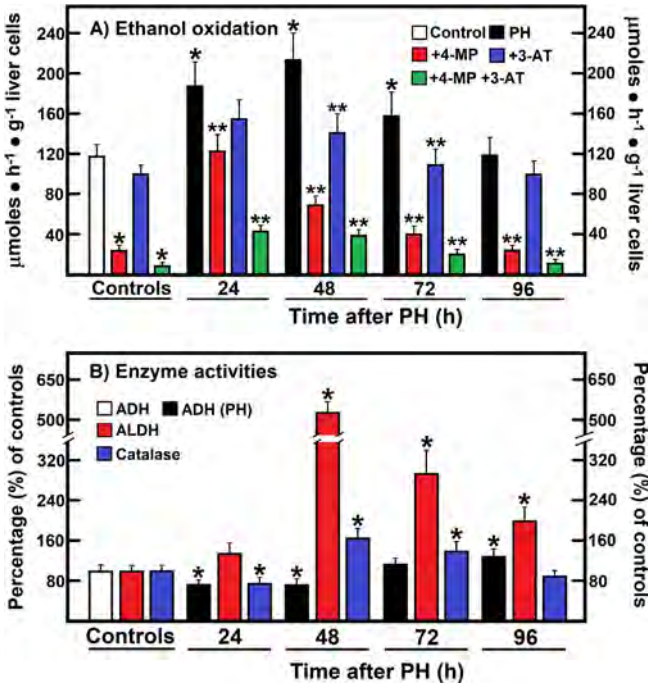

Fig. 3. Effect of inhibitors of ethanol-oxidizing enzyme pathways on ethanol catabolism by control and regenerating liver cells, and cytosolic activities of ADH, ALDH, and catalase. Results are expressed as mean ± SE of five individual observations per experimental point. Rates of ethanol oxidation were 120 ± 11, and 265 ± 24 µmoles • h^{-1} • g^{-1} of liver cells for control and hepatocytes from regenerating livers, respectively (panel A). In panel B, enzyme activities are expressed as percentage of the control values (22 ± 3 nmoles • min^{-1} • mg^{-1} of protein for ADH, 10 ± 2 nmoles • min^{-1} • mg^{-1} of protein for ALDH, and 310 ± 45 kcat • g^{-1} of total protein for catalase. Symbols at the top of each panel. Statistics: *$p < 0.01$ vs. the control group, and **$p < 0.01$ vs. the group with PH.

of glucose (5 mmoles • L^{-1}), isolated cells from regenerating livers showed a pronounced increase in ethanol oxidation (mainly during the first 48 h after surgery). At 96 h after PH, these liver cells oxidized ethanol at a similar magnitude to that found in hepatocytes from sham-operated controls (Fig. 2C).

3.3. Ethanol oxidation by hepatocytes isolated from proliferating livers and the participation of the main ethanol-oxidizing pathways

The relative contribution of the main enzymatic pathways for ethanol oxidation in hepatocytes was examined using "specific inhibitors" for ADH, catalase, and cytochrome P-4502E1 (Fig. 3). In "quiescent" liver cells, addition of 4-MP (the ADH inhibitor) decreased ethanol oxidation up to 80–85%, whereas the catalase-inhibitor (3-AT) only caused a 10–15% inhibition of ethanol disappearance. Diallyl sulfone, inhibitor of cytochrome P-450 2E1 (CYP2E1), accounted for only < 5% of the overall ethanol oxidation by control hepatocytes; moreover, the relative contribution of CYP2E1 in ethanol oxidation by hepatocytes from PH-rats was of 5, 4, 5, and 5%, at 24, 48, 72, and 96 h after surgery.

Control hepatocytes incubated in the presence of 4-MP and 3-AT showed about a 95% inhibition of ethanol catabolism (Fig. 3A). In isolated hepatocytes from proliferating livers, the contribution of the ADH pathway, as the main ethanol-oxidizing system, was much lower. The 4-MP only inhibited 45% of ethanol oxidation (at 24 h after surgery; Fig. 3A), while the magnitude of inhibition on ethanol consumption elicited by 3-AT and that of diallyl sulfone was quite similar in these cells, when compared to control hepatocytes. Indeed, addition of both, 4-MP and 3-AT, was only capable of inhibiting up to 70% of the increased ethanol oxidation found in liver cells from proliferating livers (Fig. 3A). Two days after surgery, the contribution of ADH to ethanol oxidation started to increase in proliferating liver cells, and a higher inhibitory effect of 3-AT was noted. Thus, the combination of both inhibitors of the ethanol-oxidizing pathway blocked ethanol metabolism at up to 90% at this time post-surgery (Fig. 3A). Hepatocytes, obtained 96 h after PH, oxidized ethanol and responded to the used inhibitors at the same magnitude as those from control animals (Fig. 3A).

Activities of the two main oxidizing-systems for ethanol largely contrasted with the rate of ethanol oxidation found in hepatocytes from regenerating livers (Fig. 3B). Cytosolic ADH activity was diminished as early as 24 h after PH remaining decreased up to 48 h post-surgery, and returned to the control value, thereafter (Fig. 3B). On the contrary, total activity of catalase (cytosolic and peroxisome activities) showed a mirror image in relation to that of ADH. Despite that catalase was also inhibited at 24 h after PH, it sharply augmented 48 h after surgery, returning to the control values within 3 to 4 days after PH (Fig. 3B). Moreover, ALDH activity, which removes acetaldehyde from the cytoplasm (low-affinity ALDH), showed changes evoking a mirror-image with respect to ADH (Fig. 3B). For instance, a maximum increase in ALDH activity was noted at 48 h after surgery, the time at which ADH was significantly lower as compared to controls. Thereafter, the augmented ALDH activity decreased progressively (72 to 96 h post-PH), whereas ADH increased now as compared to control livers (Fig. 3B).

3.4. Ethanol oxidation after inhibition of mitochondrial electron transport chain and the activity of the malate-aspartate shuttle

Rotenone, an inhibitor of site I of the mitochondrial electron chain, induced the same percentage of inhibition on ethanol oxidation in both normal and proliferating hepatocytes along the first 48 h after surgery (Fig. 4A). Unexpectedly, rotenone was less effective in inhibiting ethanol oxidation in cells isolated from PH-rats 96 h after surgery. Inhibition of AST activity by amino-oxyacetate (reduced activity of malate-aspartate shuttle) exerted a very small effect on hepatocyte's ethanol oxidation in control and at 24 after PH (Fig. 4A). However, apparent participation of the malate-aspartate shuttle in ethanol oxidation by proliferating hepatocytes (48 to 96 h after PH) was substantially increased (Fig. 4A).

3.5. Liver mitochondrial activities of hydrogen translocating shuttles and their involved enzyme activities

In the same context, the supplemented (reconstituted with missing cytosolic metabolites and enzymes) activities of malate-aspartate and α-glycerophosphate shuttles were determined in mitochondrial preparations (Fig. 4B). The activities of both mitochondrial shuttles were similar in control and PH-animals during the first 3 days after surgery; however, in PH-rats (4 days post-surgery), mitochondria preparations depicted enhanced activity of both pathways, mainly that of the α-glycerophosphate shuttle (Fig. 4B). The lack of early changes in the activity of the malate-aspartate shuttle in the regenerating liver (24 h after PH) contrasted with the measured activities of the participating enzymes, namely AST and MDH (Table 1). For instance, whereas the cytosolic activities of AST and MDH were not significantly modified by PH during the first 24 h after surgery, both AST and MDH activities were decreased in mitochondria from PH-animals (12–24 h after surgery; Table 1). Thereafter, mitochondrial AST and MDH activities were normalized (data not shown).

3.6. Participation of ROS and LP By-products in the rate of ethanol oxidation by hepatocytes from control and PH-rats

Since a remnant 25 to 30% of ethanol oxidation did not seem to be mediated by the main ethanol-oxidizing enzymes present in the proliferating hepatocytes (at early post-surgery times), probable non-

enzymatic routes were searched for; focusing especially on the hydroxyl radicals-mediated ethanol oxidation, which is thought to play a minor role in in vivo ethanol catabolism [33]. Addition of thiourea, a scavenger for hydroxyl radicals, did have a slight inhibitory effect on ethanol oxidation by control hepatocytes, but elicited up to 30–42% inhibition of the stimulated ethanol catabolism in proliferating livers (24 h after PH). Nonetheless, the inhibitory effect of thiourea rapidly declined, reaching the control value at 4 days after PH (Fig. 4A).

Since data support that an important fraction of ethanol catabolism could be mediated by a non-enzymatic pathway, depending on the generation of free oxygen radicals, liver sub-cellular levels of lipid peroxidation by-products (TBARS) were determined. Fig. 5B reveals that whole homogenate levels of aldehydic products derived from LP events were greatly enhanced in fractions obtained from hepatocytes at different times post-PH. This significant increase was mainly accounted for by augmented TBARS levels in the cytosolic and plasma membrane fractions (Fig. 5B). A maximum peak of cytosolic LP was found at 24 h after PH and was still significantly higher 48 h after surgery; thereafter, this parameter was promptly normalized (Fig. 5B). Indeed, increased amount of LP by-products coincided with the enhanced ethanol oxidation by hepatocytes from animals subjected to PH, which was sensitive to inhibition by thiourea (Fig. 4A).

When animals subjected to PH where in vivo administered with ethanol, the subcellular patterns for TBARS content was significantly modified (Fig. 5). During the first 48 h after PH, ethanol administration indeed promoted an unexpected diminution in either cytosol or plasma membrane fractions, when compared with PH-animals treated with the ethanol vehicle (Fig. 5B and C). On the contrary, ethanol treatment to rats undergoing PH elicited a sustained increase of liver microsomal LP (24 to 72 h after surgery; Fig. 5D), which could be related somehow to endoplasmic reticulum stress.

3.7. Changes in hepatocyte's redox states after ethanol oxidation

As previously mentioned, hepatocyte's capacity for oxidizing ethanol is accompanied by changes mainly in the cytoplasmic redox state. Therefore, the levels of lactate/pyruvate and α-glycerophosphate/dihydroxyacetone phosphate, as markers of cytoplasmic redox state, were measured in isolated hepatocytes during ethanol oxidation.

INFORME DE LABORES 2019

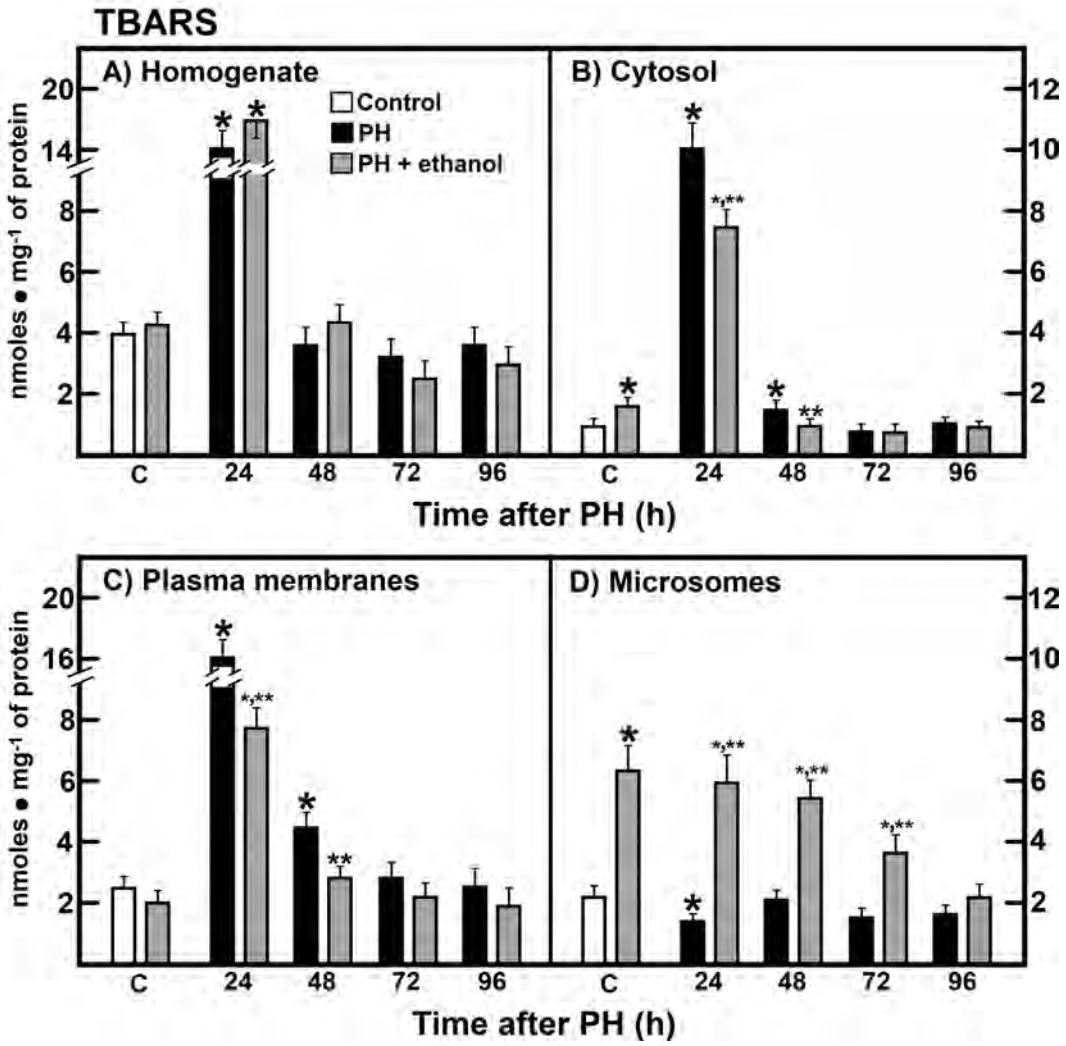

Fig. 5. Levels of TBARS in subcellular fractions from sham-operated and PH-rats, after in vivo ethanol administration. Results are expressed as mean ± SE of five individual observations per experimental point. Levels of lipid peroxidation by-products, mainly malondialdehyde, are expressed as thiobarbituric acid reactive substances (TBARS), determined in whole liver homogenate (panel A), cytosol (panel B), mitochondrial fraction (panel C), and those in microsomes (panel D). Symbols at the top of panel A. Statistical significance as pointed out in Fig. 3.

Determination of ß-hydroxybutyrate and acetoacetate were also done to calculate the mitochondrial redox state (Fig. 6). In control liver cells, ethanol oxidation diminished pyruvate and dihydroxyacetone phosphate levels whereas it increased those of α-glycerophosphate (not shown). The latter led to increases in the lactate/pyruvate and α-glycerophosphate/ dihydroxyacetone phosphate ratios (Fig. 6A). Consequently, the cytoplasmic NAD/NADH was strongly decreased when calculated by means of the equilibrium constants for lactate and α-glycerophosphate dehydrogenases (Fig. 6B). When ADH activity was inhibited by 4-MP, the ethanol-induced shift of cytoplasmic NAD/NADH ratio was largely prevented in control hepatocytes (Fig. 6A and B). Despite that ethanol did not significantly decrease mitochondrial NAD/NADH redox state (Fig. 6A), addition of 4-MP promoted a shift of mitochondrial NAD/NADH to a more oxidized state (Fig. 6A and B).

In cell preparations obtained from regenerating livers, 24 h after PH, ethanol oxidation induced smaller increases of the lactate/pyruvate and α-glycerophosphate/ dihydroxyacetone phosphate ratios (Fig. 6A), as well as a lower reduction of the cytoplasmic NAD/NADH ratio (Fig. 6B). The 4-MP also afforded protection against the ethanol-induced shift of the cytoplasmic NAD/NADH ratio, but at a much lesser magnitude. Interestingly, proliferating hepatocytes showed a more oxidized mitochondrial NAD/NADH, which was readily reduced by ethanol oxidation (Fig. 6B). Here, 4-MP failed to restore the mitochondrial NAD/NADH redox potential in the presence of ethanol (Fig. 6B).

4. Discussion

To our knowledge, the present constitutes the first study focused on investigating the participation of the known metabolic pathways to oxidize exogenous ethanol, in proliferating rat liver cells, induced by in vivo two-thirds PH. Having demonstrated that the regenerating liver shows a much enhanced metabolism of ethanol in vivo [9], the present work is an attempt to elucidate the main hepatic factors involved in the increased ethanol utilization by proliferating liver cells, as well as by subcellular fractions (mitochondria). The latter is particularly important, because we have previously shown an early decrease in the activities of the main liver ethanol-oxidizing enzymatic systems, at the onset of PH-induced liver regeneration [5]. First, we found in the in vivo experiments that removal of an important fraction of liver mass clearly influenced ethanol bioavailability in PH rats (Fig. 1). The present study shows that during the first 24 h after PH, ethanol reaching the systemic circulation, after its intragastric administration, varied in PH animals. After PH, ethanol administration elicited lower BACs than sham-operated rats (Fig. 1), which was mainly due a decreased gastric absorption for ethanol or to an increased gastric first-pass metabolism for ethanol [9]. Our results clearly show that the capacity of the

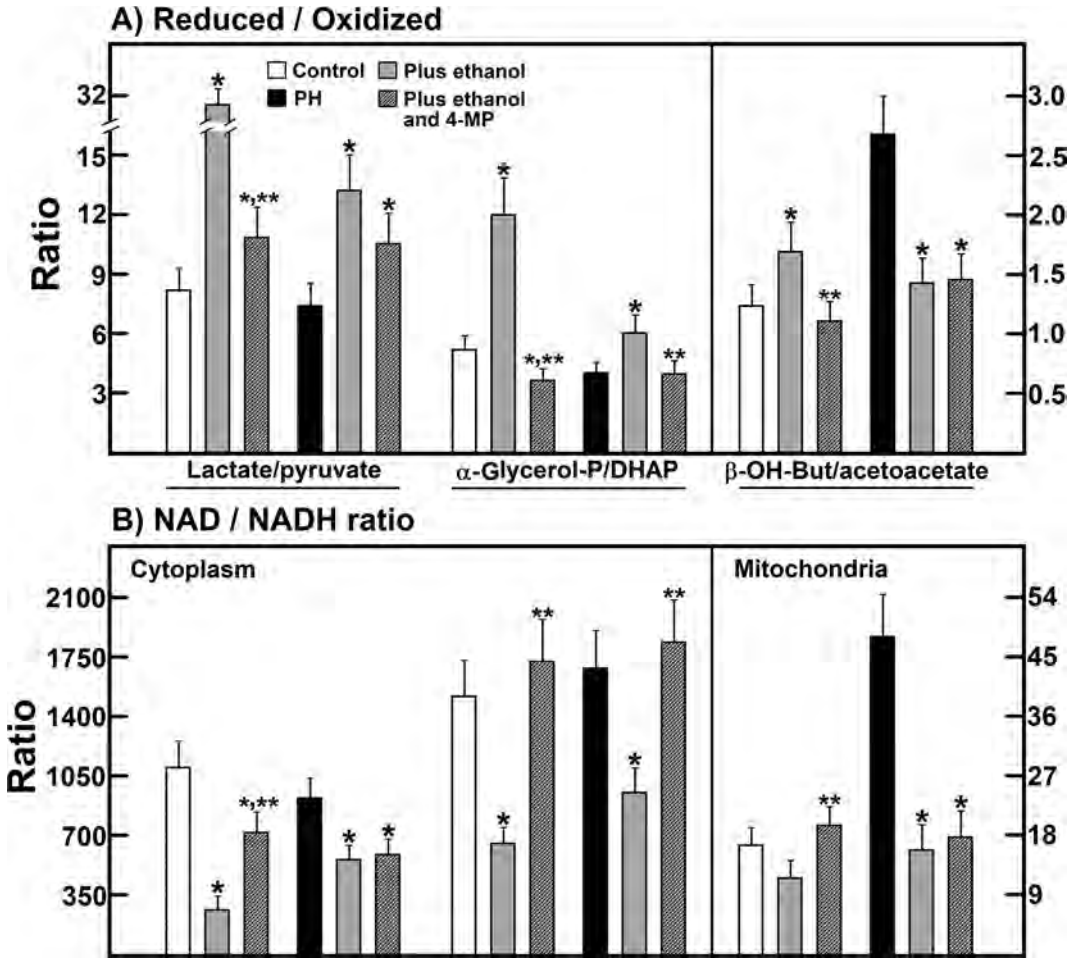

Fig. 6. Changes in cytoplasmic and mitochondrial redox state induced by ethanol oxidation in control and regenerating hepatocytes. Hepatic levels of redox-pair metabolites were determined enzymatically; the cytoplasmic and mitochondrial redox potentials (NAD/NADH ratios) were calculated from the reduced/oxidized metabolite ratios, as described under Methods. Results are expressed as mean ± SE of five individual observations per experimental point. Symbols for each experimental condition at the top of the Figure. Statistical significance as indicated in Fig. 3.

remnant liver (after 24 h of surgery; Fig. 1) to oxidize ethanol, was largely increased, which might potentiate the deleterious effect that ethanol exerts on liver regeneration.

Proliferating rat liver cells, such as those induced by PH, showed particular features in oxidizing ethanol in vitro: 1) Either in the presence or absence of glucose, isolated liver cells from animals subjected to PH had increased ethanol oxidation, despite that the main enzymatic pathways were initially decreased in these cells; 2) addition of inhibitors for ADH, catalase, and the CYP2E1 blunted ethanol oxidation in more than 90% in normal cells, whereas they only inhibited ethanol disposal at around 70% in proliferating liver cells; 3) scavengers of ROS did not significantly affect ethanol oxidation in control cells, but inhibited up to 30% of ethanol catabolism by proliferating hepatocytes; 4) inhibition of the ADH (by 4-MP) abolished ethanol-induced shifts in cytoplasmic and mitochondrial redox potentials in normal hepatocytes, while a more reduced mitochondrial redox state persisted in liver cells from proliferating livers.

Liver regeneration constitutes a unique model to study signal transduction and cell cycle events in a synchronized manner in vivo, and the extent and timing of liver regeneration are well known even to use interventional modifiers. After PH, stars the pre-replicative phase (G0 to G1), reaching the first peak of DNA synthesis 24 h post-surgery, and many participating factors lead cells to replicate (G2 cells) entering into mitosis (at 48 h post-PH). Thereafter, a second peak of DNA synthesis (72 h) is recorded, and at 96 h post-PH, many liver cells are returning to G1. In this time period (24 to 48 post-PH), we have proposed that ADH and, probably, ALDH could be actively using endogenous substrates involved in PH-induced rat liver regeneration [21]. Therefore, the diminished ADH-mediated ethanol oxidation might promote the participation of alternative pathways for the liver elimination of ethanol.

There are at least two hypotheses concerning the liver metabolic control in ethanol oxidation. The first states that this event is limited by the rate at which NADH can be re-oxidized to NAD [34], and the second hypothesis proposes that the rate of ethanol metabolism is regulated by the amount of ADH in the liver [11]. Although ADH activity is the major rate-determining enzyme, metabolic control is shared among several steps, including aldehydes dehydrogenase. Enzyme activities of the hydrogen shuttles for the transfer of cytosolic NADH into mitochondria and the electron transport chain, which are involved in the re-oxidation of the NADH that is formed during reactions driving to dehydrogenation, are also primary liver sites for the control of ethanol utilization [14,35].

Despite that ADH activity in the remnant liver after PH does not significantly change after surgery, the rate of ethanol removal is significantly faster in PH-rats [36]. In this context, Fig. 1 shows that the regenerating liver (24 h after PH) has a much enhanced capacity to metabolize ethanol, which seemed to be the main factor affecting ethanol pharmacokinetics in these animals. Here, in vivo treatment with 4-MP, a specific inhibitor of ADH, demonstrated that liver ADH was the main via oxidizing ethanol in both controls and PH-rats. However, the differential inhibitory effect of 4-MP observed in both

experimental groups could indicate that other ethanol-metabolizing systems are actively participating in removing ethanol from the systemic circulation (Fig. 1). Similarly, hepatocytes isolated from PH-rats had an enhanced in vitro oxidation of ethanol (Fig. 2).

In the liver, there is a second system located in hepatic cell peroxisomes, where ethanol oxidation is simultaneously coupled to decomposition of a H_2O_2 molecule through the catalase reaction [37]. In addition, a third enzymatic pathway for ethanol oxidation to acetaldehyde is constituted by the microsomal ethanol oxidizing system (MEOS), which requires the participation of a cytochrome P-450 isozyme (namely CYP2E1) and NADPH, reacting with an oxygen molecule and forming H_2O_2 [38]. The contribution of each enzymatic pathway to ethanol oxidation has been subjected to debate, but it is widely accepted that liver ADH plays a pivotal role in ethanol metabolism. Compared to ADH, the MEOS requires higher ethanol levels for full saturation and maximal velocity; hence, with high ethanol concentrations or after chronic ethanol consumption, the contribution of this non-ADH pathway is increased [39]. Moreover, it has been claimed that the physiological rate of H_2O_2 generation largely limits peroxidation by catalase [37].

The present results, using specific inhibitors for each enzymatic pathway, pointed toward ADH as the quantitatively most important pathway for the oxidation of ethanol to acetaldehyde, in the hepatocytes obtained from rats subjected to PH. In addition, the relative contribution of the non-ADH enzyme pathways (catalase and MEOS) was not modified in these cells (Fig. 3A). Since inhibitors used here can potentially block more than one enzymatic pathway for ethanol oxidation [40,41], this could complicate assessment of the relative participation of the main enzymatic pathways for ethanol oxidation. However, while a total blockade of ethanol oxidation was achieved when the main enzymatic systems were inhibited in normal liver cells, a remaining 30% of ethanol catabolism seemed to be carried out by a non-enzymatic mechanism in proliferating liver cells. As regard to the CYP2E1, this metabolizes and activates many toxicological substrates, including ethanol, generating in turn, ROS, such as superoxide, hydrogen peroxide and even hydroxyl radical [42]. Using Western blot analysis, it was found a significantly decreased expression of CYP 2El apoprotein as well as the dependent monooxygenase activities, after PH in rats [43], or not a significant change on CYP2E1 apoprotein expression has been also reported [44]. In this context, it is though that a close relationship between the periodicities of thymidine kinase activity and a decreased microsomal LP has some role in modulating the cell division process [27]. Whereas, an enhanced expression of CYP 2R1 and CYP 26A1 is important in the differentiation of oval cells into hepatoblast-like cells in the injured mice liver [45], an imputable role of the CYP 2E1 in the proliferating liver is still unknown.

On the other hand, the putative non-enzymatic pathways, here reported, required the presence of ROS (presumably hydroxyl radicals), which were readily inhibited by free radical scavengers (Fig. 4A), and closely correlated with cytoplasmic levels of lipid peroxidation by-products found in PH-rats (Fig. 5B). This non-enzymatic system has been previously shown to be functional in vitro and depends on iron chelation, through the Fenton reaction, which drives a spontaneous reaction given between the hydroxyl radical and ethanol [32,46]. The latter could well explain the enhanced ethanol oxidation shown by regenerating hepatocytes and, in turn, largely contribute to the deleterious action of ethanol on the regenerating liver, probably through perturbations in the cellular redox state and the production of acetaldehyde.

Some of the well-recognized effects of ethanol on hepatic metabolism are due to a substantial reduction of cytoplasm NAD (increased lactate/pyruvate ratio), promoted by a steep decline in pyruvate levels [47]. Thus, re-oxidation of cytosolic NADH partly limits the rate of ethanol oxidation and would cause several of the metabolic effects of ethanol [48]. During ethanol oxidation, fluxes through various dehydrogenases are sufficient to equilibrate both hydrogen atoms of cytosolic NADH [49]. For instance, activity of malate dehydrogenase, connected via the malate-aspartate shuttle to mitochondria [50], is high enough to account for the near-equilibrium of the hydrogen atoms of NADH. The generated cytoplasmic reducing equivalents are transferred to mitochondria by both the malate-aspartate and α-glycerophosphate shuttles [51] and, in combination with the activity on the mitochondrial respiratory chain, affect ethanol oxidation [18,37].

Using amino-oxyacetate, which inhibits both cytoplasmic and mitochondrial AST activities [52], the rates of gluconeogenesis and ureagenesis, and the oxidation of ethanol by hepatocytes are decreased, due to limitation of re-oxidation of cytosolic NADH generated by the ADH reaction [53]. In the same context, rotenone inhibits ethanol oxidation even in the presence of largely supplemented shuttles for reducing equivalents transport [54]. In both, normal and regenerating liver cells (at early times post-surgery), inhibition of the malate-aspartate shuttle had little effect on the rate of ethanol oxidation, whereas blocking the mitochondrial electron transport chain (by rotenone) induced an almost complete inhibition of ethanol oxidation (Fig. 4A). However, hepatocytes taken from PH-rats at later times post-surgery were more sensitive to the inhibition of the malate-aspartate shuttle and, surprisingly, a less inhibition was achieved with rotenone. These data correlated well with the changes previously reported in the liver cytoplasmic and mitochondrial redox states after PH [10], and found in hepatocytes obtained from regenerating livers (Fig. 6A and B). Despite that the activity of the malate-aspartate shuttle was not significantly modified by PH (Fig. 4B), mitochondrial oxidative capacity seemed to closely correlate with the ability of regenerating livers to oxidize ethanol. Indeed, our group reported that mitochondrial function, LP, and the onset of MPT are tightly regulated during progression of PH-induced liver regeneration [55].

Despite that acetaldehyde accumulates scarcely during alcohol oxidation because of its rapid conversion to acetate by aldehyde dehydrogenase, a number of ethanol-related complications may be explained by acetaldehyde production. Decreased mitochondrial NAD/NADH ratio caused by ethanol oxidation is attributable to acetaldehyde oxidation [56], as well as increased lipid peroxidation and microtubular alterations with its adverse effects on various cellular activities, including disturbances of cell division [57]. This is particularly important in view that acetaldehyde produced by the non-ADH pathways is degraded more slowly, which would contribute, indeed, to the alcoholic liver disease [58].

The LP might be the most important reaction involved in alcohol-induced liver damage [59,60] by the formation of toxic aldehydes, including MDA and 4-hydroxynonenal (4-HNE). These products, in a similar fashion to acetaldehyde, are able to react with the DNA to form exocyclic DNA adducts [61], which could be exacerbated by high concentrations of lactate during ethanol oxidation. Indeed, data indicated that early alcohol ingestion in rats subjected to PH promotes a significant change in the PH-induced LP, mainly in the microsomal fraction, probably suggesting the onset of endoplasmic reticulum stress.

It is well documented that ethanol metabolism impairs the regenerative capacity of the liver [1,3,4], and an accumulation of acetaldehyde and increased mitochondrial NADH/NAD ratio has led to an important ethanol-induced reduction in cell numbers or growth of a rat hepatic tumor cell line [19]. In fact, replenishing NAD + reduces oxidative stress and activates sirtuin-1 PGC-1α-induced mitochondrial biosynthesis, therefore, protecting against liver lipid accumulation, mitochondrial dysfunction, and promoting liver regeneration [62].

In conclusion, present results clearly show that regenerating adult liver cells (after PH) had an enhanced ethanol oxidation, largely attributable to a non-enzymatic mechanism for ethanol oxidation. This oxidative mechanism for ethanol acted mainly during the first 2 days after surgery, and involved acetaldehyde production and a consequent shift of mitochondrial NAD/NADH ratio to a more reduced state, which was not blocked by 4-MP (Fig. 3). Results suggest that an unusual ethanol metabolism, by the regenerating liver, could partly be

responsible for the deleterious actions of ethanol on liver regeneration induced by PH in rats, especially due to a “desynchronized” LP dependent on subcellular localization and temporal bases. The finding that an ADH and catalase-independent mechanism is readily oxidizing ethanol in the regenerating rat liver could have significant clinical implications.

Abstract

Objectives: Lung metastasizing leiomyomatosis (LML) is an infrequently diagnosed pathology developed after sexual maturation, commonly preceded by uterine myomas. Symptoms can include difficulties to breathe, cough, dyspnea and pain, because of mechanical obstruction exerted by expanding local growing leiomyomas. Lung leiomyomas are normally detected by imaging studies, but nowadays the precise diagnosis demands histological characterization of biopsies obtained from the affected tissues. The purpose of the present study was to determine the presence of genomic alterations in circulating cells of LML.

Methods: Immunohistochemical characterization of a lung biopsy extracted by thoracoscopy was performed. Pathologic proliferative smooth muscle cells were observed in a major lung metastasizing nodule, with a growing pattern similar to a uterine myoma. The presence of cellular linages different to smooth muscle cells was discarded by testing the presence of a battery of molecular markers. Also, a normal karyotype was determine by GTG-banding cytogenetic study, but a high density microarray analysis revealed six submicroscopic chromosomal regions displaying

INFORME DE LABORES 2019

genomic abnormalities: microduplications were detected on chromosomes 4, 14, 17 and 22; and microdeletions on chromosomes 8 and 10.

Conclusion: This study remarks the relevance of submicroscopic chromosomal analysis of unusual pathologic conditions such as Benign Metastasizing Leiomyomatosis. This propitiate a better understanding of the molecular basis on the development of the pathology, in order to reckon on minimally invasive diagnostic methods, and to design appropriate treatments.

KEYWORDS

benign metastasizing leiomyomatosis, copy number variations, lung metastasizing leiomyomas, uterine myomas

1 | INTRODUCTION

Benign Metastasizing Leiomyomatosis (BML) is characterized by abnormal proliferation of smooth muscle cells presented as secondary neoplasms in women, appearing from several months up to 26 years after presenting uterine myomas.[1] Uterine leiomyomas constitute the most frequent neoplasms in women, affecting up to 20%-30% of the female population over 30 years old.[2] Infrequently leiomyomatosis is detected outside the uterus, this condition is represented by peritoneal disseminated, intravenous, parasitic, retroperitoneal and BML.[3]

Among the sites where secondary leiomyomas can grow up, lungs are the most frequent organ presenting metastasis, although other tissues, such as mesentery, mediastinum, heart, or even dorsal spine and bones can also be affected.[4] In many cases, the lesions are indolent and discovered rather incidentally; the clinical signs vary depending on the location of metastasizing leiomyomas. When lungs are affected, multiple well-defined pulmonary nodules sizing from millimetres to some centimetres in diameter can be detected by imaging routine chest examinations.[5] The symptoms can include cough, pain, or dyspnea and sometimes these are associated with conditions, such as pneumonia or bronchitis. The precise diagnosis of the disease currently demands analysis of affected pulmonary nodules by histopathological characterization of a thoracic biopsy.

Metastasizing leiomyomatosis constitutes a big diagnostic challenge; because of their appearance and distribution, benign leiomyomas could be misidentified. The most useful modalities for detecting extrauterine leiomyomas are ultrasonography, computed tomography, magnetic resonance imaging and positron emission tomography (PET). Typically, X-ray imaging appearance of pulmonary nodules in BML varies from solitary millimetric lesions to multiple lesions.[6]

Hysterectomy is typically accomplished as a common treatment for symptomatic uterine leiomyomatosis-affected patients,[7] but several secondary effects, such as urinary incontinence, cardiovascular diseases[8] or cognitive disorders are related to this procedure.[9] Hence, less invasive procedures as myomectomy or hysteroscopy are effective surgical alternatives for benign uterine leiomyomatosis.[10,11] The clinical course of the pathology inside and outside the uterus is hormone-dependent, so when surgery is not carried out, recommended pharmacological alternative treatments include the aromatase inhibition, selective progesterone-receptor modulators and GnRH agonists.[12]

Aetiology and risk factors of BML remain unclear but several reports have provided evidences of intravenous leiomyomatosis dissemination, embolism of benign leiomyoma cells from myometrium, or independent and multifocal proliferation of smooth-muscle cells depending on oestrogenic hormones.[13,14] Cytogenetic reports of the BML tumours are non-convergent; the clonality between primary and secondary neoplasms still remains in controversy. The present study was focused on the immunohistological characterization of uterine and lung leiomyomas which appeared several years after first myomas detection and a hormone treatment. Additionally, it was investigated the presence of chromosomal abnormalities and genomic copy number variations (CNVs) in peripheral blood cells.

2 | MATERIALS AND METHODS

2.1 | Case history

The patient presented menarche at 10 years old, and consumed oral oestrogens between 17 and 24 years old because of dysmenorrhea. Uterine leiomyomas and ovarian cysts were detected for the first time at 32 years old; they were resected. The histological characterization of two excised myomas, sizing 8 and 14 cm, showed a smooth muscle cellular conformation, so they were diagnosed as benign leiomyomas. At the age of 41 years old, with a referred history as a passive smoker, the patient entered to the hospital referring shoulder and pleural chest pain, and dyspnea.

INFORME DE LABORES 2019

Laboratory studies at the hospitalization moment included blood chemistry, tumour markers and hormonal profile; all of them reflected normal parameters (CA 15-3 antigen: 11.3 U/mL; CA 19-9 antigen: 12.96 U/mL; CA 125 antigen: 20.6 U/mL; carcinoembryonic antigen: 0.49 ng/mL; estradiol: 77 pg/mL; luteinizing hormone: 8.0 mUI/mL; gonadotrophin chorionic fraction beta 0.3 mUI/mL; progesterone: 0.2 ng/mL). She had never been pregnant and reported a negative family record of cancer. Imaging studies were performed for detection of possible abnormalities in chest and lungs at the moment of hospitalization, and PET was developed after treatment to discard any derivative abnormality.

2.2 | Immunohistochemistry

Biopsies of lung and uterine nodules were fixed in paraformaldehyde solution after resection by surgery, and paraffin imbibed for later characterization by immunohistochemical assays. Briefly, slices sizing 4 μm in thick were obtained from each tissue and deparaffinized in xylene; then, slices were hydrated in ethanol decreasing concentration series. Tissues-morphology was tested firstly in hematoxylin-eosin stained sections. Antigen epitopes retrieval was performed by boiling citrate-buffered (pH 6.0) slices in a pressure cooker. The endogenous peroxidase activity was blocked by incubating in a 3% H_2O_2/methanol solution during 10 minutes at room temperature, and rinsed in phosphates buffered solution for 5 minutes. Afterward, tissue sections were incubated with the corresponding primary antibody, as specified below, for 40 minutes; then, phosphate buffered saline rinses were carried out twice followed by incubation with the secondary antibody conjugated with peroxidase enzyme for 30 minutes. Peroxidase activity was revealed by incubation with diaminobenzidine/H_2O_2 for 5 minutes. Appropriate immunoreactive tissue samples were stained in parallel as positive controls for each antibody. Slices were subsequently washed in water, counterstained with hematoxylin, dehydrated and mounted. The primary antibodies employed for the characterization of tissue slices were: Bcl-2 (BioSb, mouse monoclonal; 1:100 dilution); calretinin (BioSb, rabbit monoclonal; 1:250 dilution); cytokeratin AE1/AE3 (Cell Marque, mouse monoclonal; 1:200 dilution), desmin (Bio Genex, mouse monoclonal; 1:200 dilution). Smooth muscle actin (Cell Marque, mouse monoclonal; 1:1000 dilution), and S-100 protein (Cell Marque Mouse monoclonal; 1:120 dilution).

2.3 | GTG-bands and karyotype

A fresh peripheral blood sample was taken from the patient. Lymphocytes were isolated, cultured and harvested using standard methods. Chromosome preparations were banded with Wright-Giemsa and observed under microscope. To determine the karyotype a minimum of 50 metaphases were analysed.

2.4 | Microarray CytoScan HD

A fresh peripheral blood sample was centrifuged at 4500 rpm during 10 minutes at room temperature. 200 μL of the buffy coat fraction was processed to isolate genomic DNA (gDNA) using the QIAamp DNA Mini Kit, according to the manufacturer's protocol (Qiagen, Gaithersburg, Maryland). Concentration and purity of the extracted DNA was determined by spectrophotometry in a NanoDrop 1000 (Thermo Fisher Scientific, Waltham, Maryland). Then, the DNA was processed to determine CNVs and loss of heterozygosity (LOH) with an Affymetrix CytoScan HD array (Thermo Fisher Scientific), following the manufacturer's instructions.

Briefly, 250 ng of gDNA were digested with Nsp I. Then, DNA fragments were joined to Adaptors using T4 DNA ligase. The mix was used as template for DNA amplification. The PCR reaction was developed using the Titanium® DNA amplification kit (Takara, Clontech. Mountain View, California). DNA amplification was corroborated by electrophoresis in a 2% agarose gel, where ~150-2000 bp DNA fragments were observed. Concentration of purified DNA was determined by spectrophotometry. Then DNA was enzymatically fragmented using the case reagents. Fragmentation was verified by electrophoresis in a 4% agarose gel. Latter, DNA was labelled, and then mixed with the hybridization buffer. All the thermal varying programs were run in a thermo cycler Gene Amp PCR System 9700 (Applied Biosystems, Foster City, California). The DNA was injected into an Affymetrix CytoScan HD array. The covered array was incubated into a GeneChip Hybridization Oven 645. The array was washed and stained into a Gene Chip Fluidics Station 450 (Affymetrix), operated by means of the AGCC software (Thermo Fisher Scientific). Finally, the array was scanned using a GeneChip®3000 Scanner. The corresponding batch registration file was created in the Affymetrix GeneChip Command Console Portal. The array contains ~2.6 million copy number markers. Chromosome Analysis Suite (ChAS) software v3.2 (Thermo Fisher Scientific) was used after procedure for data analysis, where a minimum length of 100 000 base pairs (bp) was fixed to determine gains and losses; and 3 Mbp for LOH.

2.5 | Epigenetic *in silico* analysis

Epigenetic consequences involving deleted genomic regions were analysed based on available data from the Broad Institute, ID numbers 30003 and 30004, containing ChIP-Seq mapping of H3K4me1, H3K4me3, H3K27me3, H3K9me3 and CTCF binding profile in HUVEC cells. Human smooth muscle Hi-C data was loaded and analysed in the 3D genome

browser suite (http://promoter.bx.psu.edu/hi-c/) using the hg19 human reference sequence.

3 | RESULTS

3.1 | Imaging

Computed tomography and X-ray studies showed lungs with multiple irregular, bilateral nodular lesions suggesting a metastatic disease (Figure 1). Pleural effusion and an acute unspecific inflammatory process were noticed. No signs of malignancy or infections were detected.

One month after thoracoscopy, a PET of high resolution was accomplished to discard the presence of malignant tumours in the whole body of the patient. Intravenous non-ionic iodized contrast and 370 MBq of ^{18}F-FDG was administrated. After 60 minutes of rest, reconstruction images were taken from skull to the proximal third of thighs. It was observed a minimum focal increase in the glycolytic metabolism in lungs with multiple hypodense lesions, one of them with 35 mm in the major axis, localized in the lower left lobe. A 19 mm cyst was also detected in the same segment, possibly caused by postsurgical effects. Two cysts <5 mm were observed in segment 4 of liver. No focal lesions were detected in the rest of the body.

3.2 | Immunohistochemistry

Immunohistochemical characterization of an open thoracoscopy biopsy revealed benign proliferative smooth muscle fibres in lung nodules (Figure 2). The pathological growing pattern of the major lung metastasizing nodule was similar to the uterine leiomyoma, as revealed by hematoxylin and eosin staining (Figure 2A and H). Positive and specific reactivity was detected in the pulmonary nodule for smooth-muscle actin and desmin (Figure 2F and G). The neoplasic nature of the tissue was proved by positive staining for Bcl-2 (Figure 2E).

The negative cytokeratins staining excluded the epithelial nature of this neoplasm (Figure 2B); positive expression was detected in pneumocytes, as control (not showed). Likewise, negative expression for S-100 protein (Figure 2C), and calretinin (Figure 2D) allowed us to reject the presence of other tumour cells linages, such as schwannoma, melanoma or mesothelioma. Importantly, only several smooth muscle cells in the lung nodule were present as reveled by smooth muscle actin staining (Figure 2F), this indicates the migration of metastatic cells from uterus into lungs, probably throughout lymph vessels.

3.3 | Karyotype and molecular cytogenetics

The conventional GTG-banding cytogenetic analysis revealed a normal karyotype 46,XX in at least 50 well-defined metaphases.

The submicroscopic copy-number changes detected across the genome in the BML sample were: arr[GRCh37] 4q22.3(98593089_98768685)x3, 8p11.22(39247097_39386952)x1, 10q11.22(46981355_47147301)x1, 14q32.33(106207204_106736911)x3, 17q21.31(44212823_44784639)x3, 22q11.22(23146338_23258369)x3.

The microarray analysis identified six regions displaying CNVs: microduplications on chromosomes 4, 14, 17 and 22; and microdeletions on chromosomes 8 and 10 (Figure 3). Five of these CNVs correspond to rare alterations whose role on pathogenicity has not been well established (Table 1). Importantly, genes contained in the chromosome 10 (q11.22 deletion) modulate neurite outgrowth and branching[15]; as well as the gut–brain axis including neural, immune and endocrine signalling pathways implicated in anxiety and depression.[16]

The duplication in chromosome 17q21.31 includes the genes *ARL17A, ARL17B* and *NSF* encoding for molecular elements required for protein trafficking and intracellular vesicle-mediated transport.[17] Interestingly in the same segment, *KANSL1* was also duplicated; this gene encodes for a nuclear protein that is a subunit of two histone acetyltransferase complexes,[18] and therefore may be involved in chromatin remodelling and transcription regulation of several genes. Segments in chromosomes 14 and 22 encoding for a long non-coding RNA (lncRNA), and several microRNAs (miRNAs), were also amplified.

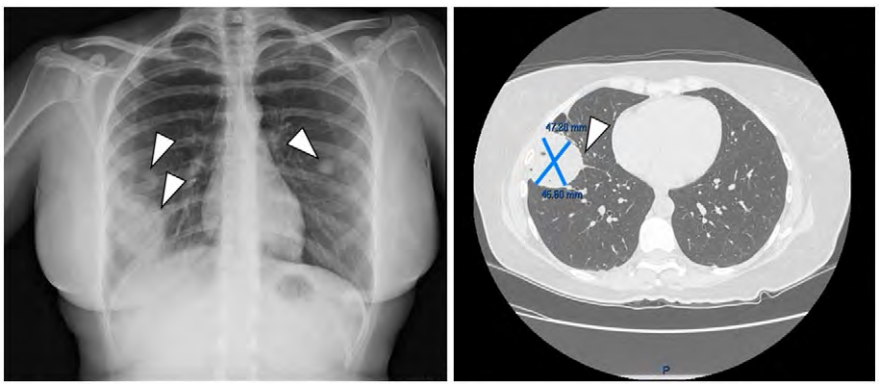

FIGURE 1 Chest radiography (left) presenting bilateral nodular lesions in lungs, indicated by arrowheads. Computed tomography scan (right) showing a well distinguished unilateral nodule sizing 47.20 × 45.60 mm (indicated by arrowhead), and several smaller nodules distributed bilaterally in lungs

INFORME DE LABORES 2019

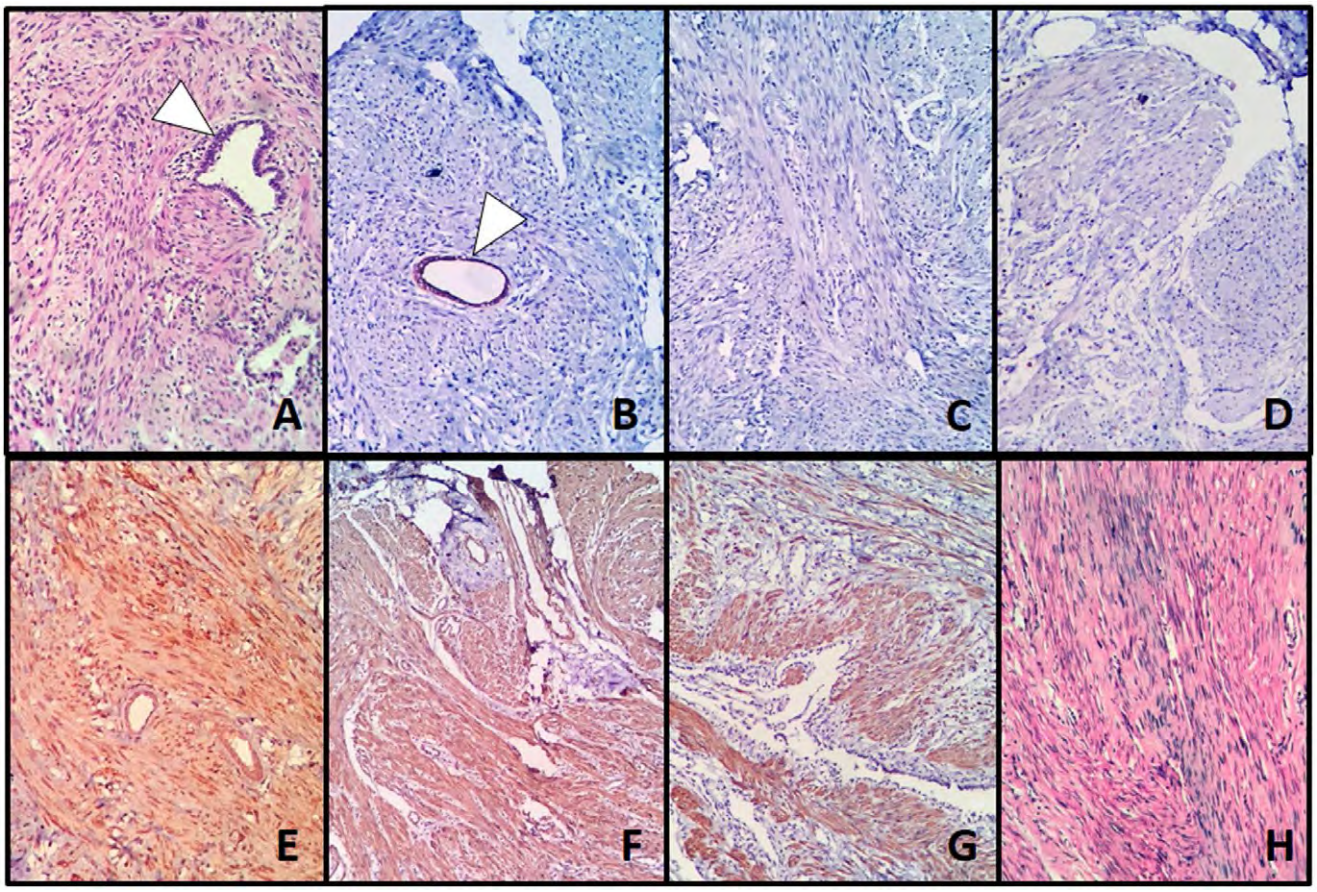

FIGURE 2 Immunohistochemical analysis of a lung metastasizing leiomyoma (LML). A, Hematoxylin and eosin staining of an LML section revealed proliferative spindle cells in random fascicles pattern; alveolar trapping is indicated with the arrowhead. Immunohistochemistry for B, cytokeratin was negative in lesion; positive signal was detected in the alveolar epithelium, as indicated by the arrowhead. No staining was observed for C, protein S-100, and D, calretinin. Positive and strong expression was detected with a diffuse cellular distribution pattern for E, Bcl-2, F, smooth muscle actin, and G, desmin. In H, a section of a uterine leiomyoma stained with hematoxylin and eosin showed similar cellular characteristics as the pulmonary lesion. Total magnification for all shown images is 100X

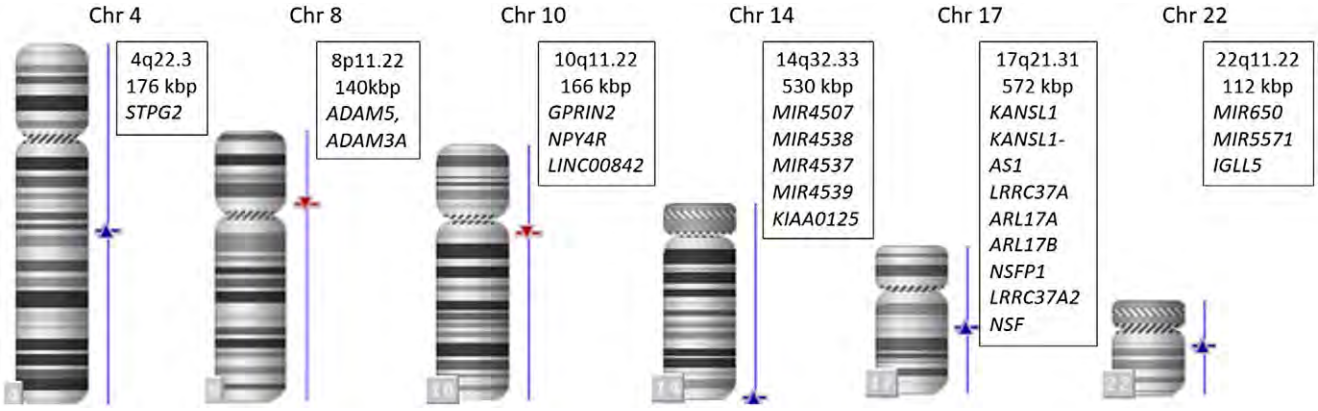

FIGURE 3 Genomic copy number variations (CNVs) observed in DNA from peripheral blood lymphocytes. ▲ represents microduplications, and ▼ represents microdeletions, which are mapped at the corresponding chromosomal band position. In each case, the size of the CNV and the gene content are indicated. Data files were generated using GeneChip Command Console Software, version 1.2, and analysed with the Chromosome Analysis Suite v3.2 using the human genome assembly GRCh 37/hg19 (July 2017), high resolution parameters, and the built-in reference model

INFORME DE LABORES 2019

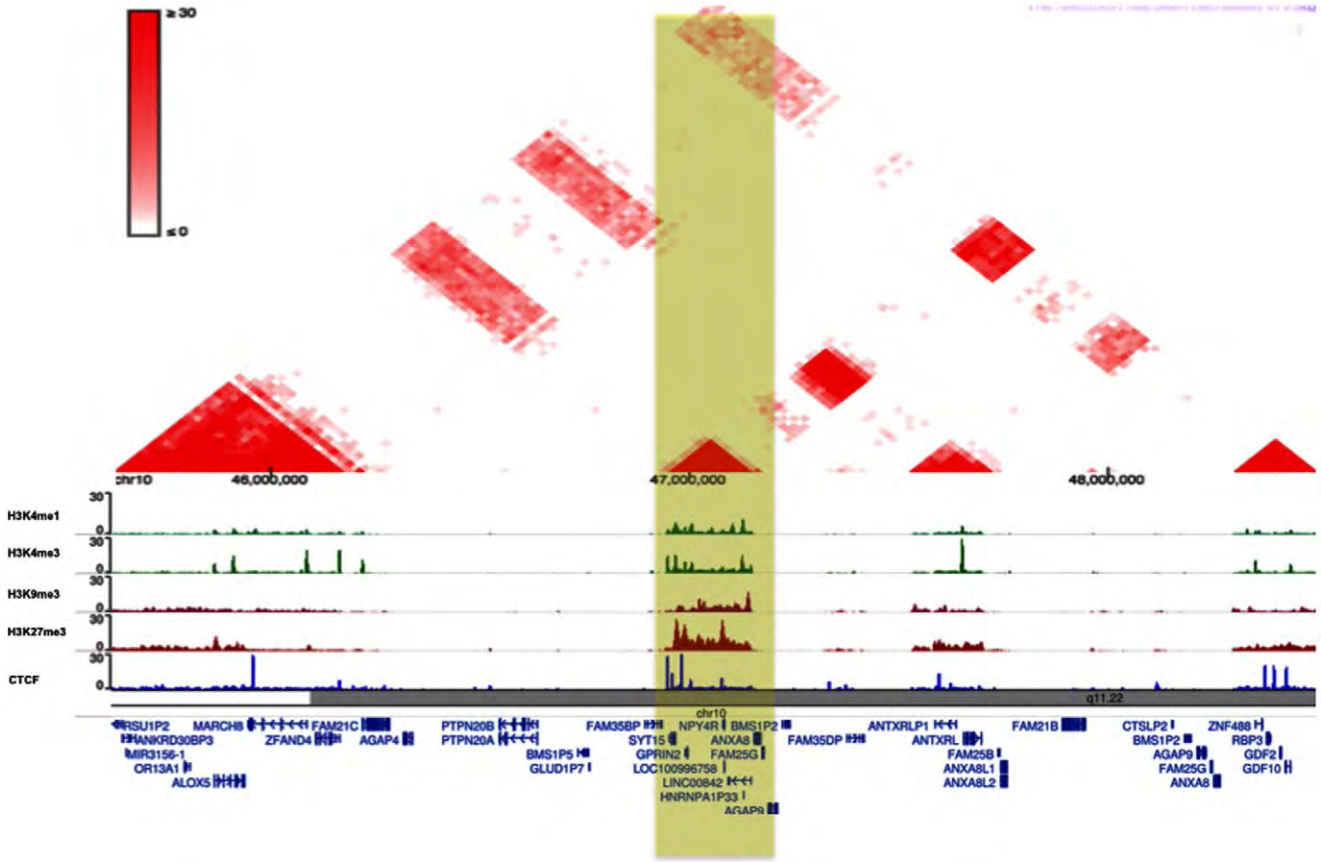

FIGURE 4 Epigenetic analysis of the 10q11.22 deleted region. The eliminated region (vertical shadowed-yellow bar) indicates the deleted genes, where dense histone modifications that mediate gene activation are enriched. Furthermore, the sequence contained in this locus corresponds to a stable domain (red triangle) that delimitates the region from the transcriptional effect of surrounding chromatin. Analysis was performed using available data from the Broad Institute, ID numbers 30003 and 30004, containing ChIP-Seq mapping of H3K4me1, H3K4me3, H3K27me3, H3K9me3 and CTCF binding profile in HUVEC cells. Human smooth muscle Hi-C data was loaded and analysed in the 3D genome browser suite (http://promoter.bx.psu.edu/hi-c/) using the hg19 human reference sequence

3.4 | Epigenetic *in silico* analysis

In addition, we performed an epigenetic in silico analysis to detect possible conformation changes that could modify the chromatin organization, and therefore, the expression of genes which may contribute to the BML development.

To determine whether the deleted region at chromosome 10 might have a role in chromatin remodelling, an epigenetic analysis was performed based on public data sets of ChIP-seq for histone marks and the transcription factor CTCF (CCCTC-binding factor). Additionally, the presence of topologically associated domains in this region was analysed using Hi-C public data for smooth muscle cells (Figure 4). The fragment where the deletion occurs is enriched by very dense histone modifications that mediate gene activation, and the lost sequence corresponds to a stable domain that

delimitates the region from the transcriptional effect of surrounding chromatin.

4 | DISCUSSION

BML is a pathology infrequently diagnosed, and normally detected by imaging techniques as a consequence of complications derived from the growing secondary myomas. The pathogenesis of the disease is not well defined. In this study, we report for the first time, submicroscopic chromosomal abnormalities detected in a patient with a history of benign uterine leiomyomas metastasized to lungs.

The smooth muscle cellular lineage of the primary and secondary neoplasms was determined by immunohistochemical assays. Leiomyomas consisted of spindle-shaped cells growing in a trabecular pattern and creating a whorled appearance (Figure 2). Conforming the major lung nodule, the presence of some smooth muscle cells positive for Bcl-2 protein (Figure 2E), suggests the infiltration of metastatic cells from uterus into the lungs, probably via lymph vessels as the most probable origin for the lung metastasizing leiomyomas.

In this case of BML an apparently normal karyotype was firstly observed with standard GTG-banding cytogenetic analysis. Similar results for this kind of alterations have been published by other groups,[14] however our study shows the relevance of chromosomal microarray analysis to identify submicroscopic genomic alterations in rare conditions such as BML.

Genomic CNVs, either amplifications or deletions, have a high impact on predisposition to human diseases.[19,20] In this study, six chromosomes presented CNVs involving genes encoding for proteins, miRNAs (short no-coding RNAs conformed by 20-25 nucleotides), or lncRNAs (long no-coding RNAs constituted by ~200 nucleotides) involved in the regulation of gene expression. The potential of these both kind of RNAs to modulate gene expression is being extensively described.[21,22] These molecules regulate gene expression finely, but their perturbed activity can disturb the normal genome behaviour and promote pathological conditions.[23]

The gain presented at 14q32.33 contains the coding sequence for miRNA4507, miRNA4537, miRNA4538, miRNA4539 and lncRNA *KIAA0125*. miRNAs 4538 and 4539 are over-expressed in Duchenne Muscular Dystrophy, where they could modulate muscular functions such as locomotion and motor motility. miR4539 is over-expressed in both colon and rectal carcinoma; and it has been proposed as a molecular tool to differentiate between carcinoma and normal mucosa. In highly metastatic gallbladder cancer cells, migration and invasion have been inhibited by means of the down-regulation of lncRNA *KIAA0125*.[24]

The duplicated DNA segment at chromosome 22q11.22 harbours the microRNA-650, whose deregulated activity promotes the epithelial-mesenchymal transition through the down-regulation of tumour suppressor genes conferring an invasive and metastasizing phenotype.[25,26] Also, there is experimental evidence showing that miR-650 is involved in lymphatic and distant metastasis in human gastric cancer. This miRNA targets the inhibitor of cellular growth 4, so its ectopic expression promotes tumourigenesis and proliferation of gastric cancer cells,[27] and modify the biology of melanoma,[28] as well as chronic lymphocytic leukaemia.[29]

The fragment in chromosome 10 where the deletion occurs is enriched by very dense histone modifications that mediate gene activation; the lost sequence corresponds to a stable domain that delimitates the region from the transcriptional effect of surrounding chromatin (Figure 4).

Therefore, we suggest that the genomic loss at 10q11.22 region creates a perturbed transcriptional environment that may affect other genes in the vicinity, promoting deregulation of pathways that could exacerbate the phenotype of BML, as occurs in other pathological conditions. A previous report showed the presence of the translocation t(10;17)(q22;q21) as the sole chromosomal abnormality in a benign retroperitoneal smooth muscle tumour detected in a woman.[30] The translocation produced the fusion gene *KAT6B-KANSL1* that could regulate transcription with affinity for chromatin. The region in chromosome 17 harbouring *KANSL1* was detected amplified in the present study, no translocations were detected, but the expression of its normally targeted genes could be modified.

Among specialists it is hypothesized that many BML cases are underdiagnosed, meanly because the pathology is detected only when the metastasizing nodules interfere importantly with physiological functions in the body; nevertheless, the symptoms vary in each case, and are linked to the affected organ or tissue. In consequence, symptomatology cannot be generalized, and specific tests based on histological analysis of biopsies could be unviable depending on the localization of the metastasizing nodules.

In order to determine if the presence of the submicroscopic genomic abnormalities reported here are the same in other patients, more studies are needed. Additionally, future analysis sampling leiomyomas in uterus comparing to early metastatic tumours; as well as metastasizing nodules compared to case-control samples, would clarify characteristic genetic abnormalities and the molecular signs of BML. This could bring to light molecular markers useful in the appropriated and timely diagnosis of the pathology, as well as the identification of molecular targets for safe treatments.

ACKNOWLEDGEMENTS

The authors thank the patient and her family for their participation in this study.

INFORME DE LABORES 2019

CONFLICT OF INTEREST

The authors declared that they have no conflict of interests with the contents of this article.

AUTHOR CONTRIBUTIONS

All the authors contribute importantly to this work. EHP collected data, analysed microarray results and wrote the paper. ACVW performed the microarray assay, collected data and participated in writing the manuscript. CJR collected data and contributed to achieve the manuscript. FFR analysed data and contributed to achieve the manuscript. LMGS realized the clinical follow-up of the patient and discussed the organization of the manuscript. CAFG performed and interpreted the histopathological characterization of the tissues. JMHH performed the in silico epigenetic analysis. HRV reviewed and provided critical comments to the manuscript. JCHM reviewed and validated the cytogenetic test reported. EEP started the clinical care of the patient, and participated in the design of the study.

ETHICS

This study was approved by the Institutional ethics committees, and the corresponding informed consent was obtained and signed by the patient.

Hazardous alcohol consumption and risk of alcohol dependence present different neurophysiological correlates

Wendy V. Herrera-Morales, Leticia Ramírez-Lugo, Efraín Santiago-Rodríguez, Julián V. Reyes-López, Luis Núñez-Jaramillo

Introduction. Hazardous alcohol consumption (HAC) is a pattern of alcohol use that may result in harm for the user and/or for those around them. Prior research has suggested that HAC and alcohol dependence share some neurophysiological features but differ in others.

Aim. To determine whether HAC and alcohol dependence presented different neurophysiological correlates.

Subjects and methods. Two hundred subjects were screened for HAC or alcohol dependence. A quantitative electroencephalographic analysis of delta, theta, alpha and beta absolute power, relative power and mean frequency in subjects with HAC but not alcohol dependence, subjects with risk of alcohol dependence and controls was performed.

Results. One hundred and fourteen subjects met inclusion criteria. The HAC group presented with higher beta absolute power and relative power, as well as a lower beta mean frequency than the control group, while the group with risk of alcohol dependence presented lower delta absolute power than controls.

Conclusions. HAC and risk of alcohol dependence present different neurophysiological correlates. There is an important effect of the severity of alcohol dependence on neurophysiological correlates of this condition. Our results support the existence of two different types of behavioral disinhibition.

Key words. Alcohol dependence. Behavioral disinhibition. Beta activity. Delta activity. Hazardous alcohol consumption. Quantitative EEG.

Introduction

Alcohol is a psychoactive substance with abuse rates among the five top risk factors for disease, disability and death worldwide. A global study revealed that alcohol use disorders (AUDs) represent 9.6% of mental and substance disorders, which in turn are responsible for 7.4% of disability-adjusted life years [1].

The most frequently studied AUD is alcohol dependence, however, hazardous alcohol consumption (HAC), 'a pattern of alcohol consumption that increases the risk of harmful consequences for the user or others', which is not necessarily accompanied by alcohol dependence [2], is another AUD that strongly impacts society. Research has shown that HAC is strongly correlated with alcohol-related injuries [3,4]. HAC is frequent among college students and leads to risky behavior such as drunk-driving and the use of other substances, as well as risky sexual practices [5-7].

Quantitative electroencephalography (qEEG) has been used to study AUDs. qEEG is an affordable and non-invasive technique that allows the study of brain electrical activity both at resting state and associated with cognitive processes [8]. An increase in theta [9], and beta absolute power (AP) [10,11] are the main resting qEEG correlates consistently found in alcohol dependent subjects. Regarding delta frequency band in alcohol dependent patients, there are reports for both increased and decreased delta activity, thus remaining inconclusive at the moment [8]. Different reports have addressed alpha activity in relation with familiar history of alcohol consumption and ethnicity [12,13]. Some reports have described a decrease in alpha activity in alcoholics, but other studies have failed to replicate this result [8].

An increase in beta and theta AP has been implicated as a homeostatic imbalance in cortical excitability [8] and as such, it has been proposed that subjects with a genetic predisposition towards developing alcohol dependence present a homeostatic imbalance leading to disinhibition/hyperexcitability in the central nervous system [8]. Behavioral disinhibition is found not only in alcohol dependence, but also in other disorders such as HAC [14], implying a deficit in impulse control [15].

Prior research on binge drinkers has found deficits in white matter integrity, cortical thickness and neurocognitive markers that are similar to that observed in alcoholic patients, suggesting that binge drinking may be the predecessor to alcoholism [16]. A study addressing basal qEEG activity found that binge drinking is associated with high delta and fast beta (20-35 Hz) activity in the eyes open condition [17].

Alcohol dependence produces important plastic changes within the central nervous system [18] and as such, it is important to rule out alcohol dependence when investigating the neurophysiological correlates of patients with HAC. We have previously reported that subjects with HAC, in the absence of alcohol dependence, present with a decrease in beta mean frequency (MF) in frontal and centro-parietal areas, as well as an increase in beta AP in centro-parietal areas [19] compared to controls. Previous reports of qEEG analyses in alcohol dependent subjects revealed increased beta and theta AP [9,11]. Thus, subjects with HAC present with some similar neurophysiological correlates observed in alcohol dependent subjects (increased beta AP) but differ in others. As mentioned earlier, both HAC and alcohol dependence are associated with behavioral disinhibition. However, alcohol dependence includes neurophysiological mechanisms underlying substance dependence, while HAC does not share this set of mechanisms. Since it has been suggested that beta activity is involved in the regulation of cortical excitability [15,20], it is important to determine whether the decrease in beta MF observed in subjects with HAC [19] represents a neurophysiological feature unique to HAC and not shared with subjects with alcohol dependence. Moreover, since no conclusive results have been obtained on delta and alpha activity in AUDs we will study these frequency bands in HAC and risk of alcohol dependence in the same population.

Subjects and methods

Participants

Participants were first year health sciences students and were verbally invited during class to participate in the study. All procedures and data management were carried out in accordance with the Declaration of Helsinki, and the protocol was approved by the Committee of Ethics in Research of the Health Sciences Division of the university. All participants signed an informed consent.

Clinical evaluation

The Spanish version of the Alcohol Use Disorders Identification Test (AUDIT) was used to assess HAC and risk of alcohol dependence. The AUDIT consists of 10 items that explore the frequency, amount of consumption, negative consequences, and associated psychosocial problems related to alcohol consumption [2]. Different cut-points in the AUDIT have been used in college students, but a study comparing four different alcohol screening tests in adolescents, found that for this age group a cut-point of two was optimal for detecting alcohol problem use and a cut-point of 3 for identifying risk of abuse or dependence [21]. In order to avoid false positives we confirmed the results analyzing specific sections of the AUDIT test. A score of 1 or above on items 2 and 3 met criteria for HAC, while a score over 0 on items 4, 5 and 6 met criteria for risk of alcohol dependence [2]. Subjects rating 3 or more in total AUDIT score, but who did not fulfill the criteria for the section assessing risk of alcohol dependence, were included in the HAC group. Thus, subjects rating positive for HAC presented a total AUDIT score of 2 or more, a score of 1 or above on items 2 and 3, and a score of 0 on items 4, 5 and 6; while subjects rating positive for risk of alcohol dependence presented a total AUDIT score of 3 or more, and a score over 0 on items 4, 5 and 6 of this test. While the AUDIT has been validated in different countries such as México, Brazil and Venezuela [2,22,23], no further clinical evaluation was performed for alcohol dependence in this work, thus subjects rating positive for alcohol dependence are considered as 'at risk'.

All participants were non-smokers. Consumption of other drugs was not determined for the subjects in this study.

Participants completed a self-reported questionnaire (ASRS v. 1.1) to test for attention deficit hyperactivity disorder (ADHD) [24,25], and the Plutchick Suicide Risk test. These instruments were selected based on our previous study [19] and are conditions related to AUDs and present in the population [26-28]. Participants had no current or previous history of neurological illness and were not taking any medication that could affect EEG activity.

Quantitative electroencephalography

EEG recording

Subjects were comfortably seated in a dimly lit room, were awake, and had their eyes closed. EEGs were recorded with a 19-channel Medicid Fenix

electroencephalograph. Amplifier was set with a low frequency filter of 0.5 Hz, a high frequency filter of 30 Hz, and a 50/60 Hz notch filter. A sampling frequency of 240 Hz, with a 16-bit resolution was used. The signal was collected through 19 electrodes from the international 10/20 system (FP1, FP2, F7, F8, F3, F4, T3, T4, C3, C4, T5, T6, P3, P4, O1, O2, FZ, CZ and PZ), fitted in an electrode cap, and linked mastoids were used as references. All EEG recordings were rigorously analyzed by a clinical neurophysiologist (E.S.R).

Quantitative analysis

Quantitative analysis was performed on EEG segments of at least 2.56 s. The segments were manually selected until summing to at least one minute. Only segments during which the subject was awake and presented alpha activity were included. Segments with muscular activity and blinking were also eliminated.

Quantitative EEG analysis software was used to calculate the AP, relative power (RP) and MF for delta (1.56-3.52 Hz), theta (3.91-7.42 Hz), alpha (7.81-12.5 Hz) and beta (12.89-19.14 Hz) frequency bands [29] using a fast Fourier transform algorithm. In order to decrease non-physiological variability, subtraction of the global scale factor (GSF) was applied to AP measures in all frequency bands. The mathematical model used to obtain GSF can be summarized as a logarithmic transformation applied to the brain electrical signal. This equation is $V_i\,(e,t) = \gamma_1\beta_1\,(e,t)$, where the brain electrical activity obtained in the EEG may be represented by a matrix where $V\,(e,t)$, V being the potential recorded at electrode e at the moment t. A global factor scale is represented by γ. The mathematical model used to obtain it is described in detail in the work published by Hernández et al [30]. The subtraction of GSF has been incorporated into some EEG software analysis, such as the one used in this study, and many papers have been published since then. EEG recordings were reformatted to the average reference for quantitative analysis [31].

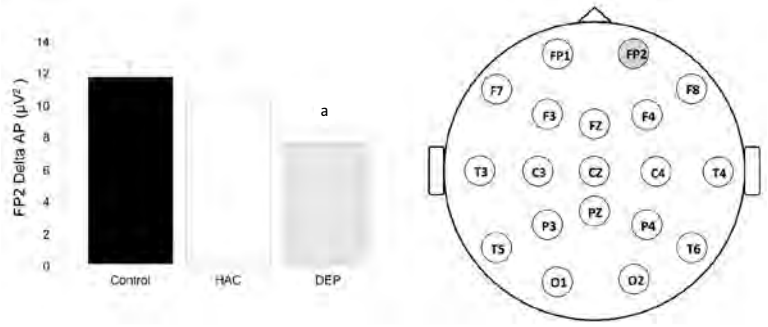
Statistical analysis

For the analysis of AUDIT, suicide risk and ADHD raw scores, as well as age, we performed ANOVA's tests followed by Bonferroni's post hoc test.

For qEEG analysis a mixed design analysis of variance (mixed ANOVA) with electrode as a within-subject variable and group as between-subject variable was performed. Greenhouse-Geisser corrected degrees of freedom were used to assess the significance of the corresponding *F*-value when necessary. Partial eta squared (η^2_p) was used to determine effect size. The AP, RP and MF for delta, theta, alpha and beta frequency bands were analyzed through separated mixed ANOVAs. Where an effect of group was found, pairwise comparison revealed specific inter-group differences, and an ANOVA test was carried out to determine in which electrodes this effect was found. *P*-values were adjusted for multiple comparisons using a Bonferroni correction (Table I).

Table I. Outcomes of mixed ANOVAs performed for absolute power, relative power and mean frequency values of delta, theta, alpha and beta frequency bands. Specification of the groups differing is indicated in those measures where an effect of group was found.

	Absolute power	Relative power	Mean frequency
Delta	DEP < control ($p < 0.05$)	Non-significant	Non-significant
Theta	Non-significant	Non-significant	Non-significant
Alpha	Non-significant	Non-significant	Non-significant
Beta	HAC > control ($p < 0.01$)	HAC > control ($p < 0.01$)	HAC < control ($p < 0.05$)



DEP: risk of alcohol dependence; HAC: hazardous alcohol consumption.

Results

A total of 200 students participated in the study (106 females, age 19.6 ± 0.25, and 94 males, age 19.8 ± 0.35). Subjects older than 22 years, with a present or previous history of neurological disorders, and those in which EEG visual analysis revealed abnormalities were excluded from the analysis.

Only 114 subjects were included in the statistical analysis. Of the 114 subjects, 48 subjects scored negatively for all clinical conditions evaluated (HAC, risk of alcohol dependence, suicide risk and ADHD) and were included in the control group; 45 subjects scored positive for HAC but negatively for risk of alcohol dependence, as well as negative for all other tests (suicide risk, ADHD) and were included in the HAC group; and 21 subjects scored positively for risk of alcohol dependence and were included in the risk of alcohol dependence group (DEP). The majority of subjects within the DEP group presented comorbidities; 18 rated positive for HAC, 6 rated positive for suicide risk and 8 rated positive for ADHD. Age and gender composition of each group is depicted in table II.

Figure 1. Site where ANOVA revealed an effect of group on delta AP (mean ± standard error). Differences revealed by Bonferroni post hoc test are shown. [a] $p < 0.05$ (DEP vs control). Electrode in grey indicate lower value in DEP when compared with controls. HAC: hazardous alcohol consumption; DEP: risk of alcohol dependence.

There was no difference in age between groups. ANOVA performed on raw scores for the tests applied revealed a difference in total scores for ADHD ($F_{2,111}$ = 11.59; $p < 0.0001$) and suicide risk ($F_{2,111}$ = 16.49; $p < 0.0001$) tests. For suicide risk, DEP group presented higher scores than control (DEP 4.434 ± 0.6; control 2.0 ± 0.17; $p < 0.0001$) and HAC (2.33 ± 0.21; $p < 0.0001$) groups, while in the ADHD test DEP group scored higher than control (DEP 2.67 ± 0.37; control 1.39 ± 0.16; $p < 0.01$) and HAC (0.18 ± 0.15; $p < 0.0001$). The three groups also differed in AUDIT total score ($F_{2,111}$ = 57.11; $p < 0.0001$), as well as in the score analyzed for HAC ($F_{2,111}$ = 240.66; $p < 0.0001$) and DEP ($F_{2,111}$ = 70.86; $p < 0.0001$). In AUDIT total score DEP group presented higher scores than HAC (DEP 5.24 ± 0.62; HAC 2.89 ± 0.33; $p < 0.0001$) and control (control 0.208 ± 0.09; $p < 0.0001$) groups, while HAC presented a higher score than control group ($p < 0.0001$). In the AUDIT section analyzed for HAC, Bonferroni's post hoc test revealed that control group presented lower scores than HAC (control 0.0 ± 0.0; HAC 1.11 ± 0.47; $p < 0.0001$) and DEP (DEP 0.86 ± 0.078; $p < 0.0001$) groups, while DEP and HAC also differed from each other ($p < 0.01$). In the section evaluated to determine risk of alcohol dependence, Bonferroni's post hoc test showed that DEP group presented higher scores than HAC (DEP 1.48 ± 0.26; HAC 0.0 ± 0.0; $p < 0.0001$) and control (control 0.0 ± 0.0; $p < 0.0001$) groups, while no difference was found between control and HAC groups.

Delta activity

There was an effect of the electrode studied on delta AP ($F_{4.71,\ 522.35}$ = 57.98; $p < 0.001$; η^2_p = 0.343), as well as an effect of group ($F_{2,\ 111\ =}$ 3.25; $p < 0.05$; η^2_p = 0.055). Pairwise comparison revealed a difference between control and DEP groups ($p < 0.05$). ANOVA revealed an effect of group at Fp2 ($F_{2,11}$ = 3.12; $p < 0.05$) (Fig. 1).

There was an effect of electrode on delta RP ($F_{7.45,\ 827.84}$ = 153.91; $p < 0.001$; η^2_p = 0.581) and MF ($F_{10.67,\ 1185.15}$ = 28.83; $p < 0.001$; η^2_p = 0.206). No effect of group or electrode × group interaction was found for these measures.

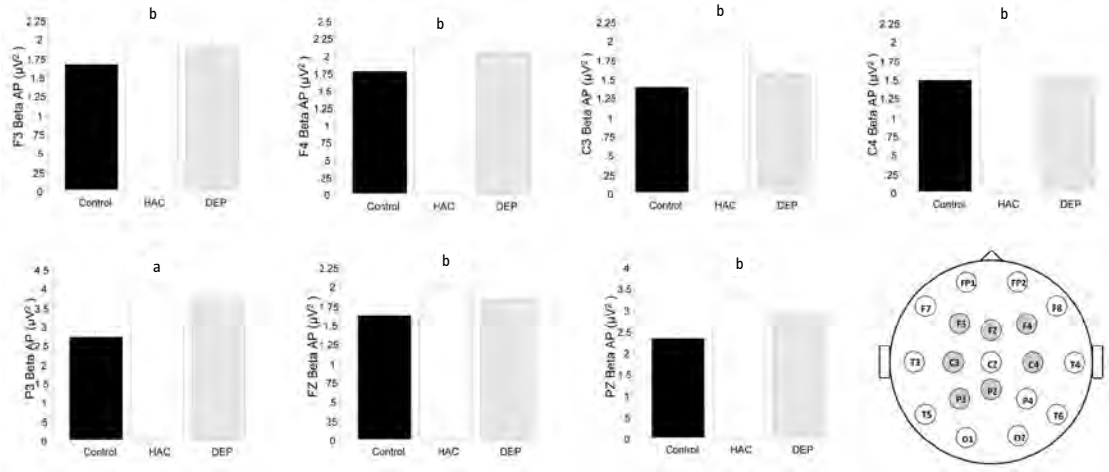
Table II. Age and gender composition of control, hazardous alcohol consumption (HAC) and risk of alcohol dependence (DEP) groups.

	Female (mean age)	Male (mean age)
Control	26 (19.15 ± 0.21 years)	22 (19.08 ± 0.13 years)
HAC	17 (19.11 ± 0.21 years)	28 (19.30 ± 0.19 years)
DEP	16 (19.05 ± 0.23 years)	5 (18.90 ± 0.18 years)

Theta activity

There was an effect of the electrode on theta AP ($F_{5.08,\ 563.4}$ = 50.99; $p < 0.001$; η^2_p = 0.315), RP ($F_{8.6,\ 954.38}$ = 92.58; $p < 0.001$; η^2_p = 0.455) and MF ($F_{8.97,\ 995.58}$ = 32.95; $p < 0.001$; η^2_p = 0.229). There was no effect of group or electrode × group interaction on any measure of theta activity.

Alpha activity



Mixed ANOVA revealed an effect of electrode on alpha AP ($F_{3.73,\ 374.42}$ = 90.35; $p < 0.001$; η^2_p = 0.449), RP ($F_{70.9,\ 787.19}$ = 149.73; $p < 0.001$; η^2_p = 0.574) and MF ($F_{7.72,\ 856.61}$ = 28.39; $p < 0.001$; η^2_p = 0.204). However, no effect of group or electrode × group interaction was found for any of them.

Beta activity

Mixed ANOVA on beta AP values revealed an effect of electrode ($F_{6.89,\ 764.42}$ = 60.59; $p < 0.001$; η^2_p = 0.353) and an effect of group ($F_{2,111}$ = 5.81; p = 0.004; η^2_p = 0.095). There was no electrode × group interaction. Pairwise comparison revealed a difference between control and HAC groups (p = 0.003). Figure 2 shows the sites in which a difference between these groups was found.

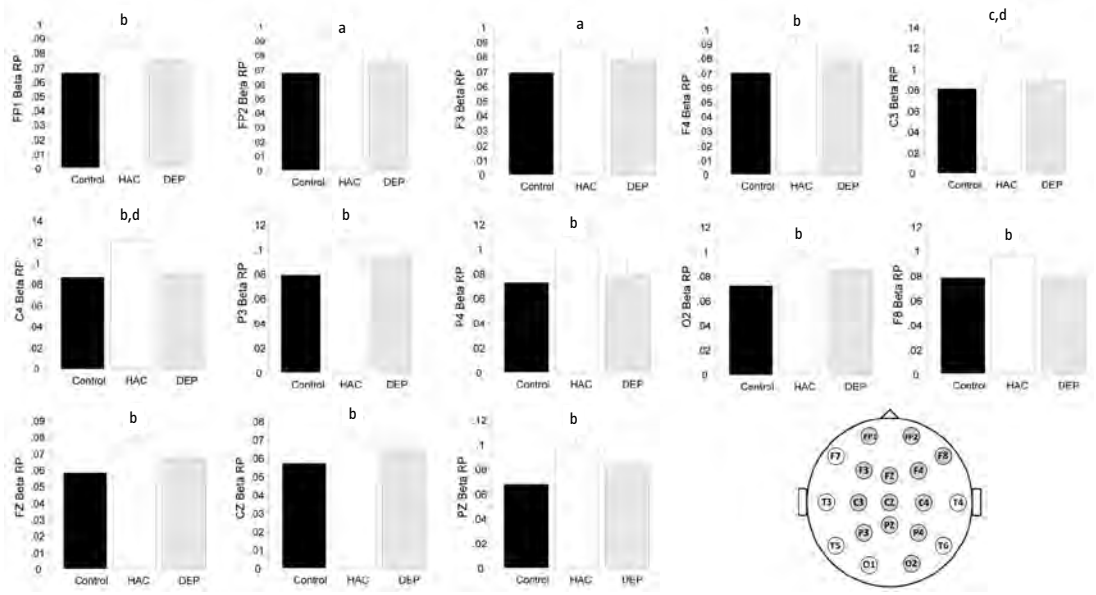
There was an effect of electrode ($F_{60.3,\ 669.2}$ = 29.78; $p < 0.001$; η^2_p = 0.212) and an effect of group ($F_{2,111}$

Figure 2. Sites where ANOVA revealed an effect of group on beta AP (mean ± standard error). Differences revealed by Bonferroni post hoc test are shown. [a] $p < 0.05$; [b] $p < 0.01$. Electrodes in grey indicate higher values in HAC when compared with controls. HAC: hazardous alcohol consumption; DEP: risk of alcohol dependence.

= 6.08; $p = 0.003$; $\eta^2_p = 0.099$) on beta RP. There was no electrode × group interaction. Pairwise comparison showed a difference between control and HAC groups ($p = 0.002$). Figure 3 shows the sites in which a difference between these groups was found.

There was an effect of electrode ($F_{8.18,\ 908.19} = 27.34$; $p < 0.001$, $\eta^2_p = 0.198$) and an effect of group ($F_{2,111} = 4.26$; $p = 0.017$; $\eta^2_p = 0.071$) on beta MF. However, there was no electrode × group interaction. Pairwise comparison showed a difference between control and HAC groups ($p = 0.004$). Figure 4 shows the sites in which a difference between these groups was found.

Discussion



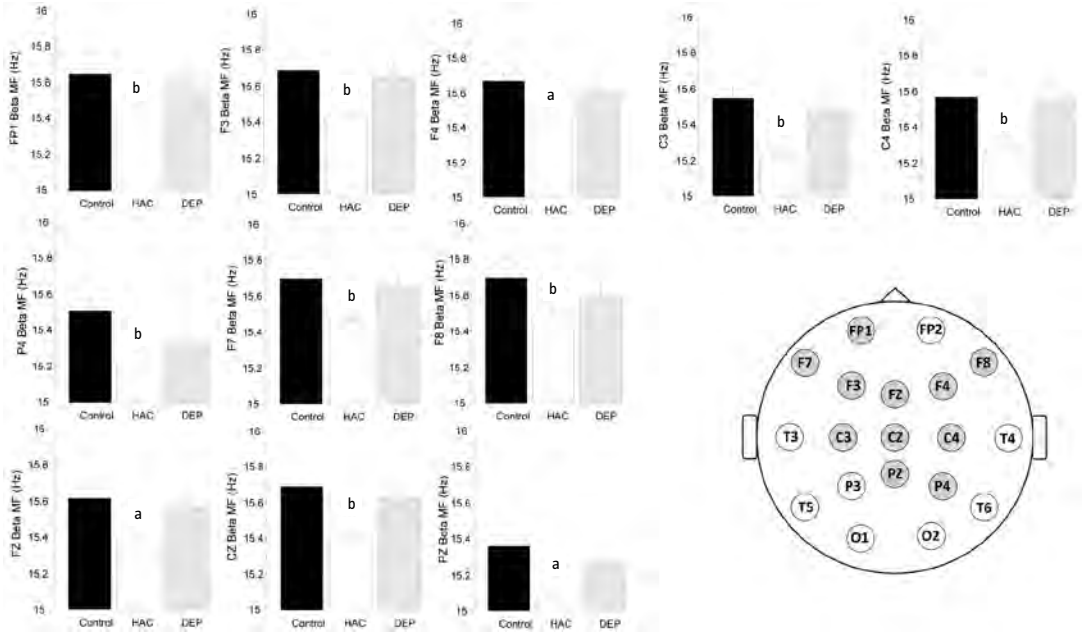
The current study explored qEEG activity between subjects with HAC and risk of alcohol dependence along with a control population without an alcohol-related disorder. Subjects with HAC presented higher beta AP, higher beta RP, and lower beta MF when compared with controls. Subjects with risk of alcohol dependence presented lower delta AP when compared with controls.

Beta activity has been linked with activity of cortical GABAergic interneurons, and as such has been related to inhibition/excitability homeostasis in the cortex. Changes in beta activity have therefore been associated with a homeostatic imbalance leading to central nervous system disinhibition/hyperexcitability [8], and this association has been supported by electrophysiological and genetic analyses [15]. Both HAC and alcohol dependence are manifestations of behavioral disinhibition [8,14,15], and prior research has proposed that behavioral and central nervous system disinhibition share common neurophysiological markers [8,15]. Thus, the higher beta AP and RP, as well as the lower beta MF present in the HAC group suggest an imbalance in central nervous system disinhibition/hyperexcitability.

As mentioned earlier, available data on delta activity in alcoholics is non-conclusive, while earlier works point to an increase in delta activity, more recent works reveal an decrease in delta activity in these patients [8]. A very interesting study performed on alcohol dependent subjects identified two different profiles within the same population based on qEEG analysis, one with increased delta and theta activity, and another with decreased delta and theta activity. Both groups presented a delay in P300 and impairments in attention and memory, although these effects were stronger in the first group (increased delta and theta activity). Authors suggest that this could be reflecting different stages of alcohol dependence [32], although other factors (different types of alcohol dependence, ethnic influence, etc.) cannot be discarded.

Thus, decreased delta AP is present only in some patients with alcohol dependence. We believe that

Figure 3. Sites where ANOVA revealed an effect of group on beta RP (mean ± standard error). Differences revealed by Bonferroni post hoc test are shown. [a] $p < 0.05$; [b] $p < 0.01$; [c] $p < 0.0001$ (HAC vs control); [d] $p < 0.01$ (HAC vs DEP). Electrodes in grey indicate higher values in HAC when compared with controls. HAC: hazardous alcohol consumption; DEP: risk of alcohol dependence.



this might represent variations in the type of alcohol dependence. One of the studies showing a decrease in delta activity in alcohol dependent patients shed some light about the possible relevance of this finding, since decreased slow-wave activity (decreased delta and theta activity) correlated with cortical atrophy and onset age of alcohol consumption below 20 years [33]. While cortical atrophy and decreased delta activity might be the result of prolonged alcohol abuse, it might also be possible that decreased delta activity be found primarily in subjects beginning alcohol consumption at an early age, which would also be the case of our study. The implications of this requires further studies characterizing the two subtypes of alcohol dependent subjects, since variation in delta activity probably is not the only neurophysiological difference.

In this work we found statistically significant differences revealed by the ANOVA, but small effect sizes. It is noteworthy that effect size and statistical significance serve different purposes, while statistical significance test reveals the probability of obtaining the between groups difference by chance, effect size provides information about the magnitude of that difference and its possible practical implications [34]. Different works have assessed the importance of small changes on qEEG activity. For example, carbamazepine treatment produces impairment in neuropsychological performance in those patients whose alpha mean frequency in the occipital region slows 0.5-0.6 Hz after treatment, and has been used to determine possible outcome of different antiepileptic drugs [35]. Even though effect size is not always reported along with statistical significance in qEEG studies, previous reports have revealed important findings in studies of alcohol use disorders with small (but significant) differences between groups in different qEEG parameters such as P300 [32,36,37], AP [38] and event related oscillations [39,40].

Gender composition was not equal in all groups, particularly in the DEP group we had a small number of males. Previous reports addressing possible gender differences in neurophysiological correlates of alcohol dependence have found that males present with higher theta AP at central and parietal regions, while females present with higher theta AP at parietal regions only [9]. Another study found that both males and females with alcohol dependence had an increase in beta AP, although for fe-

Figure 4. Sites where ANOVA revealed an effect of group on beta MF (mean ± standard error). Differences revealed by Bonferroni post hoc test are shown. males this increase did not reach statistical significance [11]. However, a more recent study performed on only women with alcohol use disorders found that alcohol dependent women presented a significant increase in beta AP and RP [10]. Thus, previous studies addressing gender influence on the neurophysiological correlates of alcohol use disorders suggest a mild influence, mostly in regard to the particular distribution of qEEG changes in both genders. However, further studies are warranted to fully confirm the precise influence of gender.

The majority of studies on the neurophysiological correlates of alcohol dependence to date have been carried out in adult populations of medically treated alcohol dependent subjects, which by definition have a more severe alcoholism than the population in the current study. However, studies performed with adult treatment-naïve alcohol dependent subjects have revealed a mild non-significant ($p = 0.05$) decrease in P300 [37], and treatment-naïve adolescents with alcohol dependence do not present any reduction in P300 [41], while studies on adult treated population revealed a significant decrease in P300 amplitude [8]. P300 signifies brain activity during cognitive functioning, and as such, it is a very different type of neurophysiological marker than the resting EEG activity reported herein. However, taken together the results allow us to have a better understanding of the differences in brain electrical activity in subjects with early and more severe alcohol dependence.

Although the subjects in the current study presented with alcohol use disorders, they had not yet sought medical treatment, and therefore, it is not surprising that our neurophysiological results differ from those that studied participants with a more severe alcoholism who had sought treatment or were already in treatment [37,41]. The results from resting qEEGs of subjects with risk of alcohol dependence in the current study were inconsistent with features previously described in alcoholic patients, namely, increased theta and beta AP [9-11]. The participants in the current study were young (age 17 to 22 years old) and treatment-naïve, meaning that their alcohol use disorder was not yet severe enough to seek for medical help. All subjects were first-year university students, and attended classes and other academic activities on a regular basis. Therefore, the risk of alcohol dependence had not yet caused a serious impairment in daily activi-

ties, suggesting an early stage of alcohol addiction [42]. Thus, we believe that a low addiction severity may account for the lack of differences in theta and beta activity between subjects with risk of alcohol dependence and control subjects in the current study. However, we found a lower delta AP, significant at Fp2, in the group with risk of alcohol dependence when compared versus controls, indicating a differential qEEG activity associated with risk of alcohol dependence. Moreover, in this work we did not analyze other EEG parameters reported to be altered in association with alcohol dependence such as event related potentials, thus differences in these measures cannot be ruled out.

Despite the fact that most of the subjects with risk of alcohol dependence in the current study also presented with HAC (82.6%); high beta AP and RP, as well as low beta MF, were found only in subjects with HAC, but not alcohol dependence. One possible interpretation suggests the existence of a different etiology for HAC in the two groups (HAC only and DEP).

There is some controversy on whether HAC is a prelude of alcohol dependence or if HAC and alcohol dependence are two separate conditions [16]. If these two conditions are not linked, then alcohol dependence is not a 'higher level' of HAC, allowing the existence of neurophysiological correlates exclusive to HAC, as may be the case for the lower beta MF. However, the question remains as to why differences in neurophysiological correlates differ between the HAC and DEP groups when most of the DEP group also presents with HAC.

HAC can be present in an individual with or without alcohol dependence [2] since alcohol dependence includes factors associated with addiction. The possibility exists that HAC that is associated with alcohol dependence has a different etiology than HAC not associated with addiction. Interestingly, a previous study among cocaine abusers with and without comorbid personality disorders, found that subjects with cocaine dependence and comorbid personality disorders reported higher behavioral disinhibition than those without comorbid personality disorders and this disinhibition was present prior to the development of cocaine dependence. Comparatively, while cocaine dependent subjects without comorbidities also presented increased disinhibition, this behavior developed along with cocaine dependence, suggesting a difference in disinhibition trajectory between these two groups [43]. These results suggest the existence of at least two subtypes of disinhibition: one resulting from the development of addiction and another that precedes addictive behavior. The current results suggest that these two types of disinhibition may have different neurophysiological correlates. Applied to our results, this theory implies that HAC observed in individuals in the DEP group would be secondary to an addiction process, while in the HAC group this condition would not be related with the development of alcohol dependence.

While HAC and DEP are manifestation of behavioral disinhibition [8,14,15], it is reasonable that they differ in their neurophysiological correlates, since alcohol dependence implies neurophysiological mechanisms associated with addiction. However, if higher beta activity is related with cortical and behavioral disinhibition [8], why is it present only in the HAC group, and not in the DEP group? In the work of Albein-Urios et al [43] they report two different types of disinhibition, one preceding addiction and the other developing along with addiction. We believe that our subjects in the HAC group have the first type and our subjects in the DEP group the second. According to this, and given that we are observing the first stages of alcohol dependence, the increase in beta activity associated with disinhibition would be under development in these subjects. In agreement with this proposal we can observe that, although DEP group does not differ from controls in beta AP, RP and MF, it does not differ from the HAC group either in most of the cases observed in this study. However, further studies on subjects with more advanced alcohol dependence are necessary in order to prove this idea.

El consumo de riesgo de alcohol y el riesgo de dependencia al alcohol presentan correlatos neurofisiológicos diferentes

Introducción. El consumo de riesgo de alcohol (CRA) es un patrón de consumo que puede resultar dañino para el usuario o para los demás. Investigaciones previas sugieren que el CRA y la dependencia al alcohol comparten algunas características neurofisiológicas, pero difieren en otras.

Objetivo. Determinar si el CRA y la dependencia al alcohol presentan correlatos neurofisiológicos diferentes.

Sujetos y métodos. Doscientos sujetos realizaron la prueba de detección de CRA y riesgo de dependencia al alcohol (DEP). Se realizó un estudio de electroencefalografía cuantitativa para determinar la potencia absoluta, la potencia relativa y la frecuencia media de las bandas delta, theta, alfa y beta en sujetos con CRA, con DEP y controles.

Resultados. Un total de 114 sujetos cumplió los criterios de inclusión. El grupo con CRA presentó mayor potencia absoluta, mayor potencia relativa y menor frecuencia media de la banda beta en comparación con los controles, mientras que el grupo con DEP presentó menor potencia absoluta de la banda delta que los controles.

Conclusiones. El DEP y el CRA presentan diferentes correlatos neurofisiológicos. Hay un efecto importante de la gravedad de la dependencia al alcohol sobre sus correlatos neurofisiológicos. Nuestros resultados apoyan la existencia de dos tipos distintos de desinhibición conductual.

Palabras clave. Actividad beta. Actividad delta. Consumo de riesgo de alcohol. Dependencia al alcohol. Desinhibición conductual. EEG cuantitativo.

Development-Dependent Changes in the NR2 Subtype of the N-Methyl-D-Aspartate Receptor in the Suprachiasmatic Nucleus of the Rat

Abstract The suprachiasmatic nucleus (SCN) is the main brain clock that regulates circadian rhythms in mammals. The SCN synchronizes to the LD cycle through the retinohypothalamic tract (RHT), which projects to ventral SCN neurons via glutamatergic synapses. Released glutamate activates N-methyl-D-aspartate (NMDA) receptors, which play a critical role in the activation of signaling cascades to enable phase shifts. Previous evidence indicates that presynaptic changes during postnatal development consist of an increase in RHT fibers impinging on SCN neurons between postnatal day (P) 1 to 4 and P15. The aim of this study was to evaluate postsynaptic developmental changes in the NR2 subunits that determine the pharmacological and biophysical properties of the neuronal NMDA receptors in the ventral SCN. To identify the expression of NR2 subtypes, we utilized RT-PCR, immunohistochemical fluorescence, and electrophysiological recordings of synaptic activity. We identified development-dependent changes in NR2A, C, and D subtypes in mRNA and protein expression, whereas NR2B protein was equally present at all analyzed postnatal ages. The NR2A antagonist PEAQX (100 nM) reduced the frequency of NMDA excitatory postsynaptic currents (EPSCs) at P8 significantly more than at P34, but the antagonists for NR2B (3 μM Ro 25-6981) and NR2C/D (150 nM PPDA) did not influence NMDA EPSCs differently at the 2 analyzed postnatal ages. Our results point to P8 as the earliest analyzed postnatal age that shows mRNA and protein expression similar to those found at the juvenile stage P34. Taken together, our findings indicate that postsynaptic development-dependent modifications in the NR2 subtypes of the NMDA receptor could be important for the synchronization of ventral SCN neurons to the LD cycle at adult stages.

The hypothalamic suprachiasmatic nucleus (SCN) is the main clock responsible for the regulation of circadian rhythms. The SCN synchronizes with the environmental LD cycle through the retinohypothalamic tract (RHT). Ablation of the RHT abolishes the synchronization of circadian rhythms to the LD cycle, allowing its free-running expression (Johnson et al., 1988). The RHT originates from a population of melanopsin-containing photosensitive ganglion cells in the retina (Hankins et al., 2008) and projects its fibers to various hypothalamic nuclei, including the SCN. The RHT releases glutamate and the pituitary adenylate cyclase-activating polypeptide (Hannibal, 2006; You et al., 2012) to the ventrolateral part of the SCN, which receives its principal innervation from the retina (Abrahamson and Moore, 2001). Glutamate released from the RHT activates ionotropic glutamatergic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate and N-methyl-D-Aspartate (NMDA) receptors (Kim and Dudek, 1991). Activation of NMDA receptors is a crucial step in phase shifts induced by light (Colwell and Menaker, 1992), which subsequently activate signaling pathways to achieve phase advances or delays (Ding et al., 1994; Ding et al., 1997).

The NMDA receptor is a heteromeric protein principally composed of 2 NR1 and 2 NR2 subunits. The 4 known types of subunits are termed NR2A to NR2D. The 2 NR2 subunits of the NMDA receptor can comprise the same or different types, thus providing diversity to the biophysical and pharmacological properties of NMDA receptors (see Cull-Candy and Leszkiewicz, 2004). Several reports indicate that the NR2B subtype plays an important role in the synchronization to light. In SCN neurons, Clark and Kofuji (2010) found that the NMDA current is reduced to about 50% by the NR2B antagonist ifenprodil. It was furthermore shown in mice that ifenprodil microinjected into the SCN region significantly reduces light-induced phase shifts in wheel running activity and that the phosphorylated form of this NR2 subtype varies in the ventral SCN according to circadian rhythms (Wang et al., 2008).

When NR2A and NR2C are individually knocked out in the whole animal, they do not seem to play a role in the synchronization of SCN neurons to light, even though there is biophysical and pharmacological evidence of their presence in NMDA currents of SCN neurons. Clark and Kofuji (2010) showed that the remaining NMDA current after NR2B inhibition with ifenprodil presents pharmacological characteristics of the NR2A subtype, even though they exhibit a $Mg^{2}+$ sensitivity similar to that of NR2C and NR2D subunits. Thus, these authors suggest that a subpopulation of NMDA receptors in SCN neurons consists of NR2A and NR2C/D heteromers. Moriya and colleagues (2000) showed that synchronization to light was slower in NR2A-knockout animals under low-intensity light conditions, indicating that NR2A indeed plays a role in synchronization. However, no effects were found in NR2C-knockout animals, and the role of the NR2D subunit in the synchronization of SCN neurons to light has not been reported yet.

Pre- and postsynaptic changes during development are critical for all sensory systems to prepare them for an optimal performance at adult stages, and the photic circadian system is no exception. It has been reported that RHT fibers start the SCN innervation at an early stage, i.e., postnatal days (P) 1 to 4 (Mason et al., 1977; Munoz Llamosas et al., 2000; Speh and Moore, 1993; Stanfield and Cowan, 1976); although, functional Fos immunoreactivity is already found at P0 (Hannibal and Fahrenkrug, 2004; Sekaran et al., 2005). The RHT achieves an adult appearance at P10 to P15 (Frost et al., 1979; Guldner, 1978; Mason et al., 1977; Munoz Llamosas et al., 2000; Speh and Moore, 1993). At the behavioral level, neonatal rats synchronize to LD cycles by P7 (Duncan et al., 1986), when the maternal influence wanes (Reppert and Schwartz, 1986) and the RHT synaptic terminals innervate the SCN neurons. Anatomical and behavioral evidence of the maturation in RHT - SCN connections may imply pre- and postsynaptic changes during this development that help to prepare the circadian system to correctly synchronize to light. To further understand these processes, this study was aimed to determine the postsynaptic changes in NR2 subunit expression (both at the mRNA and protein levels) in rats during development and determine their influence on synaptic activity.

MATERIALS AND METHODS

All studies were performed in accordance with the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (NIH Publication No. 85-23, revised 1996). All procedures were approved by the Institutional Bioethics Committee of the University Center for Biomedical Research of the University of Colima. Experiments were carried out in Wistar rat pups (n = 111) bred in our animal facilities from parents supplied by Harlan (Mexico). We analyzed postnatal developmental changes in the ventral SCN of animals at the ages of P4, P8, P12, and P34. For tissue sampling, animals were euthanized (between ZT 3 and 6) with sodium pentobarbital (125 mg/kg, i.p.).

RNA Extraction and Quantitative Real-Time PCR Analysis

Coronal brain slices (300 µm) containing the hypothalamus were obtained with a VT1000 microtome (Leica Microsystems; Wetzlar, Germany). Brain slices were maintained in artificial cerebrospinal fluid (ACSF) containing 124 mM NaCl, 1 mM $MgSO_4$, 5 mM KCl, 1.25 mM KH_2PO_4, 10 mM dextrose, 26 mM $NaHCO_3$, 2 mM $CaCl_2$; bubbled with 95% O_2/5% CO_2; pH 7.4. Tissue from the SCN was microdissected from 8 animals belonging to each of the above-mentioned postnatal ages (Fig. 1A). Total RNA was extracted from the pool (20 mg) of SCN samples using the Aurum Total RNA Mini Kit (Bio-Rad; Hercules, CA). RNA (500 ng) was reverse transcribed using an iScript cDNA Synthesis Kit (Bio-Rad). The cDNA was used as a template for real-time PCR experiments using the iQ SYBR Green Supermix (Bio-Rad) with the primers for the following genes that code for the different NR2 subtypes *Grin2a* (NR2A), *Grin2b* (NR2B), *Grin2c* (NR2C), and *Grin2d* (NR2D) in addition to the housekeeping genes *Gapdh* (glyceraldehyde-3-phosphate dehydrogenase) and *Actb* (β-actin) (Table 1). Specific primers were purchased from Invitrogen (Carlsbad, CA). Real-time PCR was performed using a CFX96 detection system (Bio-Rad). The thermal cycling parameters were 95°C for 3 min, 40 cycles of 95°C for 15 s, followed by 60°C for 1 min. The experiment for each postnatal age was run in triplicate and normalized to *Gapdh* and *Actb* mRNA levels. We used *Actb* as an additional housekeeping gene because it has been shown that the mRNA levels remain very steady throughout the development of the whole brain in Wistar rats (Fedoseeva et al., 2014). Three replicates of measurements from the same pool were then averaged, and the fold induction was determined in a $\Delta\Delta C_T$-based fold-change calculation. Furthermore, raw data (not normalized to P4) were obtained with the ΔC_T method (Schmittgen and Livak, 2008). A melting curve analysis was performed to confirm the specificity of the PCR products.

Immunohistochemistry

A total of 47 rat pups were used at different postnatal ages: 15 animals for P4, 14 animals for P8, 11 for P12, and 7 for P34. After the animals were euthanized with sodium pentobarbital (125 mg/kg), the brain was perfused transcardially with 0.1 M phosphate-buffered saline (PBS; pH 7.4), followed by cold (4°C) 4% paraformaldehyde diluted in 0.1 M phosphate buffer (PB; pH 7.4). Thereafter, the brain was extracted and post-fixed in 4% paraformaldehyde for 1 h before being transferred to 10% sucrose (overnight), 20% sucrose (24 h),

INFORME DE LABORES 2019

Table 2. Specifications of antibodies used in this research.

Antigen	Immunogen	Manufacturer, Species, Type, Catalog number, Test performed	Dilution Tested (Used •)	Reference
NR2A	Synthetic peptide within Human NMDA2A aa 850-900.	Abcam, rabbit, polyclonal, # ab203197, IHC.	1:50 1:100• 1:200	-
NR2B (phospho Y1252)	Synthetic peptide conjugated to LKH derived from within residues 1200-1300 of mouse NMDAR2B.	Abcam, rabbit, polyclonal, # ab18532, IHC.	1:50 1:100• 1:200	Delint et al., (2010)
NR2C	Antibody raised against 21-100 amino acids mapping near the human N-terminus of NMDAR2C.	Santa Cruz Biotechnology (Dallas, TX, USA), rabbit, polyclonal, # sc-50437, IHC.	1:50 1:250• 1:500	Liu and Wong-Riley (2010)
NR2D	Synthetic peptide corresponding to 661-710 amino acids of NMDAR2D of human.	Thermo Fisher Scientific (Rockford, IL, USA), rabbit, polyclonal, # PA5-36539, IHC.	1:50, 1:100• 1:200	-
PSD-95	Recombinant full length protein corresponding to PSD-95	Abcam, mouse, monoclonal, # ab2723, IHC.	1:1000 1:2000 1:3000 1:4000•	Zhao et al., (2016)

and finally 30% sucrose (48 h). Consecutive frozen coronal sections (40 µm) containing the hypothalamus were obtained with an SM2010R microtome (Leica) and collected into 0.1 M PBS. Brain sections belonging to the different postnatal ages were stained for the antibodies listed below and imaged at the same time for consistency between runs. On average, 4 consecutive sections (per brain) were carefully chosen with the help of a stereomicroscope (MicroscoSB; Commack, NY). They contained the medial SCN and were immunostained for protein pairs consisting of 1 of the 4 NR2 subunit subtypes of the NMDA receptor (A to D) and the scaffolding protein PSD-95; i.e., NR2A and PSD-95, NR2B and PSD-95, NR2C and PSD-95, NR2D and PSD-95. Immunofluorescence labeling was performed with free-floating sections at 4°C for 72 h in 1% normal donkey serum and 0.03% Triton X-100 in 0.1 M PBS (PBSDT). Secondary antibodies were incubated in PBSDT for 2 h at room temperature in black tubes protected from light. Slices were then washed in PBS (3 times, 10 min each), mounted, and coverslipped with 97% 2,2′-thiodiethanol (Staudt et al., 2007).

Antibodies

All antibodies used in this study (Table 2) were tested and characterized by the supplier companies. Negative control experiments were performed by incubation with only the secondary antibody, and no unspecific immunolabeling was observed (Suppl. Fig. S1A). Dilution-fluorescence curves were carried out for primary antibodies (Table 2, Suppl. Fig. S1B). Secondary antibodies (anti-rabbit Alexa Fluor 488 and anti-mouse Alexa Fluor 647; both from Abcam, Cambridge, UK) were used at a 1:500 dilution.

Image Acquisition and Analysis

SCNs were imaged with an LSM-700 confocal microscope (Carl Zeiss; Oberkochen, Baden-Württemberg, Germany). The best mounted and coverslipped brain slices containing the medial SCN were chosen for imaging by confocal microscopy (1 or 2 slices were selected from each animal at every stage of postnatal development) using the Zen software (Carl Zeiss) for image acquisition. A 10× objective (NA 0.3) was used to obtain a panoramic view of the SCN and adjacent structures. Then, 40× (NA 1.3) and 63× (NA 1.4) objectives were used to visualize the ventral SCN (Abrahamson and Moore, 2001) (Fig. 1B), and optical slices were obtained at 1 µm steps (on average, we obtained more than 20 optical slices per image). Two images (medial and lateral) were taken for each ventral SCN (left and right) for a total of 4 images for each slice. For intensity fluorescence measurements, PMT gain, laser intensity, and all other parameters (e.g., acquisition and exposure time) were adjusted for each age to show the highest brightness without saturation and were maintained constant for all subsequent images obtained within the same run.

Images were 3D blind deconvoluted using the AutoQuant X3 (Media Cybernetics Inc., Rockville, MD) and then analyzed using the ImageJ software (National Institutes of Health, Bethesda, MD). The signals were separated into 2 channels, and the mean pixel immunofluorescence intensity was measured in the entire image, i.e., the stack of optical slices (at least 20). A stack of optical slices was obtained with the maximum intensity projection function of the Zen software. Immunofluorescence intensity measurement obtained from medial and lateral images were pooled. Co-localization was analyzed on the entire image using the Zen software, and this co-localization

analysis was performed on a pixel by pixel basis. Each pixel was plotted in a scatter diagram based on its intensity level from each channel. Thereafter, the Pearson correlation coefficient was calculated with a value of 1 indicating a perfect co-localization.

Electrophysiological Recordings

Spontaneous postsynaptic currents from ventral SCN neurons of slices obtained at P8 and P34 were recorded at room temperature (22°C to 24°C) in the whole-cell configuration of the patch-clamp technique using an Axopatch 200B amplifier (Molecular Devices; Sunnyvale, CA). Neurons were visualized with an upright Axioexaminer A1 microscope (Carl Zeiss). Data acquisition and command potentials were carried out with a Digidata 1322A interface controlled by the pClamp 8.2 software (Molecular Devices). Recording electrodes of 2 to 4 MΩ were made in a P97 puller (Sutter Instrument Co., Novato, CA) and filled with intracellular solution containing 64 mM D-gluconic acid, 64 mM CsOH, 11 mM EGTA, 56 mM CsCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10 mM HEPES, and 5 mM QX-314. Series resistance was compensated (~80%), and the seal was monitored throughout the whole experiment. ACSF Mg^2+-free solution (124 mM NaCl, 1 mM K_2SO_4, 5 mM KCl, 1.25 mM KH_2PO_4, 10 mM dextrose, 26 mM $NaHCO_3$, 2 mM $CaCl_2$; bubbled with 95% O_2/5% CO_2; pH 7.4) was used as the external recording solution. Cells were discarded if the input resistance was less than 150 MΩ or the access resistance greater than 15 MΩ, or changed more than 15%. Currents were low-pass filtered at 2 kHz and sampled at 10 kHz.

Contribution of NR2 Subtypes to the Frequency and Amplitude of NMDA EPSCs

To analyze the contribution of NR2 subtypes to isolated spontaneous NMDA excitatory postsynaptic currents (EPSCs), 50 µM picrotoxin (a GABA-A receptor antagonist) and 5 µM 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, an antagonist of AMPA/kainate receptors) were added to the external recording solution (ACSF Mg^2+-free solution). After 5 min of recording basal NMDA isolated currents, each of the selective NR2 subtype antagonists were applied in a random sequence; for NR2A, 100 nM [[[(1*S*)-1-(4-Bromophenyl) ethyl]amino] (1,2,3,4-tetrahydro-2,3-dioxo-5-quinoxalinyl)methyl] phosphonic acid tetrasodium salt (PEAQX); for NR2B, 3 µM (α*R*,β*S*)-α-(4-Hydroxyphenyl)-β-methyl-4-(phenylmethyl)-1-piperidinepropanol maleate (Ro 25-6981); or for NR2C/D, 150 nM (2*S**,3*R**)-1-(Phenanthren-2-carbonyl)piperazine-2,3-dicarboxylic acid (PPDA). PEAQX has an IC_{50} of 8 nM on NMDA receptors containing the NR2A subunit. PEAQX is over 100-fold more selective to NR2A than NR2B subunits (Auberson et al., 2002). Thus, we chose a concentration of 100 nM, according to previous reports demonstrating the highest specificity for NR2A (Tackenberg et al., 2013). By contrast, Ro 25-6981 exhibits a higher affinity for NR2B over the NR2A subtype, since its IC_{50} values are 0.009 and 52 µM, respectively (Fischer et al., 1997). Hence, we used 3 µM Ro 25-6981 to detect the presence of NR2B subunits, which agrees with previous studies (Alamilla and Gillespie, 2011). Likewise, PPDA exhibits a K_i of 0.096, 0.125, 0.31, and 0.55 µM for the NR2C, D, B, and A subtypes, respectively (Morley et al., 2005). Based on this information, we assumed that 150 nM would be sufficient to distinguish between NR2C/D and NR2B/A subunits. The effects of these NR2 subtype blockers on the frequency and amplitude of NMDA EPSCs were analyzed, and the percentages of NR2A, NR2B, and NR2C/D subunit contributions were calculated for each recorded neuron.

Drugs and Reagents

Picrotoxin, CNQX, PEAQX, PPDA, and Ro 25-6981 were obtained from Tocris Bioscience (Ellisville, MO), and all other reagents were purchased from Sigma-Aldrich (St. Louis, MO).

Data Analysis

Data are reported as the mean ± SEM. GraphPad Prism 5 (GraphPad Software; La Jolla, CA) was used to perform statistical analyses. Where appropriate, the unpaired *t*-test or one-way ANOVA with Dunnett's post-hoc test were used to evaluate statistical differences. The non-parametric Kruskal–Wallis test with Dunn's post-hoc test was used to analyze the fold-change in mRNA expression (Hoang et al., 2009). A two-tailed alpha value of 0.05 ($P < 0.05$) was considered statistically significant.

RESULTS

mRNA Expression of NR2 Subunits during Postnatal Development in the SCN

As mRNA expression of NR2 subtypes must be normalized to that of housekeeping genes according to the $\Delta\Delta C_T$ method, we first sought to validate that the mRNA levels of the housekeeping genes

INFORME DE LABORES 2019

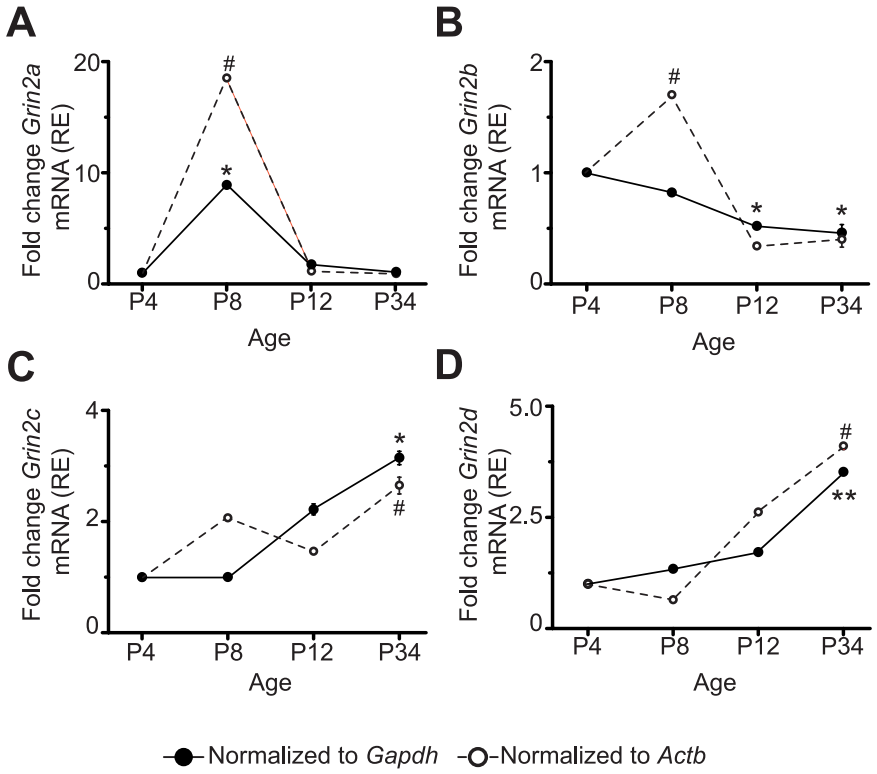

Figure 2. mRNA expression relative (RE) to P4 of the different NR2 subunits during the postnatal development of the rat. mRNA of *Grin2a* that encodes for NR2A (A), *Grin2b* for NR2B (B), *Grin2c* for NR2C (C), and *Grin2d* for NR2D (D) at postnatal ages 4, 8, 12, and 34. Data correspond to triplicate experiments of the same mRNA pool from 8 animals belonging to each analyzed postnatal age. *$P < 0.05$, **$P < 0.01$ vs. P4 normalized to *Gapdh*; #$P < 0.05$ normalized to *Actb*.

displayed no development-dependent variation. Although there was a statistically significant *Gapdh* variation between P8 and P12, we did not find a significant difference in C_T between the control age P4 and any other analyzed age (Suppl. Fig. S2). Likewise, *Actb* did not show a development-dependent variation in C_T at all analyzed ages (Suppl. Fig. S2).

Next, the mRNA expression levels of NMDAR2 subtypes in the SCN were analyzed at different postnatal ages (Fig. 1A), using P4 as a reference (Fig. 2). Normalized to both housekeeping genes, *Grin2a* (NR2A subtype) mRNA expression levels only peaked at P8 (Fig. 2A). When normalized to *Gapdh*, *Grin2b* (NR2B) showed a decrease in mRNA expression at P12 and P34, whereas when normalized to *Actb*, mRNA levels significantly increased at P8 (Fig. 2B). The mRNA levels of *Grin2c* (NR2C) were elevated at P34 with respect to those at P4 (Fig. 2C) with a similar result for *Grin2d* (NR2D), which also displayed a significant increase in mRNA expression at P34 (Fig. 2D). Similar tendencies were found when data were not normalized to P4 (ΔC_T) (Suppl. Fig. S3). These results indicate that mRNA levels of NR2 subtypes in SCN neurons are differentially expressed during postnatal development.

Developmental Expression of NR2 Subtypes and Scaffolding Protein PSD-95 in the Ventral SCN

Immunofluorescence intensities of NR2 subtypes were analyzed at different ages of postnatal development (Figs. 3A, 4A, 5A, and 6A). For NR2A, a higher fluorescence intensity was observed at P8 (79 ± 7 arbitrary units [a.u.]) and P34 (72 ± 8 a.u.) compared with P4 (49 ± 4 a.u.; $F_{[3,56]} = 5$, $P = 0.010$; Fig. 3B). No significant differences in immunofluorescence were found for the NR2B subtype among all postnatal ages investigated (54 ± 6 a.u., 68 ± 13 a.u., 68 ± 15 a.u., and 63.4 ± 10 a.u. at P4, P8, P12, and P34, respectively; $F_{[3,56]} = 0.34$, $P = 0.8$; Fig. 4B). The immunofluorescence intensities of the NR2C subunit were significantly increased at all time points (70 ± 5 a.u., 64 ± 3 a.u., and 69 ± 3 a.u. at P8, P12, and P34, respectively) compared with P4 (52 ± 3 a.u.; $F_{[3,50]} = 6.0$, $P = 0.0013$; Fig. 5B). For the NR2D subtype, the immunofluorescence intensities were increased at all analyzed ages compared with that at P4 (47 ± 3 a.u., 71 ± 4 a.u., 67 ± 3 a.u., and 67 ± 2 a.u. at P4, P8, P12, and P34, respectively; $F_{[3,60]} = 3.7$, $P = 0.017$; Fig. 6B). Similarly, the protein PSD-95 showed a development-dependent expression that was significantly

INFORME DE LABORES 2019

A white letter *N* indicates a putative neuronal soma, and arrowheads depict co-localization dots of the NR2 subtype with PSD-95. Scale bars, 10 μm. (B) Fluorescence intensity (Fluor. int) in arbitrary units (a.u.) of the NR2A subtype at the 4 examined postnatal ages. (C) Co-localization of NR2A and PSD-95 denoted by Pearson's coefficient. *$P < 0.05$, **$P < 0.01$ vs. P4.

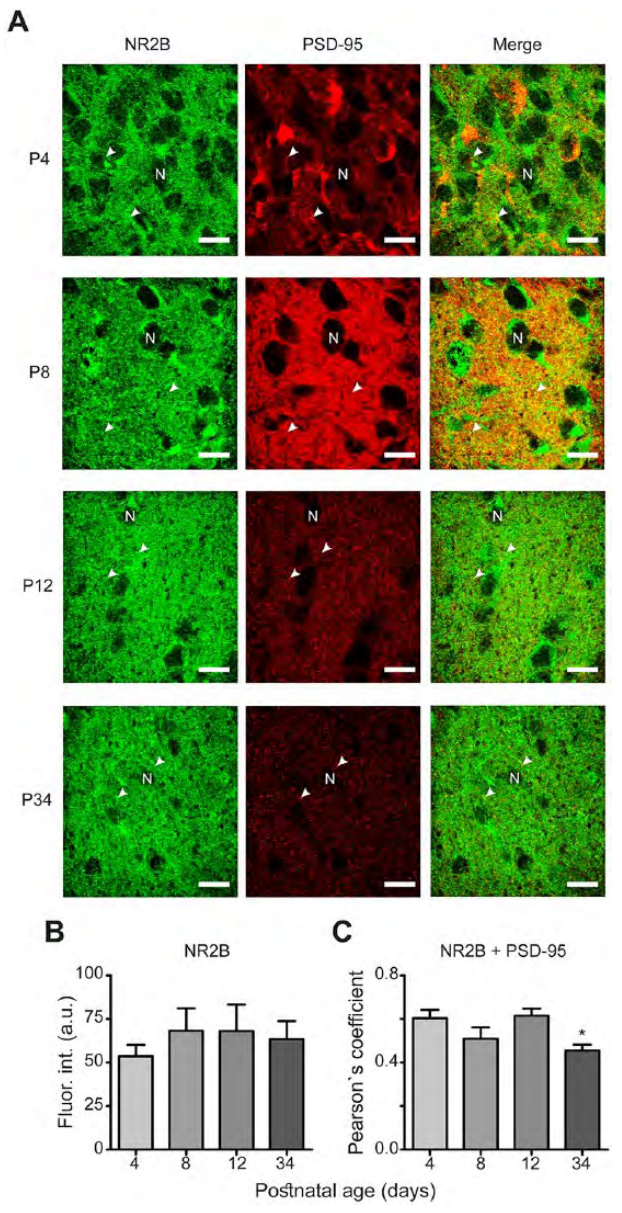

Figure 4. Expression of the NR2B subtype during postnatal development. (A) Similar micrographs as described for Fig. 3A (scale bars, 10 μm). (B) The fluorescence intensity of the NR2B subtype does not exhibit developmental changes at the analyzed postnatal ages. (C) Data from co-localization analyses of NR2B with the PSD-95 protein.

higher at P8 and P12; although, the mean intensity at P34 did not differ compared with that at P4 (66 ± 4 a.u., 97 ± 4 a.u., 113 ± 8 a.u., and 78 ± 5 a.u. at P4, P8, P12, and P34, respectively; $F_{[3,150]} = 12$, $P < 0.0001$; Fig. 7). Overall, these results suggest a differential developmental pattern of the protein expression of NMDA-NR2 subtypes as well as that of the NMDA scaffolding protein PSD-95.

Co-Localization of NR2 Subunits and PSD-95 Protein

PSD-95 functions as a platform for NMDA receptors, and it is therefore expected that NR2 subtypes and PSD-95 are co-localized. We analyzed the degree

INFORME DE LABORES 2019

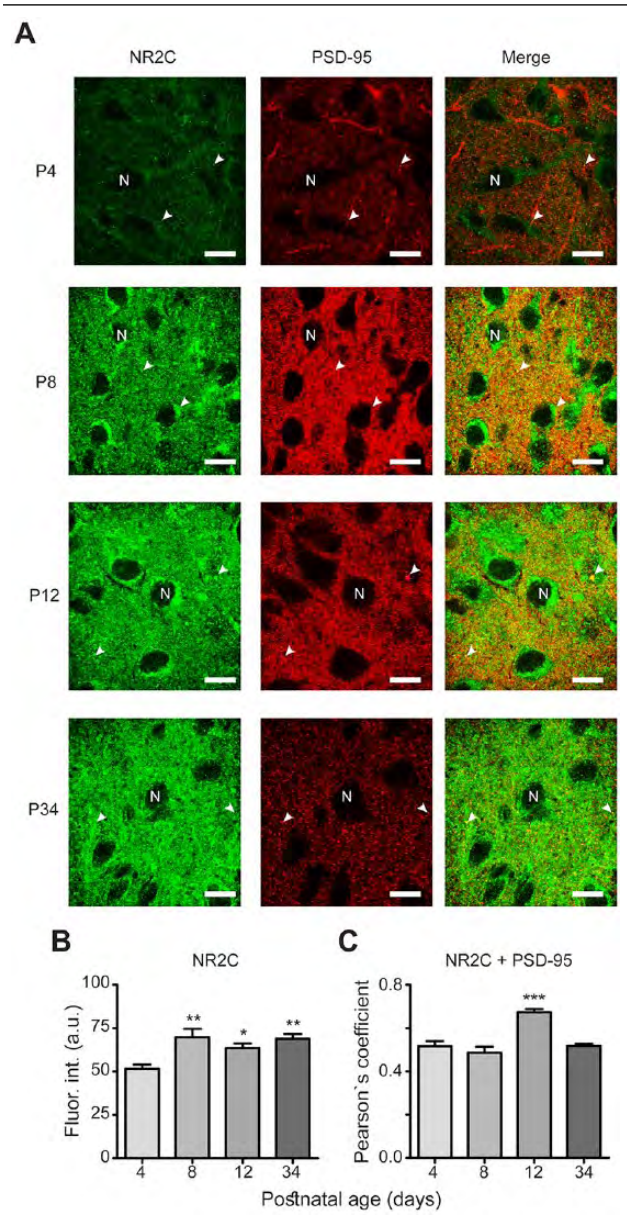

Figure 5. Development-dependent expression of the NR2C subtype. (A) Similar micrographs as described for Fig. 3A (scale bars, 10 μm). (B) Significant increase in NR2C immunofluorescence intensity at P8, P12, and P34. (C) Significantly augmented co-localization of NR2C and PSD-95 at P12. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ vs. P4.

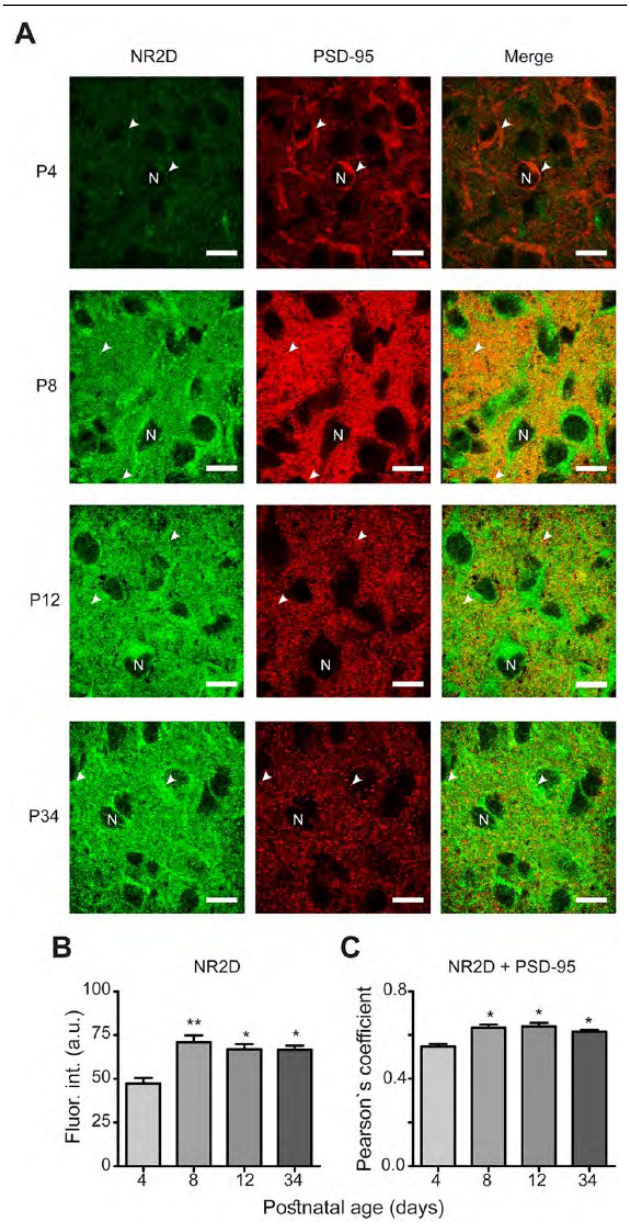

Figure 6. NR2D subtype expression during postnatal development. (A) Similar micrographs as described for Fig. 3A (scale bars, 10 μm). Immunofluorescence intensity is significantly increased after P8 (B), and similar situation in co-localization analyses (C). *$P < 0.05$, **$P < 0.01$ vs. P4.

of this co-localization, and our results revealed high co-localization between NR2 subtypes and PSD-95 (0.6 Pearson's coefficient on average; Figs. 3-6, merge panels). Particularly, NR2A and PSD-95 showed an increased co-localization index at P8 and P12 (Pearson's coefficient of 0.57 ± 0.02 and 0.59 ± 0.03, respectively) compared with that at P4 (0.48 ± 0.02) (Fig. 3C). NR2B showed a reduction at P34 (0.45 ± 0.02) compared with P4 (0.6 ± 0.04), whereas NR2C increased at P12 (0.67 ± 0.01) relative to P4 (0.51 ± 0.02). Similarly, co-localization of NR2D and PSD-95 was larger at all studied postnatal ages (0.63 ± 0.01, 0.64 ± 0.01, and 0.61 ± 0.01 at P8, P12, and P34, respectively) compared with P4 (0.54 ± 0.01) (Fig. 6C). These results suggest that NR2 subunits co-localize with PSD-95 in the developing ventral SCN, and the higher co-localization index at specific postnatal ages may imply that NR2 subtypes are recruited into postsynaptic densities.

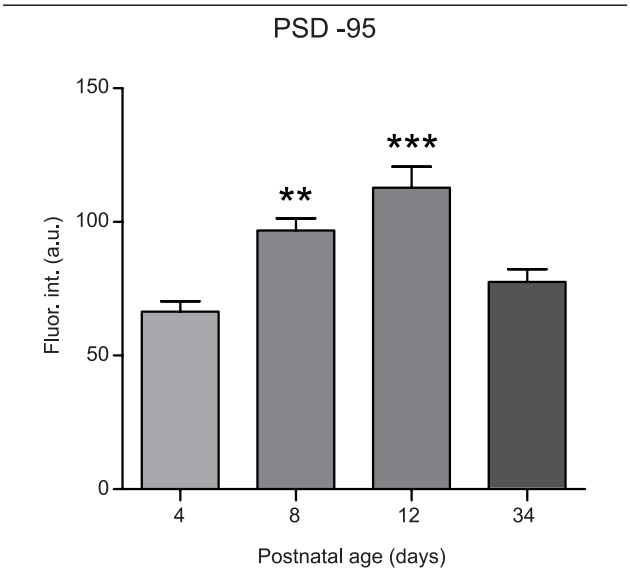

Figure 7. Postnatal expression of PSD-95. Significant changes in this scaffolding protein at P8 and P12. PSD-95 expression (illustrated in the middle columns of Figs. 3A, 4A, 5A, and 6A) supports a development-dependent expression. **$P < 0.01$, ***$P < 0.001$ vs. P4.

Electrophysiological Changes of NR2 Subtypes during Development

Because we found developmental changes in mRNA and protein expression of the diverse NR2 subtypes, we hypothesized that these changes have an impact on the physiology of SCN ventral neurons receiving glutamatergic RHT inputs. Consequently, we analyzed the effects of a selective antagonist for the different NR2 subtypes and determined their contributions to the frequency and amplitude of spontaneous NMDA EPSCs recorded in ventral SCN neurons at the 2 developmental ages, P8 and P34. We selected these 2 postnatal ages because we wanted to elucidate if there are changes in the physiology of NMDA receptors between the age where the initial synchronization to light starts (P8) (Duncan et al., 1986) and an older juvenile age (P34). The NR2A subtype had a larger contribution at P8 compared with that at P34, with reductions in EPSC frequencies by PEAQX of 57% ± 11% and 18% ± 10%, respectively ($t = 2.6$, $df = 15$, $P = 0.01$, unpaired t-test) (Fig. 8A). No statistically significant differences in antagonist-induced changes were found in the frequencies of NMDA EPSCs attributable to the NR2B subunit at the 2 analyzed ages. The reductions in EPSC frequencies by Ro 25-6981 were 33% ± 11% and 51% ± 12% at P8 and P34, respectively ($t = 1$, $df = 15$, $P = 0.3$, unpaired t-test) (Fig. 8B). Similar results were found in NMDA EPSC frequencies attainable to the NR2C/D subtype participation because the PPDA-induced reductions in EPSC frequencies were 19% ± 10% at P8 and 34% ± 10% at P34 ($t = 1$, $df = 12$, $P = 0.1$, unpaired t-test; Fig. 8C).

The analysis of the NMDA EPSC amplitudes indicated no developmental changes in NR2 subtype contributions at the examined time points P8 and P34 (Table 3). NR2A showed a similar participation at the 2 analyzed ages (30% ± 6% and 41% ± 14% at P8 and P34, respectively; $t = 1.2$, $P = 0.11$, unpaired t-test) (Table 3). The NR2B subtype displayed an age-independent performance (22% ± 7% and 31% ± 7% at P8 and P34, respectively; $t = 0.9$, $P = 0.2$, unpaired t-test; Table 3). Comparable results were also obtained for the NR2C/D subtypes (25% ± 11% and 24% ± 7% at P8 and P34, respectively; $t = 0.1$, $P = 0.44$, unpaired t-test; Table 3).

To investigate the effects of the 2 variables (drug administration and developmental ages) on NMDA EPSCs, a 2-way ANOVA test was carried out to analyze the contribution of NR2 subtypes on the frequency and amplitude of NMDA EPSCs. The interaction test indicated that the participation of NR2 subtypes on the reduction in EPSC frequency was dependent on age (P8 vs. P34; $F_{[2, 90]} = 4.6$, $p = 0.01$; data not shown). Regarding the amplitude of EPSCs, the interaction test showed that the contribution of NR2 subtypes did not depend on the developmental age ($F_{[2,90]} = 0.43$, $p = 0.64$; data not shown).

Taken together, our results indicate that NR2 subtypes, at least NR2A, exhibit a development-dependent contribution to the EPSC frequency of SCN neurons at P8 and P34.

DISCUSSION

The main result of this study is that we found developmental changes in the expression of the NR2 subtypes of glutamatergic NMDA receptors both in mRNA content and protein expression, which were consistent with the findings in experiments measuring the postsynaptic electrical activity. To our knowledge, this is the first study focused on an investigation of postsynaptic changes in SCN neurons related to light synchronization that occurs at adult stages. Previous studies were aimed at analyzing presynaptic changes by examining the innervations connecting the retina with SCN neurons during postnatal development (Speh and Moore, 1993).

In the current study, we found that the NR2A subtype had a stronger influence on the frequency of NMDA EPSCs at P8, just when the pup starts synchronizing to light via its RHT, whereas the NR2A contribution is decreased afterwards at age P34. Behavioral studies performed in adult animals implicate the NR2A subtype in the synchronization to light, with knockout animals taking longer to synchronize to damped light conditions (Moriya et al., 2000). The NR2B subtype did not show developmental changes

INFORME DE LABORES 2019

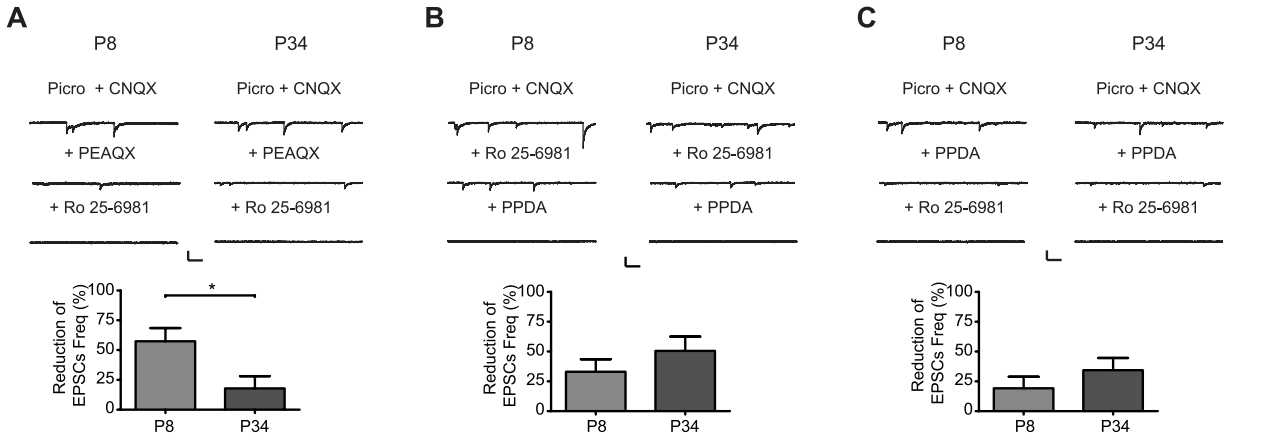

Figure 8. Contribution of the different NR2 subtypes on EPSC frequency (Freq) at 2 postnatal ages (P8 and P34). NMDA EPSCs recorded before (Control = Picro + CNQX) and after application of the NR2A antagonist PEAQX (A), the NR2B antagonist Ro 25-6981 (B), and the NR2C/D antagonist PPDA (C) at the 2 analyzed developmental ages. Scale bars: 40 pA, 200 ms. Bar graphs show the reduction in NMDA EPSC frequency induced by the respective NR2 antagonist. *$P < 0.05$.

in protein expression at all of the examined postnatal ages; although, its mRNA expression progressively decreased with age when normalized to *Gapdh.* However, it peaked at P8 when normalized to *Actb*. The latter result is probably more reliable since the levels of this housekeeping gene remain very steady throughout development. The data regarding the expression of the NR2B protein and its co-localization with PSD-95 are consistent with our electrophysiological results. Several lines of evidence indicate that the NR2B subunit is already present at pre- and early postnatal ages (see Cull-Candy et al., 2001). NR2B plays an important role in the synaptic communication of the RHT–SCN pathway at adult stages (Clark and Kofuji, 2010). We believe that the presence of NR2B at all analyzed ages supports the notion of the main influence of this subtype on RHT–SCN synaptic transmission, from early postnatal ages until a young stage. Wang and colleagues (2008) elicited phase-shift reductions in animals by ifenprodil administration but not their complete abolition, which indicates that other NR2 subtypes could participate in the synchronization of SCN neurons to light.

As shown in knockout animals, the NR2C subtype does not seem to be involved in the synchronization to light at adult ages (Moriya et al., 2000). In the present study, we found larger mRNA levels and protein expression of NR2C at juvenile ages; i.e., P34, in which synchronization to light is completed. Similar results (major mRNA content and protein expression) were obtained for the NR2D subtype at the same age. The electrophysiological experiments measuring the EPSC frequencies did not show developmental changes between P8 and P34 according to the effects of an NR2C/D antagonist, which is in agreement with the immunohistochemical experiments because the protein expression of the NR2D subtype was increased at P8 and afterwards. To date, there are no specific antagonists for NR2C and NR2D subtypes, and thus there are no functional studies focused on the contribution of the NR2D subtype to the light synchronization of SCN neurons. Although there are reports indicating that NR2D is not present at the synapses (in a diheteromeric form) (see Cull-Candy, 2001), our co-localization analyses of NR2D and PSD-95 suggest that this subtype is present in the postsynaptic membrane. Clark and Kofuji (2010) proposed that, in SCN neurons, there is a subpopulation of triheteromeric NMDA receptors formed by NR2A and NR2C/D proteins, because the NMDA current remaining after application of the NR2B antagonist ifenprodil shows pharmacological properties of the NR2A subtype with a Mg^2+ sensitivity more similar to that of the NR2C/D than the NR2A subtype.

Even though the developmental expression of NR2 subtypes in the brain indicates that NR2B/C and D are mainly expressed at early postnatal ages (P0-P12) while NR2A predominates at later developmental stages (Monyer et al., 1994), our results indicate that the NR2 subtypes of the NMDA receptors in ventral SCN neurons do not follow this pattern. In fact, the functional performance of NR2A showed a reduction

at later postnatal ages, NR2B did not present any developmental modification regarding electrophysiology and protein expression, and NR2C and D expressions were not reduced but rather increased at more advanced developmental stages compared with the earlier postnatal age, P4.

PSD-95 has been described as a scaffolding protein for NMDA receptors, localized specifically at the postsynaptic membrane of glutamatergic synapses (Hunt et al., 1996). The increased number of synapses could explain the increase in PSD-95 expression that we found at P8 and P12. Moore and Bernstein (1989) have shown an increase in synaptogenesis between P6 and P10, which is in accordance with our results. Additionally, our analysis of the PSD-95 co-localization with the NR2 subtypes resulted in values higher than 0.5, suggesting that at least half of the immunofluorescence signal is found in the postsynaptic membrane, whereas the remaining fluorescence could be due to NR2 subtypes present in the presynaptic membrane or other cellular structures, such as glial cells (Bouvier et al., 2015; Steinhäuser and Gallo, 1996).

Moreover, our results point to P8 as the developmental stage where NMDA receptors, specifically the NR2 subunit, have reached an adequate level of maturation to allow SCN neuron synchronization to light, which is consistent with a pioneering study that shows that around P7 the rat pup is able to synchronize to the LD cycle without maternal influence (Duncan et al., 1986).

In conclusion, our results indicate that ventral SCN neurons present a development-dependent change in the mRNA content, protein expression, and postsynaptic electrical activity of NR2 subtypes of glutamatergic NMDA receptors that may be important for the synchronization to light at adult stages.
