A, *Plpp3* expression (fold change; mean±SEM) from SMC isolated from fl/fl (dark) and SM22-Δ (open) mice on the *Ldlr*$^{-/-}$ background (n=3/group). **B**, At 6 to 8 wk of age, fl/fl (dark circles) and SM22-Δ (open circles) mice on the *Ldlr*$^{-/-}$ background were placed on Western diet for 12 wk and total plasma cholesterol (mg/dL) measured (n=7/group). **C**, Plasma lysophosphatidic acid (LPA) species quantification from fl/fl (black bars) and Sm22-Δ (white bars) mice on the *Ldlr*$^{-/-}$ background after 12 wk on Western diet (n=9–11/group). **D**, En face analysis of atherosclerosis (% of arch area; n=7–9/group). **E**, Oil red-O (ORO) staining of aortic sinus lesions reported as % area of aortic sinus (n=5–6/group). **F**, **Left**: Immunohistological quantification of CD68 from sections of aortic roots from fl/fl and MX1-Δ mice on the *Ldlr*$^{-/-}$ background after 12 wk on Western diet (n=5–6/group). **Right**: Representative images of CD68 staining in the aortic sinus. **G**, Plpp3 (phospholipid phosphatase 3) and *Il-6* (interleukin 6) expression (fold change; mean±SEM) in proximal aortas from fl/fl and SM22-Δ (n=5/group). **H**, Total LPA content (pmol/mg) in proximal aortas of fl/fl and SM22-Δ (n=7–9/group).

dynamic upregulation of LPP3 during the development of atherosclerosis in porcine and murine models of atherosclerosis. Herein, we report that LPP3 serves as an intrinsic negative regulator of plaque formation in experimental models of murine atherosclerosis and its loss either globally or in SMCs coincide with increased plaque macrophage cellularity, increased inflammatory cytokine expression and elevated LPA levels in

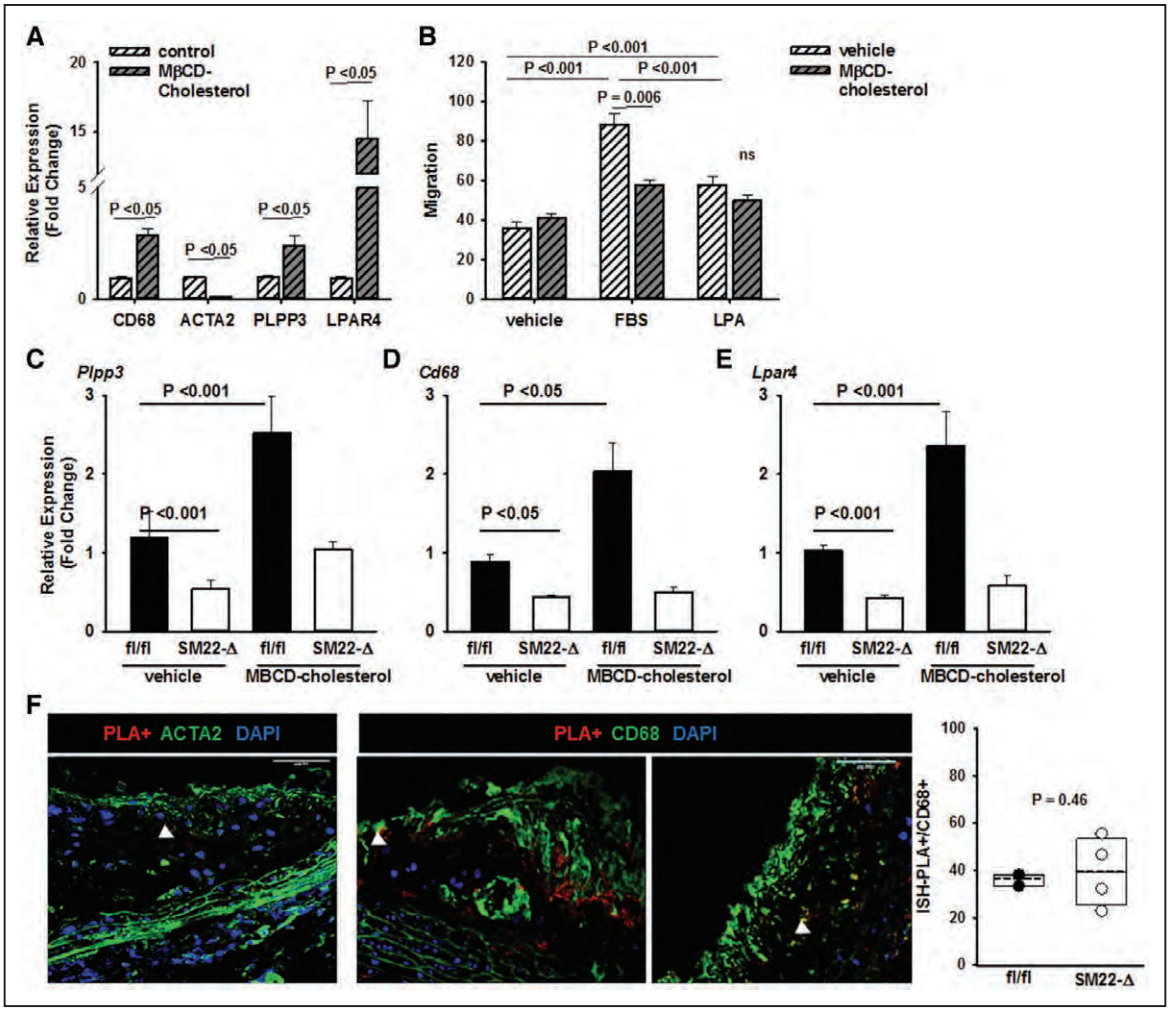

Figure 4. *PLPP3* expression is dynamically regulated during smooth muscle cell (SMC) phenotypic modulation.
A, Expression of the indicated genes in primary human coronary artery SMC treated with vehicle control or methyl-β-cyclodextrin (MβCD) complexed cholesterol (20 μg/mL) for 48 h to induce modulation towards a foam cell-like phenotype. Relative gene expression (fold change; mean±SEM) was determined. **B**, Cell migration to vehicle (DMEM with 0.01% FBS), FBS (DMEM with 10% FBS), or LPA (DMEM with 10 μmol/L 18:1 LPA) for 24 h (**right**; mean numbers of migrated cells±SEM). Two-way ANOVA was used to determine differences between treatment groups and chemotaxis agent. Relative gene expression (fold change; mean±SEM) of (**C**) *Plpp3*, (**D**) *Cd68*, and (**E**) *Lpar4* in primary SMCs from fl/fl and SM22-Δ on the *Ldlr*$^{-/-}$ background treated with vehicle or MβCD-cholesterol (20 μg/mL) for 48 h. Two-way ANOVA was used to determine differences between treatment groups and genotypes. **F**, H3K4me2 marker of the MYH11 (myosin heavy chain 11) promoter (red) visualized by in situ hybridization and proximity ligation assays in aortic root sections stained with ACTA (actin, alpha, skeletal muscle 1; green) and DAPI (blue). Cells positive for the H3K4me2 marker as a percentage of total CD68+cells (cells/field quantified) in aortic root sections from fl/fl and SM22-Δ animals on the *Ldlr*$^{-/-}$ background fed Western diet for 12 wk (n=2–4/group).

atheromas. Importantly, *Lpar4* expression is modulated by cholesterol loading in both human and murine SMCs and *Lpar4*$^{-/-}$ mice prone to atherosclerosis are protected against plaque formation suggesting that elevated LPA signaling may directly modulate CAD in mice. These findings provide functional validation and support a causal relationship of observations linking *PLPP3* alleles with LPP3 expression and risk of CAD.

Global reductions in LPP3 expression using the *Mx1-Cre* system substantially increase atherosclerosis and are accompanied by elevations in plaque-associated LPA and inflammation. Interestingly, although LPP3 expression increases during ox-LDL-induced phenotypic modulation of BMDM, myeloid *Plpp3* does not appear to regulate the development of atherosclerosis. Instead, SMC expression of LPP3 is a major determinant of the extent of both atherosclerosis and LPA content in lesions. Importantly, the pro-atherosclerotic effects of targeting LPP3 with either *Mx1-Cre* or *Sm22-Cre* are independent of changes in circulating lipoprotein or plasma triglyceride levels.

We previously reported that SMC LPP3 is a negative regulator of neointimal formation in the absence of hyperlipidemia, in part due to an ability to attenuate inflammatory cell accumulation and SMC migration.[22] In SMCs, LPP3 regulates LPA-induced ERK activity, Rho activation, and migration, and lentiviral expression of human or mouse LPP3 (but not catalytically inactive variants)

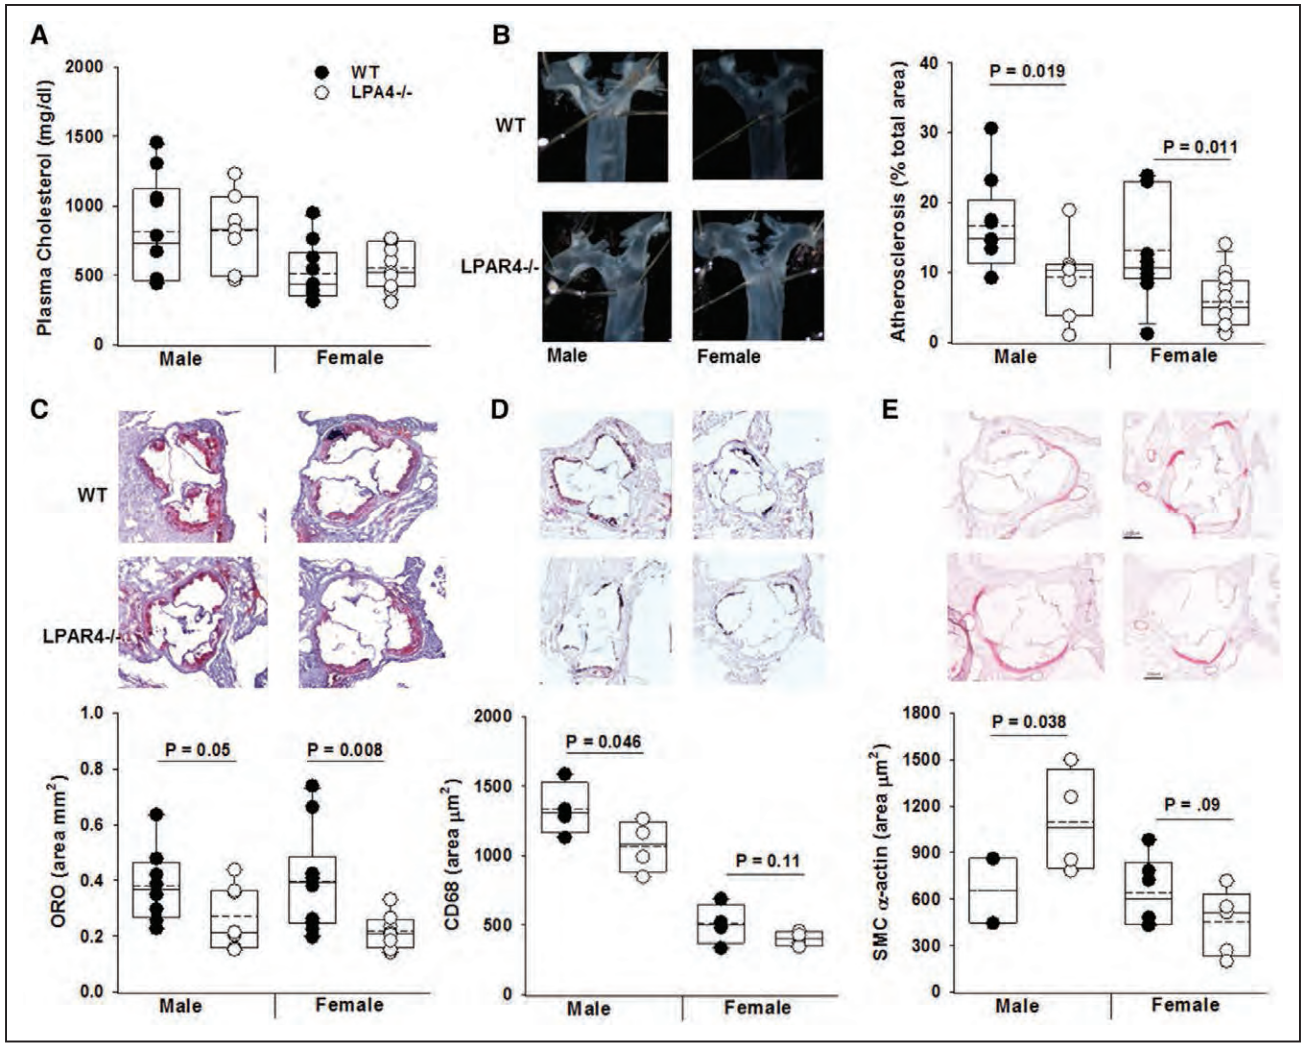

Figure 5. LPAR4 (LPA receptor 4) regulates experimental atherosclerosis.
A, Six to 8-week-old wild-type (WT; closed circle) control or *Lpar4*$^{-/-}$ (open circles) mice were infected with PCSK9 (proprotein convertase subtilisin/kexin type 9) adeno-associated virus. One week later, they were placed on Western diet for 16- weeks and total plasma cholesterol (mg/dL; n=7–9/group). **B**, **Left**: Representative images of proximal aorta. **Right**: En face analysis of atherosclerosis (% of arch area) in male and female WT (closed circle) and *Lpar4*$^{-/-}$ (open circles) mice infected with PCSK9 adeno-associated virus and Western diet-fed for 16-weeks (n=7–9/group). **C**, Oil red-O (ORO) staining and lesion area (% total aorta in root section; n=7–9/group). **D**, CD68 immunostaining (n=4/group) and (**E**) Smooth muscle cell (SM) α-actin staining from aortic root sections of male mice (n=2–5/group).

attenuates these effects.[22] These results imply that LPP3 may function within the vasculature to regulate responses to bioactive lipids, such as LPA. Herein, we expand these findings to demonstrate that LPP3 expression is upregulated in both human and murine primary SMCs as they assume a foam cell like phenotype characterized by upregulation of *CD68* and downregulation of SMC marker *ACTA2* in response to cholesterol uptake. In this context, upregulation of LPP3 is associated with decreased FBS-stimulated SMC migration. We also demonstrate that LPP3 regulates LPA levels in atherosclerotic vessels, in that tissue LPA levels are higher from mice with reduced LPP3. Thus, the effect of LPP3 on inflammation may be a consequence of broad effects on extracellular bioactive lipid levels and hence signaling responses of multiple cell types during the development of atherosclerosis.

While LPA is not the only substrate of LPP3, in support of a role for LPA-mediated pro-atherosclerotic effects, we demonstrate that global deletion of *Lpar4* in hyperlipidemic mice significantly reduced the development of atherosclerosis in the absence of an effect on plasma cholesterol. As to be expected with decreased atheroma size, we observed significantly less macrophage content in male *Lpar4*$^{-/-}$ mice; however, this effect was not observed in female mice. Additionally, we characterized SMC cell content in these knockout mice and observed a significant increase in SMC area in male *Lpar4*$^{-/-}$ lesions that also was not present in females. These data suggest that loss of *Lpar4*$^{-/-}$ may affect SMC proliferation and migration during atherosclerosis progression differently in males than females. Regardless of LPAR4's role in SMC modulation during atherosclerosis, the overall

Downloaded from http://ahajournals.org by on October 20, 2020

result was protection from atherosclerotic lesion formation. LPA signaling can promote CD14 and SR-A1 expression in these cells which may influence the mechanisms linking ox-LDL uptake and foam cell formation. Indeed, previous studies have reported an atherogenic role for LPA signaling via inducing endothelial expression of the monocyte adhesion molecule CXCL1.[12] Zhou et al[12] report that treatment of mice with unsaturated but not saturated LPA species increases atherogenesis and macrophage accumulation in aortic sinus lesions that can be attenuated via treatment with an inhibitor to LPA receptors 1 and 3. These data are supported by another report wherein intestinally derived unsaturated LPA species increased atherosclerotic lesion size in mice relative to normal rodent diet and saturated LPA fed mice.[13] It is important to note that our MX1 model of Plpp3 reduction did increase circulating LPA content; however, there were no species-specific modulation of LPA by global loss of LPP3. Additionally, the loss of SMC-derived LPP3 accelerated atherosclerosis progression independently of changes in circulating LPA. Our findings reported here propose a novel LPA signaling pathway through LPAR4 that modulates atherosclerosis progression.

While our work focuses attention on SMC LPP3 and LPAR4 as regulators of atherosclerosis, expression of LPP3 in other cell-types may also attenuate development of atherosclerotic lesions. We also observed increases in endothelial LPP3 in atherosclerotic lesions. We and others have demonstrated that LPP3 controls endothelial barrier function[8,31] perhaps by spatial restriction of LPA receptor signaling.[32] LPP3 also modulates mechanotransduction in endothelial cells in an anti-inflammatory manner[10,33]; thus, endothelial LPP3 expression may also protect against atherosclerosis progression. A recent report implicates hepatocyte LPP3 as a regulator of plasma LPA levels and experimental atherosclerosis.[11] These findings are intriguing because they suggest that LPP3 expression in the liver could have a systemic effect, likely by regulating levels of key bioactive lipids that stimulate atherosclerosis. However, in the models reported here, inactivation of mouse *Plpp3* was not associated with significant differences in plasma lipid or lipoprotein profiles or, as observed in the SM22-model, circulating levels of LPA.

It is important to note that *Sm22* expression has been observed in cells other than SMC, such as in monocytes and neutrophils in mice.[34] Therefore, it is possible that the results observed are not the result of the lack of LPP3 in SMC. However, loss of *Plpp3* in myeloid derived cells achieved with the LysM promoter had no impact on atherogenesis, suggesting that the primary effect of SM22-mediated knockdown of *Plpp3* is unlikely to be mediated by loss of expression in granulocytes. Importantly, due to the fact that SM22-mediated *Plpp3* deletion is constitutive, we cannot rule out that loss of SMC-derived LPP3 during development did not impact susceptibility of these mice to the development of atherosclerosis. Finally, it is worth mentioning that we did not directly test whether activation of the MX1-Cre recombinase alone modulated atherogenesis. While this cannot be excluded as a possibility, our model using MX1-Cre mediated deletion of *Plpp3* demonstrates increased plasma and atherosclerotic plaque LPA, the former of which has been previously reported as a mechanism driving atherogenesis.[11,13]

Allelic variation of *loci* within the final intron of *PLPP3* associates with inter individual differences in CAD risk. Functional genomic studies identify this as a dynamically regulated locus containing regulatory elements for C/EBP and AP1 family transcription factors. While these *loci* could act in *trans* to modulate expression of distal genes, our finding that *Plpp3* deficiency exacerbates experimental atherosclerosis is consistent with the concept that *cis* actions of these *loci* on activity of the *PLPP3* promoter account for or contribute to the CAD risk effect. Taken together, our results identify and validate the *PLPP3* gene as an associated biological pathway that regulates CAD risk but is not obviously related to traditional risk factors, in particular those involving elevations in circulating cholesterol and triglycerides. While strategies to elevate *PLPP3* expression to protect against atherosclerosis may not be feasible, our findings suggest that pharmacological targeting of LPA synthesis and signaling might offer an orthogonal approach to lipid-lowering drugs for mitigation of CAD risk.

Abstract: The emergence of microbes resistant to common antibiotics represent a current treat to human health. It has been recently recognized that non-antibiotic labeled drugs may promote antibiotic-resistance mechanisms in the human microbiome by presenting a secondary antibiotic activity; hence, the development of computer-assisted procedures to identify antibiotic activity in human-targeted compounds may assist in preventing the emergence of resistant microbes. In this regard, it is worth noting that while most antibiotics used to treat human infectious diseases are non-peptidic compounds, most known antimicrobials nowadays are peptides, therefore all computer-based models aimed to predict antimicrobials either use small datasets of non-peptidic compounds rendering predictions with poor reliability or they predict antimicrobial peptides that are not currently used in humans. Here we report a machine-learning-based approach trained to identify gut antimicrobial compounds; a unique aspect of our model is the use of heterologous training sets, in which peptide and non-peptide antimicrobial compounds were used to increase the size of the training data set. Our results show that combining peptide and non-peptide antimicrobial compounds rendered the best classification of gut antimicrobial compounds. Furthermore, this classification model was tested on the latest human-approved drugs expecting to identify antibiotics with broad-spectrum activity and our results show that the model rendered predictions consistent with current knowledge about broad-spectrum antibiotics. Therefore, heterologous machine learning rendered an efficient computational approach to classify antimicrobial compounds.

Keywords: machine-learning; antimicrobial peptide; non-peptidic antimicrobial compound; antimicrobial activity

1. Introduction

Drug-resistant microbes are one of the most important challenges for modern medicine [1] considering the increased rate in morbidity and mortality associated with antibiotic-resistant pathogens [2]. It is now commonly accepted that misuse of antibiotics is a major factor that promotes microbial resistance to these agents [3]; such is the case of broad-spectrum antibiotics that tend to promote resistance and are now prescribed in very restricted situations [4]. Furthermore, it has been noted that many non-antibiotic human-targeted drugs alter the gut microbiome in patients taking such drugs [5,6]. This alteration has been shown to be the consequence of a non-reported colateral antimicrobial activity, suggesting that microbe resistance to an antibiotic may emerge as

INFORME DE LABORES 2019

a consequence of using those human-targeted drugs [7]. Furthermore, some antibiotics may have not been tested against the gut microbiome and may as well promote the emergence of resistant microbes. Since the experimental validation of antimicrobial activity for the gut microbiome requires tests on hundreds/thousands of cultivable and non-cultivable microorganisms and the number of new human-targeted drugs may include dozens of compounds, it is relevant to develop efficient computational strategies for the identification of secondary antimicrobial activity of human-targeted drugs. In the present work we present a computational strategy aimed to improve the identification of compounds with antimicrobial activity using machine-learning-based approaches.

Previous computational approaches to identify antibiotics using Quantitative Structure-Activity Relationships (QSAR) [8,9] and machine-learning-based [10,11] procedures have been reported. In these computational approaches, non-peptidic chemical compounds (from now on referred to as NPCC) are represented by chemical descriptors (e.g., *LogP*, molecular weight, polarizability) and each compound is labeled as antibiotic or non-antibiotic; then a clustering algorithm separates antibiotics from non-antibiotics. An important limitation of these previous studies is that the number of chemical compounds used to train the models is limited (less than one thousand NPCC have been described with antimicrobial activity) and the reliability of these models requires further improvement. Alternatively, antimicrobial peptides now accumulate in more than 10,000 in different databases [12–14], and several computational models have been reported to effectively classify antimicrobial from non-antimicrobial peptides [15–17]. Although peptides represent an important new focus to develop pharmaceuticals, most human-targeted drugs are NPCC; therefore computational models to identify antimicrobial activity in these compounds should focus on NPCC. The need to use common molecular descriptors between polypeptides and NPCC has been previously noted for protein-ligand recognition and protein folding, as a fundamental aspect to deal with induced-fit or conformer selection mechanisms for molecular recognition [18]; the aim of this work though, is not to find common descriptors to peptides and NPCC since there are already packages that solve this problem (see below). Here we propose that combining peptides and NPCC increases the training set size and this should improve the reliability of the computational models. The present work tests this proposal and validates the idea that heterelogous (NPCC and peptides) training sets render the best classifying models. We then show how this improved model may assist in the identification of broad-spectrum antibiotics on FDA-approved NPCC.

2. Results

2.1. Training and Testing Gut Antimicrobial Classifiers

Building data sets to combine peptides and NPCC required the use of molecular descriptors common to both types of compounds; in our case, we used 1444 descriptors calculated by PadelDescriptor (see Methods). Then, to identify the best machine-learning model to classify gut antimicrobials, three groups of training sets were used (see Table 1). The first group included only peptides (TrOnlyPeptides), the second group comprises 4 sets and included only NPCC (TrNPCC1-4) and the third group combined these two previous sets (TrHeterologous1-4) resulting in a total of 9 training sets (see Table 1); this rendered a total of 45 training sets. These 45 sets were further processed to substitute any null or "Infinity" values using three different approaches, and a reduction of dimensions was performed via principal-component analysis (PCA, see Methods). This procedure rendered a total of 50 Training Sets; all these sets are included in Supplemental Tables S1(A–E)–S9(A–E).

Nine testing sets were built using the NPCC recently reported by Maier et al. [7] with and without gut antimicrobial activity (see Table 2). The same processing of these testing sets was performed as in the case of the training sets (see above), rendering again a total of 50 data sets (see Supplemental Tables S10(A–E)–S18(A–E)). Please note that in both training and testing sets all peptides included were tested against only one gut microbe assayed against the NPCC used in these sets and that although there are

INFORME DE LABORES 2019

many more peptides than NPCC in our training and testing sets, this imbalance is not relevant to find the border between antimicrobials and non-antimicrobials compounds.

Table 1. Training data sets.

Training Set	Entries	Description
TrOnlyPeptides	11,546	8000 antimicrobial peptides, 3546 peptides with no known antimicrobial activity
TrNPCC1	431	164 antimicrobial non-peptides, 267 non-peptides with no known antimicrobial activity
TrNPCC2	430	164 antimicrobial non-peptides, 266 non-peptides with no known antimicrobial activity
TrNPCC3	430	164 antimicrobial non-peptides, 266 non-peptides with no known antimicrobial activity
TrNPCC4	431	164 antimicrobial non-peptides, 267 non-peptides with no known antimicrobial activity
TrHeterologous1	6204	4164 antimicrobial compounds (4000 peptides and 164 non-peptidic compounds), 2040 no antimicrobial compounds (1773 peptides and 267 non-peptidic compounds)
TrHeterologous2	6203	4164 antimicrobial compounds (4000 peptides and 164 non-peptidic compounds), 2039 no antimicrobial compounds (1773 peptides and 266 non-peptidic compounds)
TrHeterologous3	6203	4164 antimicrobial compounds (4000 peptides and 164 non-peptidic compounds), 2039 no antimicrobial compounds (1773 peptides and 266 non-peptidic compounds)
TrHeterologous4	6204	4164 antimicrobial compounds (4000 peptides and 164 non-peptidic compounds), 2040 no antimicrobial compounds (1773 peptides and 267 non-peptidic compounds)

The original NPCC from Maier et al. [7], here referred to as OnlyNonPeptides, was used to build TrNPCC1 by taking only the odd listed compounds, TrNPCC2 by taking even listed compounds, TrNPCC3 and TrNPCC4, included the first and second half of the data set respectively. The OnlyPeptides data set was divided to generate TrHeterologous1, TrHeterologous2, TrHeterologous3 and TrHeterologous4 by taking the odds listed peptides, even listed peptides, first and second half, respectively. Then, these TrHeterologous1-4 data sets with peptides were combined with the TrNPCC1-4 to complete these sets.

Table 2. Testing data sets.

Testing Set	Entries	Description
TeOnlyPeptides	861	328 antimicrobial and 533 non-antimicrobial non-peptides
TeNPCC1	430	164 antimicrobial non-peptides, 266 non-peptides with no known antimicrobial activity. Same as TrNPCC2.
TeNPCC2	431	164 antimicrobial non-peptides, 267 non-peptides with no known antimicrobial activity. Same as TrNPCC1.
TeNPCC3	431	164 antimicrobial non-peptides, 267 non-peptides with no known antimicrobial activity. Same as TrNPCC4.
TeNPCC4	430	164 antimicrobial non-peptides, 266 non-peptides with no known antimicrobial activity. Same as TrNPCC3.
TeHeterologous1	430	Same as TeNPCC1.
TeHeterologous2	431	Same as TeNPCC2.
TeHeterologous3	431	Same as TeNPCC3.
TeHeterologous4	430	Same as TeNPCC4.

The original NPCC from Maier et al. [7], here referred to as OnlyNonPeptides, was used to build all Testing Sets. TeOnlyPeptides was built taking all the 861 listed compounds. TeNPCC1 and TeHeterologous1 were built by taking only the even listed compounds. TeNPCC2 and TeHeterologous2 included only the odd listed compounds. TeNPCC3 and TeHeterologous3 included the second half of OnlyNonPeptides, TeNPCC4 and TeHeterologous4 included the first half of the data set. Testing sets were built so they were the complement of the compounds listed for their Training sets, so, for example, if a training set was built using the even listed compounds (e.g., TrNPCC1), its Testing set would be built with the odd listed compounds (e.g., TeNPCC1). Heterologous Testing Sets were the same as OnlyNonPeptides Testing sets, due to the fact that the interest compounds are of non-peptidic nature.

INFORME DE LABORES 2019

Five different statistical parameters (adjusted estimated error rate on the training set (AEER); correctly classified instances in the training set after splitting 33% for testing (%Split); 10-fold cross-validation (%10FCV); correctly classified instances on the testing set (%CC); area under the receiver operator characteristic curve on the testing set (AUROC)) that evaluated the performance on either the training or testing sets (see Methods) were used to identify the best classifier.

As shown in Figure 1, the best models included heterologous compounds (peptides and NPCC): circles in Figure 1 represent heterologous training sets and accumulate on the upper part of Figure 1, that is, those models with highest statistical parameters evaluating the model performance (the actual data in this figure for these models are included in Supplemental Table S19). Treating the training set rendering the best model with the K-nearest neighbor or mean-imputation approaches did not improve the performance of the best model (see Supplemental Tables S6G, S6I, S6J and its corresponding test set in Table S15G; supplemental Tables S6K, S6L and their corresponding test sets in Supplemental Tables S15I and S15J).

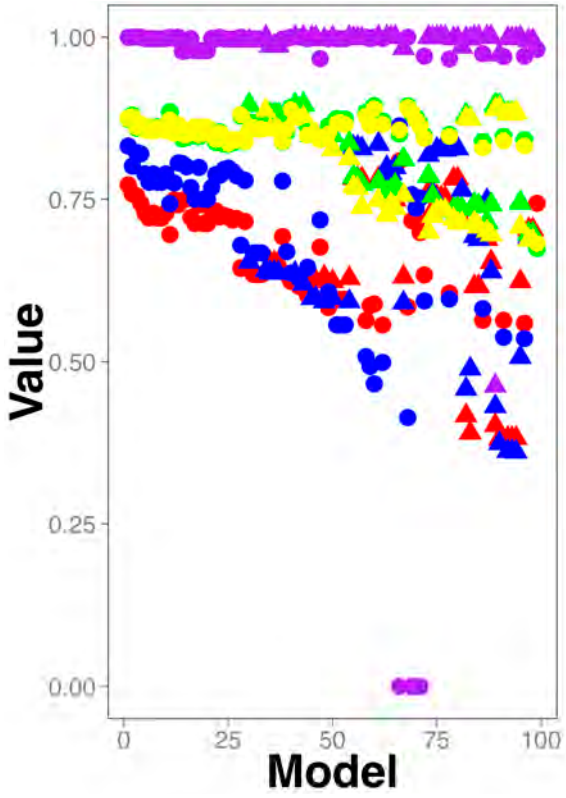

Figure 1. Classifiers performance. Five statistical parameters (yellow circle: Correctly classified instances in the test set after 67% of split validation of the training set; green circle: 10-fold cross-validation on training set; red circle: Correctly classified instances on the testing set; blue circle: AUROC on the testing set; purple circle: adjusted estimated error rate on the training set where the minimum error was represented by number 1.0) are sorted from highest to lowest values. Hence, the best parameter values are located on the left-upper part of the figure. The models using heterologous data are represented as circles; triangles are used otherwise. The actual data of this plot can be found in Supplementary Table S19.

Yet, none of these models surpassed the others in all 5 parameters. To aid in the visualization of this aspect of our results, Figure 1 displays the values in descending order from left to right; therefore, the models on the left side of the plot have better scores than those on the right. For instance, models using heterologous (represented by circles) testing sets (the red and blue circles, corresponding with the statistical parameters correctly classified instances and *AUROC*, respectively) laying on the left side of Figure 1, have better performance than those models using heterologous testing sets on the right

side of the plot, yet, those on the right side including either heterologous or non-heterologous training sets (green and yellow circles or triangles) have better scores than those models using heterologous or non-heterologous training sets on the left side of the plot. The models in the middle of the plot have on the other hand, intermediate performances. Please note that the statistical parameter adjusted estimated error rate is the value that AutoWeka optimizes, hence for all the reported models is close to 1.0 and consequently does not contribute to differentiate the performance of the models. This statistical parameter is shown in Figure 1 to note that all models have similar error rates, yet different statistical parameters, hence, the best model obtained from AutoWeka cannot be selected simply by considering the error rate value reported.

Thus, to aid in the identification of the best models, we used a previous score developed by our group that takes into account multiple statistical parameters, the Combined Score or simply *CScore* [19]:

$$CScore_i = \frac{1}{5}\sum_{n=1}^{5}\left[\sqrt{\frac{MaxS_n - S_{i,n}}{MaxS_n - MinS_n}}\right] \quad (1)$$

where $MaxS_n$ and $MinS_n$ represent the maximum and minimum scores for a given statistical parameter n over all models; $S_{i,n}$ is the score observed for a given statistical parameter n and model i; n represents the index of the statistical parameter to evaluate (in our case were 5 parameters: AEER, %Split, %10FCV, %CC and AUROC). Thus, formula 1 calculates *CScore* for each model i.

CScore averages the difference of each statistical parameter to its best value (e.g., true-positive rate best value is 1, so the difference between the observed true positive rate and 1 is included in the *CScore*), therefore the lower the *CScore* value the better the classifying model. Figure 2 (and Supplementary Table S20) shows that the five best models are those using heterologous training sets (the ones below the 0.3 line in Figure 2). Furthermore, we noticed that the top 5 best models overlapped on average in more than 70% of their classifications hence, these were mainly redundant (see Figure 3).

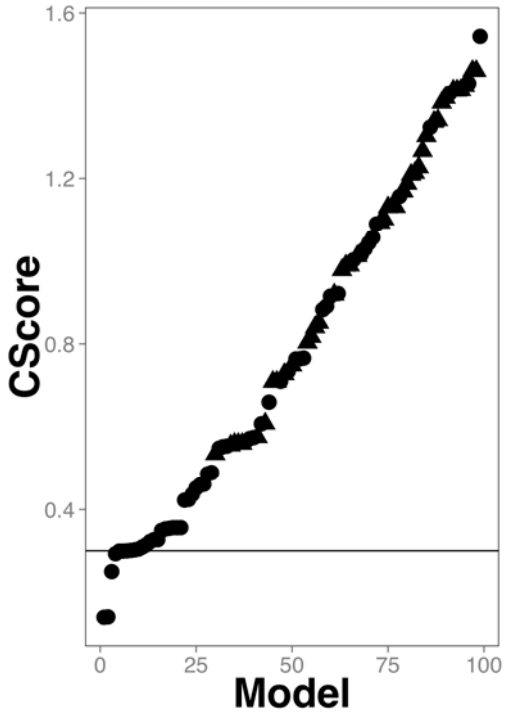

Figure 2. Classifiers combined scores. A circle represents each model; the best model has the lowest *CScore*. The line represents the *CScore* = 0.3, that separates the top 5 models from the rest. The models using heterologous data are represented as circles; triangles are used otherwise. The actual data of this plot can be found in Supplementary Table S20.

INFORME DE LABORES 2019

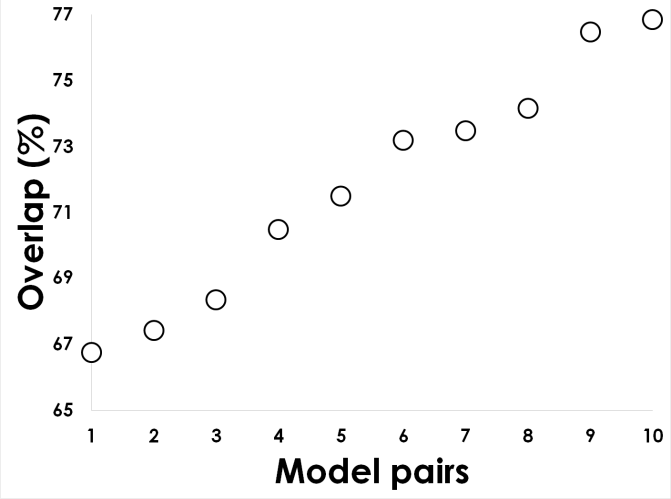

Figure 3. Classifiers overlap. The predictions of antimicrobial compounds of the top 5 models were compared to quantify their overlap. The image shows the 10 pairs of models generated from these 5 top models. The comparison was performed on the discovery set (see Methods) because not every model had the same testing set.

Therefore, we selected the best model based on the lowest *CScore*; such model was built using the RandomCommittee algorithm (see Supplemental Table S21 for the algorithm parameters) on the TrHeterologous1 set (see Table 1) that included 86 molecular PCA-reduced descriptors and achieved the following performance: AEER: 0.99955; %Split: 87.4; %10FCV: 87.3; %CC: 77.2; AUROC: 0.83 (model named TrHeterologous1-Reduced-With-99M-CRC20_CRF in Supplemental Table S21; the corresponding data set for this model is reported in Supplemental Table S6E).

2.2. Identifying Broad-Spectrum Antibiotics among FDA-Approved Compounds

We used the best model to predict NPCC with expected gut antimicrobial activity among FDA-approved drugs. The motivation to perform this prediction is not for testing purposes, as in the case of the training and testing sets used before. Hence, the set of compounds used in this prediction stage is referred to as the discovery set, because we aimed to discover potential compounds with gut antimicrobial activity. We used 756 FDA-approved compounds included in the ZINC database (see Methods) that were not part of the training or testing sets; these compounds included 111 antimicrobials and 645 compounds without any known antimicrobial activity; we also added 73 NPCC that included 22 antifungal compounds and 51 without any reported antifungal activity (see Supplementary Table S22). We have previously reported that these 22 antifungals work through a mechanism (alter calcium intake [20]) different from antibacterial compounds (e.g., penicillin derivates, sulphonamides, etc), thus we expected our model to predict few of these compounds as antibacterials. FDA-approved compounds on the other hand are expected not to have, or to have minor, gut antimicrobial activity otherwise their secondary gastrointestinal effects would be significant. We would expect that FDA-approved drugs would be less likely predicted to act against non-athogenic gut microbes than antifungals. To evaluate the reliability of our predictions using the discovery set, we considered that antibiotic compounds against the non-pathogenic gut flora among the FDA-approved drugs should be considered broad-spectrum antibiotics; please note that our classifier was not trained to predict this class of antibiotics, yet the combination of the predictions of our classifier on the FDA-approved drugs would render this information. The definition of broad-spectrum antibiotics is somehow arbitrary, for instance, it is considered that antibiotics that act on G(+) and G(−) are broad-spectrum antibiotics for some authors, while those acting against pathogenic and non-pathogenic microorganisms are classified as broad-spectrum antibiotics by others [21,22]. The list of broad-spectrum antibiotics was obtained from five recent works (see Methods), including 19

INFORME DE LABORES 2019

broad-spectrum and 3 narrow-spectrum antibiotics (see Supplementary Table S22). We were able to identify 72 true positives (FDA-approved antibiotics against pathogenic microbes predicted to act against non-pathogenic gut microbes) in the discovery set that we predicted should be considered as broad-spectrum antibiotics (see Table 3).

Table 3. Confusion matrix for the discovery set.

	Predicted Gut Antimicrobial	Predicted No Antimicrobial
Pathogenic antimicrobial	72	61
No antimicrobial	140	556

The actual data for this table can be found in Supplementary Table S22.

From these 72 antimicrobials, only 16 had been annotated as broad-spectrum antibiotics and 3 as narrow-spectrum antibiotics (see Supplemental Table S22). Hence, we propose that these 3 annotated narrow-spectrum antibiotics should be considered more likely as broad-spectrum antibiotics (see Table 4).

Table 4. True pathogenic antimicrobials predicted by the best classifier on the discovery set.

Compound Name	Annotation
Amoxicillin	Narrow spectrum
Phenoxymethylpenicillin	Narrow spectrum
Cephalexin	Narrow spectrum

On the other hand, among the 61 false negatives, 3 compounds were annotated as broad-spectrum antibiotics (see Supplemental Table S22). This annotation is consistent with our predictions, since these antibiotics directed towards pathogenic microorganisms are unlikely to affect the non-pathogenic gut microbes. Furthermore, 17 out of the 22 antifungal compounds were predicted as antimicrobials.

Thus, in total we were able to correctly identify 16 out of the 19 known broad-spectrum antibiotics and we suggest that 3 of the annotated narrow-spectrum antibiotics should be re-evaluated; hence, the reliability to identify broad-spectrum antibiotics was 84.2%. Furthermore, our results suggest that 56 (61 true negatives less 5 antifungals) (50.4%) out of 111 antibiotics approved by the FDA included in our discovery set are unlikely to affect gut microbes. In comparison, 5 (22.7%) out of 22 antifungals were predicted not to act against the gut microbes (see Supplemental Table S21). Thus, it is twice as much less likely that FDA-approved antibiotics would be toxic against gut microbes than antifungals.

3. Discussion

The identification of antimicrobial compounds assisted by machine-learning techniques has multiple advantages, such as reduction of the invested time to develop novel pharmaceuticals or to flag molecules that could have secondary antimicrobial activity [17]. An important aspect of these techniques is how to improve the reliability of these predictions. One way to achieve this is to increase the number of examples in the training and testing sets. In this work we propose that it is possible to use chemical compounds of different nature (peptides and NPCC) that are commonly modeled separately as antimicrobials to improve the reliability of the predictions. Here we show that indeed, the training sets that rendered the best classifiers of antimicrobial compounds were heterologous, those including NPCC and peptides (see Figures 1 and 2). We can compare our best classifier with previous works in terms of the learnability of our classes, that is, how well gut antimicrobial compounds are differentiated from non-antimicrobial gut compounds. In that sense, the numeric performance achieved by the best classifier on the testing set (AUC = 0.83) is comparable with the performance achieved with one of the best antimicrobial peptide classifiers (AUC = 0.85) recently reported [23], indicating that the learnability of heterologous training sets is as good as those of only peptides.

INFORME DE LABORES 2019

Another important aspect of our work is the molecular descriptors obtained to best classify gut antimicrobial compounds that included both peptides and NPCC. Although our goal was not to identify common descriptors for NPCC and peptides (these are already calculated by available packages, see Methods), we did look for those descriptors that are relevant to learn the difference between antimicrobials from non-antimicrobials. Our results indicate that the solution to this problem requires the transformation of 86 computed molecular descriptors, suggesting that other molecular descriptors, most likely associated to these 86 descriptors, may improve the current best-model performance.

In terms of improving the performance reported in this work, it is worth mentioning that we used peptides that were not tested by Maier et al. [7] yet, these peptides had reported antibiotic activity against at least one microorganism (*Escherichia coli*) found in the gut and tested by Maier and collaborators. On the other hand, the NPCC included in our work had antibiotic activity against at least one of the 40 gut microorganisms tested by Maier and collaborators. Hence, one alternative approach to improve the performance of classifiers aimed at identifying gut microorganisms would be to include antibiotics that target more common gut microorganisms; that would require further experimental data that is not currently available at present.

To the best of our knowledge, no previous machine-learning efforts to assist in the identification of broad-spectrum antibiotics have been reported; here the definition of broad-spectrum antibiotics was restricted to those acting against both pathogenic and non-pathogenic microorganisms. Hence, using a classifier trained to identify gut non-pathogenic antimicrobial compounds to predict this activity in FDA-approved antibiotics targeted against pathogenic microorganisms represents a way to identify broad-spectrum antibiotics. Our results suggest that half of the FDA-approved antibiotics are likely to have antimicrobial activity against the gut microorganisms indicating that these require further testing or investigation. For instance, two annotated narrow-spectrum antibiotics, amoxicillin and cephalexin, that were predicted to alter gut microbes are known to affect the gastrointestinal flora [24]. On the other hand, the broad-spectrum antibiotic ceftaroline fosamil recently approved by the FDA to treat bacterial pneumonia and skin infections, which was not predicted to affect the gut flora, was reported to have minor gastrointestinal effects during clinical trials [25].

How significant is our finding that almost half of the FDA-approved antibiotics are predicted to have a broad-spectrum activity? To address this question, we included in the discovery set a group of antifungal compounds. All microorganisms used to train our models were bacteria, hence we expected that these antifungals that act through a mechanism different from those reported for bacteria would be unlikely predicted to act against bacteria; lets refer to this negative prediction as *expectation-antifungal*. On the other hand, most FDA-approved antibiotics should unlikely present antibiotic activity against gut microbes, otherwise these would frequently have secondary gastrointestinal effects on patients; lets refer to this negative prediction as *expectation-FDA*. Then, to address the significance of our findings about broad-spectrum antibiotics requires evaluating *expectation-antifungal* and *expectation-FDA*; if FDA-approved drugs are less likely to act on gut microbes than antifungals then *expectation-FDA* < *expectation-antifungal*. Indeed, we observed that FDA-approved antibiotics are twice as much less likely to act against gut microbes than antifungals. Thus, our results indicate that even when FDA-approved antibiotics are safer (do not act against non-pathogenic resident gut bacteria) than our control group (antifungals), we identified some of these compounds that need to be re-assessed as potential promoters of resistance among microbes for their potential broad-spectrum activity.

In summary, we report a computational approach to use heterologous antimicrobial compounds (peptides and non-peptides) to improve the discriminatory power of machine-learning approaches. We show that training a classifier to identify antibiotics against the gut flora using heterologous training sets correctly anticipate adverse gastrointestinal reactions in patients receiving these antibiotics.

4. Materials and Methods

4.1. Materials

Peptides included in the training sets were obtained from the non-redundant data set of 20 public databases (see Table 5). Testing sets were derived from the work reported by Maier and collaborators (see Supplemental Tables S10–S18). Finally, a discovery set containing 750 FDA-approved drugs for treating human infectious diseases and 76 antifungal drugs was built from the ZINC database [26]. Molecular descriptors were computed with PadelDescriptor [27]. For every training and test set, we performed five different approaches to process the molecular descriptors for each peptide and/or NPCC. These included: no processing; eliminate every null value; substitute every "Infinity" value for 0 or 99,999,999; reduction of the dimensionality applying a principal component analysis implemented in WEKA package (see below). Since the substitution of Infinity values for 0 or 99,999,999 is not a conventional strategy, we performed an imputation of the Infinity and null values using the K nearest neighbor or mean imputation approaches, but only on the best model data set for comparison. That is, from the 9 training sets we generated a total of 45 training sets following the different approaches described before; the same applies to the 9 testing sets. For the discovery set only the transformation applied to the best classifier was performed.

Table 5. Antimicrobial peptide databases used in the present study.

Database	Focused on	Reference
BACTIBASE	Bacteriocins	[28]
Bagel	Bacteriocins	[29]
CAMP	General and Patented AMPs	[14]
DADP	Anuran AMPs	[30]
DAMPD	General AMPs *	[31]
DBAASP	General AMPs	[13]
Defensins	Defensins	[32]
HIPdb	Anti-HIV peptides	[33]
LAMP	General and Patented AMPs	[34]
MilkAMP	AMPs of dairy origin	[35]
PhytAMP	Plant AMPs	[36]
PenBase	Penaeidin AMPs	[37]
Peptaibol	Peptaibols	[38]
RAPD	Recombinant AMPs	[39]
AMPer	Eukaryotic AMPs	[40]
UniprotKb	General AMPs	[41]
YADAMP	General AMPs	[42]
AMSDb	Eukaryotic AMPs	[43]
APD	General AMPs	[44]
AVPdb	Antiviral peptides	[45]

* AMPs stands for Antimicrobial Peptides.

4.2. Method

To identify the best model to classify gut antimicrobial compounds, we followed a systematic method previously reported by our group [46]. Briefly, given the training sets, 52 different machine-learning algorithms implemented in WEKA [47] and their parameters were systematically

INFORME DE LABORES 2019

analyzed to identify the algorithm, parameters and molecular descriptors that renders the lowest possible error in classification; this systematic analysis was performed by the Bayesian optimization algorithm implemented in AutoWEKA [48]. We ran AutoWEKA against any training set for 10, 90, 720, 2880 and 4320 minutes to identify when the optimization has reached a plateau in the classification error. Afterwards, a 10-fold cross validation and 67% split tests were performed in WEKA. Finally, these classifiers were evaluated against their corresponding testing sets. Two statistical parameters were chosen to evaluate the performance of the classifiers during the testing, including: Area under the ROC curve and correctly classified instances on the testing set. Therefore, a total of 5 statistical parameters were used to define the best classifiers, three for the training phase (adjusted estimated error rate on the training set; correctly classified instances in the training set after splitting 33% for testing; 10-fold cross-validation) and two for the testing phase (AUROC and correctly classified instances).

To identify the intersection set between the top 5 classifiers, we compared the predictions of these classifiers rendering 10 possible pairs of predictions on the discovery set; we used this set because not every classifier had the same testing set. The best model was identified using a combined score (see formula 1): the model with the lowest combined score was chosen. The model then was used to predict gut antimicrobial compounds in the discovery set using WEKA command line (see Supplemental File S1). To annotate as broad-spectrum or narrow-spectrum antibiotics, we used five different previous works that classified antibiotic action [22,49–52].

Through somatic exocytosis neurons liberate immense amounts of transmitter molecules that modulate the functioning of the nervous system. A stream of action potentials triggers an ATP-dependent transport of transmitter-containing vesicles to the plasma membrane, that ends with a large-scale exocytosis. It is commonly assumed that biological processes use metabolic energy with a high thermodynamic efficiency, meaning that most energy generates work with minor dissipation. However, the intricate ultrastructure underlying the pathway for the vesicle flow necessary for somatic exocytosis challenges this possibility. To study this problem here we first applied thermodynamic theory to quantify the efficiency of somatic exocytosis of the vital transmitter serotonin. Then we correlated the efficiency to the ultrastructure of the transport pathway of the vesicles. Exocytosis was evoked in cultured Retzius neurons of the leech by trains of 10 impulses delivered at 20 Hz. The kinetics of exocytosis was quantified from the gradual fluorescence increase of FM1-43 dye as it became incorporated into vesicles that underwent their exo-endocytosis cycle. By fitting a model of the vesicle transport carried by motor forces to the kinetics of exocytosis, we calculated the thermodynamic efficiency of the ATP expenses per vesicle, as the power of the transport divided by total energy ideally produced by the hydrolysis of ATP during the process. The efficiency was remarkably low (0.1–6.4%) and the values formed a W-shape distribution with the transport distances of the vesicles. Electron micrographs and fluorescent staining of the actin cortex indicated that the slopes of the W chart could be explained by the interaction of vesicles with the actin cortex and the calcium-releasing endoplasmic reticulum. We showed that the application of thermodynamic theory permitted to predict aspects of the intracellular structure. Our results suggest that the distribution of subcellular structures that are essential for somatic exocytosis abates the thermodynamic efficiency of the transport by hampering vesicle mobilization. It is remarkable that the modulation of the nervous system occurs at the expenses of an efficient use of metabolic energy.

INTRODUCTION

Extrasynaptic exocytosis, namely the release of transmitters and peptides from the neuronal soma, dendrites, and axons, is a source of modulators of the activity of the nervous system (De-Miguel and Fuxe, 2012; De-Miguel and Nicholls, 2015). Most low molecular weight transmitters and different peptides are released extrasynaptically by exocytosis (for review see Trueta and De-Miguel, 2012).

Molecules released in this manner diversify the responses of neural circuits to a given stimulus by integrating the activity of neurons, glia and capillaries (Fuxe et al., 2007; Rozanski et al., 2012; Hirasawa et al., 2015; Newman, 2015).

The mechanism for extrasynaptic exocytosis is substantially different from that for release at synapses and similar to the mechanism for exocytosis from endocrine cells. Somatic exocytosis involves a multi-regulated sequence of serial and parallel reactions that couple excitation with exocytosis (Ludwig and Stern, 2015; Del-Bel and De-Miguel, 2018). Vesicles -usually large and electrodense (see Trueta and De-Miguel, 2012) filled with signaling molecules, rest far from the plasma membrane. Bursts of electrical activity evoke a transmembrane calcium entry that triggers calcium release from the endoplasmic reticulum (review see Trueta and De-Miguel, 2012; Del-Bel and De-Miguel, 2018). The calcium wave induces an increase of cytosolic ATP that triggers the vesicle transport by the activation of molecular motors (Nicholls et al., 2003; Llorente-Folch et al., 2013; Rueda et al., 2014; Del-Pozo and De-Miguel, in preparation). Exocytosis starts as vesicles arrive at the plasma membrane (De-Miguel and Trueta, 2005). Calculations of the ATP expenses per vesicle fusing (ATP_{ves}) made by applying thermodynamic theory to the kinetics of somatic exocytosis of serotonin, unveiled that the amount of ATP_{ves} has a W-shape dependence on the transport distance of the vesicles (De-Miguel et al., 2012). This relationship may reflect the cytoarchitecture of the transport pathway, since electron micrographs contain endoplasmic reticulum and mitochondria -which are engines for somatic exocytosis- often invading the transport pathway of the vesicles (Trueta et al., 2004, 2012; De-Miguel et al., 2012). In addition, the actin cortex at rest prevents the vesicle transport, but after the onset of electrical activity turns into a component of the transport system by binding to myosin motors (Wang and Hatton, 2006; Tobin and Ludwig, 2007). Such observations raised the possibility that somatic exocytosis operates under low thermodynamic efficiency, opposing to the common assumption that biological processes make a high efficiency use of their metabolic energy. Theoretically, when friction forces hamper the work, a fraction of the energy dissipates in the form of heat, reducing the thermodynamic efficiency of the process. For this reason, measurements of the amount of energy provide only a partial story; it is also necessary to estimate how efficiently the energy is used. This focal problem was studied here by making use of the advantages of the well-known somatic exocytosis of serotonin by the Retzius neuron of the leech.

The large (~70 μm) soma of a Retzius neuron stores serotonin in astronomic numbers of 100 nm diameter electrodense vesicles (Coggeshall, 1972). At rest or following electrical stimulation with trains of 10 action potentials at 1 Hz (a frequency similar to the spontaneous firing of serotonergic neurons), vesicles remain

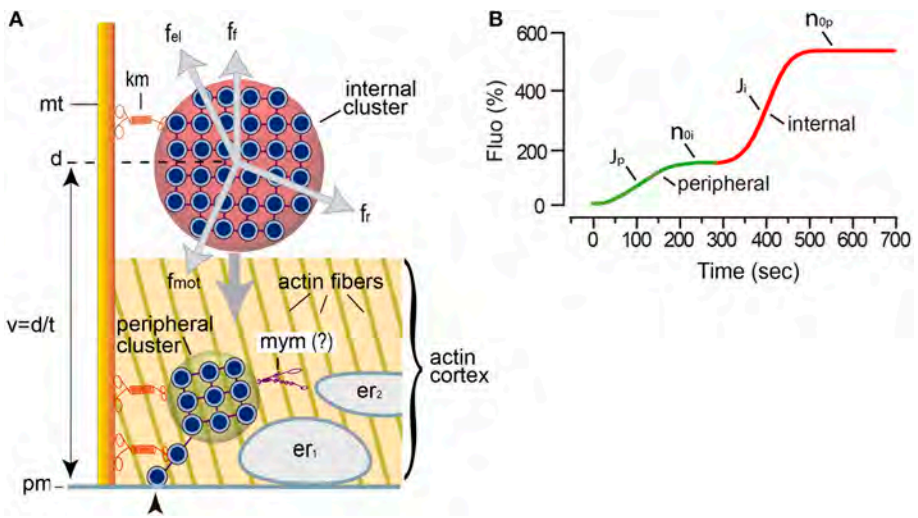

FIGURE 1 | Mechanism for somatic exocytosis in the Retzius neuron. **(A)** Schematic representation of the vesicle transport system. The scheme incorporates findings from this study. Vesicle clusters rest at variable distances from the plasma membrane. More than one cluster can be attached to the same microtubule (mt) bundle by kinesin motors (km). Internal clusters (red) lay across the actin cortex. The transport of vesicle clusters depends on four forces: the motor forces (f_{mot}), elastic forces (f_{el}), friction forces (f_f), and random forces (f_r). At rest, these forces are in equilibrium. The motor forces are microtubule- and kinesin-dependent (De-Miguel et al., 2012). Electrical stimulation produces a cascade of calcium-dependent events that activate the motor forces. Vesicle clusters are transported to the plasma membrane along a distance (d), at a velocity ($v = d/t$). Peripheral clusters (green) rest immersed in the actin cortex at the time of stimulation, flanked by two layers of endoplasmic reticulum (er_1, er_2). Inside the actin cortex, myosin motors (mym) add to kinesin motors to transport the vesicle clusters to the plasma membrane (pm). The reduced number of vesicles as clusters approach the plasma membrane seems to obey a continuous vesicle detachment and transport to the plasma membrane (Leon-Pinzon et al., 2014). Fusion of these vesicles (arrowhead) produces the constitutive release of serotonin that permits the large-scale exocytosis when whole clusters arrive at the plasma membrane in response to electrical stimulation. **(B)** Biophysical parameters measured from the FM1-43 kinetics upon electrical stimulation of exocytosis. The green segment is the contribution of a peripheral cluster; the red segment is the contribution of an internal cluster. The latency to the onset of release contains information on the distance and velocity ($t = d/v$) of the vesicle transport. The J value is the flux of vesicles (vesicles fused per second). The n_o values are the number of vesicles that fused per vesicle cluster.

clustered at variable distances from the plasma membrane and exocytosis does not occur (**Figure 1**; De-Miguel et al., 2012). By contrast, the same number of action potentials evoked at a high 20 Hz frequency triggers the massive transport of vesicle clusters to the plasma membrane and the large-scale exocytosis. Within the following hundreds of seconds, tens of thousands of vesicles distributed in ∼90 clusters will discharge their content from different parts of the soma (Trueta et al., 2003; De-Miguel et al., 2012). The large-scale exocytosis is sustained for long periods in absence of further transmembrane calcium entry, by the serotonin that has been released (Leon-Pinzon et al., 2014). Activation of serotonin autoreceptors evoke an intracellular IP3-dependent release of calcium from the endoplasmic reticulum adjacent to the plasma membrane. This localized calcium elevation maintains exocytosis until the fusion of the last vesicles in the clusters (Leon-Pinzon et al., 2014). It is common that a second and larger cluster of vesicles arrives at the same release site producing a second bulk of exocytosis (De-Miguel et al., 2012; Leon-Pinzon et al., 2014). **Figure 1** recapitulates the elementary aspects of this mechanism.

In this study we applied a thermodynamic theoretical approach to calculate the efficiency of somatic exocytosis of serotonin. As the reporter of exocytosis we used the fluorescence increase of FM1-43 dye, which stains the inside of vesicles that undergo their exocytosis/endocytosis cycle (Betz et al., 1992; De-Miguel et al., 2012). A mathematical approach applied to the kinetics of exocytosis permitted to calculate the transport distance, velocity and power of the whole process of somatic exocytosis from individual release sites. By incorporating new experimental data to the model fittings, we improved our previous estimates of the ATP expenses per vesicle fused (ATP_{ves}). The thermodynamic efficiency of the ATP_{ves} expenses was calculated from the work in the presence of friction forces, divided by the ideal energy generated by the ATP cleavage. The thermodynamic efficiency along the traveling distance of the vesicles was correlated with the ultrastructure of the transport pathway, analyzed from electron micrographs, and fluorescent staining of the actin cortex.

MATERIALS AND METHODS

Ethics Statement

Animal research was approved by the Animal Committee of the Instituto de Fisiología Celular, Universidad Nacional Autónoma de México.

Isolation and Culture of Neurons

Experiments were made using Retzius neurons of the medicinal leech *Hirudo sp*. For experiments with FM1-43, neurons were individually isolated by suction through a glass pipette after an enzyme treatment (Dietzel et al., 1986) and plated in glass-bottom culture dishes coated with concanavalin-A (Sigma, St. Louis, MO). The culture medium was L-15 (Sigma) supplemented with 6 mg/mL glucose, 0.1 mg/mL gentamycin and 2% fetal bovine serum (Gibco, Gaithersburg, MD). Experiments were made at 18°C after 1–3 days in culture.

Stimulation and Detection of Exocytosis

Exocytosis was quantified from the fluorescence increases produced by the incorporation of FM1-43 (2 μM; Molecular Probes) by the vesicles that undergo fusion and endocytosis (Betz and Bewick, 1993). Vesicle fusion permits the dye to enter the vesicles and stain their internal membrane. Endocytosis keeps the dye inside the vesicle. Therefore, each vesicle fusion contributes with a step to the fluorescence in the release site. We have previously shown that the large-scale exocytosis from vesicles arriving in a cluster lasts for hundreds of seconds, depending on the number of vesicles in the distance and the velocity of the transport. Upon endocytosis, the stained vesicles accumulate near the plasma membrane without being recycled to the releasable pool. Instead, they get packed forming multivesicular bodies that are later transported to the perikaryon (Trueta et al., 2012). Therefore, the gradual increase of fluorescence reflects accurately the kinetics of exocytosis; the plateau is reached once all the electrodense vesicles in the cluster have fused and the intensity of fluorescence indicates the number of vesicles that fused (De-Miguel et al., 2012). If any stained vesicle fuses again the amount of fluorescence does not increase because the vesicle is already stained.

Stimulation of exocytosis consisted of trains of 10 action potentials produced by intracellular injection of 10 ms current pulses at 20 Hz delivered every 2 min. The amplitude of the current pulses was adjusted in every neuron between 5 and 8 nA, to guarantee that each pulse in the train produced one action potential. The intracellular voltage was recorded using a Getting pre-amplifier operating in bridge balance mode. In eight other neurons the actin cortex was uncoupled by incubation with 1 μM cytochalasin D (Sigma-Aldrich) for 30 min at 18°C before stimulation.

Individual neurons were focused on their equator with a Nikon Eclipse TE 200 inverted microscope using a Nikon 100x oil immersion objective (NA 1.40). FM1-43 was excited at 488 nm and its fluorescent emission was measured at 543 nm. Images were taken every 2 s with a cooled CCD camera (IMAGO, Till Vision, Germany) at a 640 × 480-pixel resolution. Processing was made offline by using TILLvisION software.

The fluorescence measurements were made by linear interpolation, after non-specific fluorescence in each sequential image was subtracted from the intensity of the membrane. The area of release was estimated from the length of membrane in which fluorescence increased, by assuming that it was circular (De-Miguel et al., 2012). This number served as a reference for the model estimates of the number of vesicles (see Equation 1).

Exclusion Criteria

Neurons commonly moved after electrical stimulation. Therefore, the focus of each spot in the time series analysis had to be confirmed from a z axis scanning of the neurons at the end of the experiment. Only fluorescent spots that remained in focus during the whole experiment or that could be aligned digitally were included in the analysis. Clusters extending for more than 1 μm of membrane length were excluded to avoid out-of-focus fluorescent emissions due to large numbers of vesicles (De-Miguel et al., 2012). For these reasons, we eliminated

from our analysis a vast number of observations. However, the data from nine different neurons in which subsequent uncorrelated clusters of vesicles arrived at the same spot were a fair representation of the population.

Quantitative Analysis of Exocytosis

The model was developed based on the kinetic properties of the FM1-43 fluorescence increases during exocytosis (**Figure 2**). A full account of the theoretical development of the model is presented in De-Miguel et al. (2012). In brief, the fluorescence kinetics $F_{(t)}$ is proportional to the flux J_{ves} of vesicles arriving at the plasma membrane. The process of exocytosis is orders of magnitude faster than the speed of the vesicle transport. Therefore, the flux reflects the transport and can be defined as the number of vesicles fusing per second at an area A of the plasma membrane, according to:

$$F(t) = F_0 + Ab \int_0^t J_{ves}(d, t')dt' \quad (1)$$

In Equation (1), F_0 is the basal fluorescence produced by the interaction of the fluorescent dye with the extracellular layer of the plasma membrane; b is a proportionality factor relating the amount of fluorescence contributed by each vesicle. This proportionality stems from the fact that the internal membrane surface of the population of electrodense vesicles can be considered constant. The parameter "t" is the time, while "d" is the transport distance from the center of mass of the resting cluster to the plasma membrane. The distance was estimated by the model and was correlated with distances measured from electron micrographs of neurons stimulated with 1 Hz trains of impulses (De-Miguel et al., 2012). The plateau of the fluorescence increase indicates the total the number of vesicles (n_0) that fused (**Figure 1B**). The parameters used in the model are in **Table 1**. The contribution of the distance, velocity and number of vesicles to the kinetics of fluorescence are presented schematically in **Figure 1**.

As shown also in **Figure 1**, the flux of vesicles, J_{ves}, depends on four forces. The first two are a frictional force due to the resistance opposed by the medium to the vesicle motion and a random force produced by thermal agitation. These two forces produce the Brownian motion of the vesicles at the experimental temperature. The third force is elastic and confines the individual vesicles in a cluster. These forces are considered harmonic because the vesicle displacements they produce are small. This assumption simplifies the model. The fourth force is used by the motors to carry the vesicle clusters plus mitochondria at an average velocity "v_{ves}" (Svoboda and Block, 1994; Schnitzer and Block, 1997). The Force of the motor and the elastic forces acting together on the vesicles can be defined as:

$$F = f_{el} + f_{mot} = \omega^2(d - vt) \quad (2)$$

Where ω is the characteristic frequency at which the elastic forces confine the vesicles, as described by:

$$\omega = \sqrt{\frac{k}{m}} \quad (3)$$

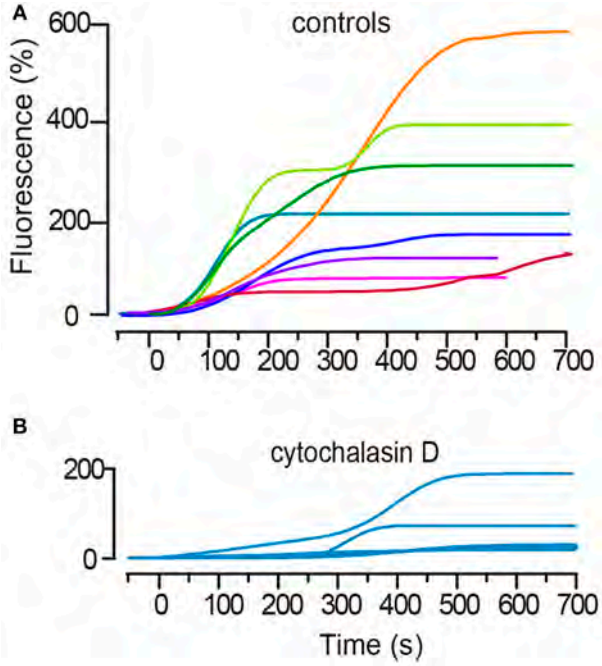

FIGURE 2 | Kinetics of the large-scale exocytosis as measured from the fluorescence increases of FM1-43. **(A)** Superimposition of the FM fluorescence (Fluo) kinetics of eight representative spots from an equal number of neurons. Stimulation occurred at $t = 0$. A subsequent stimulation train was delivered every 2 min. Fluorescence is plotted as the percentage increase over the baseline. Subsequent sigmoidal increases appear in most kinetics, with each reflecting exocytosis from a subsequent vesicle cluster. **(B)** Treatment of neurons with cytochalasin D that uncouples the actin cortex delayed and reduced the fluorescence increases in response to stimulation and abolished the second sigmoidal fluorescence increase. The plot superimposes six kinetics from an equal number of neurons. Note the difference in the fluorescence scale bars between **(A,B)**.

We consider that the vesicle motion toward the cell membrane is unidimensional and can be described in terms of the distance coordinate. Therefore, J_{ves} depends on the friction and motor forces plus the contribution of diffusion, where $J_{ves} = \rho v_{ves}$ and $v_{ves} = \beta^{-1}F$. Then J_{ves} can also be expressed as:

$$J_{ves} = -D\frac{\partial \rho}{\partial x} + \beta^{-1}\rho F \quad (4)$$

where the term $-D\frac{\partial \rho}{\partial x}$ accounts for diffusion, with D the being the diffusion coefficient, and the second term is the product of the friction ($\beta^{-1}\rho$) and the motor (F) forces, due to the effect of the driving force (De-Miguel et al., 2012).

These forces are modeled by a linear function of the position, which corresponds to a harmonic force. Harmonic forces yield in general an oscillatory motion in which the velocity of the particle decreases until it vanishes at a certain point, and then increases in the opposite direction. In this case the harmonic force acts only during forward motion. Therefore, that sole force can model the main movement of the vesicles to the plasma membrane.

TABLE 1 | Definition of the parameters used in the model.

Symbol	Definition	Dimensions
A	Area of a release site measured from the diameter of the fluorescence increase	L^2
ATP_{ves}	Number of ATP molecules hydrolyzed per vesicle fused.	–
β	Dimensionless constant referring to the fluorescence increase per vesicle fused	–
d	Transport distance of vesicle clusters measured from the center of mass of the cluster to the plasma membrane	L
ΔG	Gibb's free energy	ML^2T^{-2}
ΔG_{ATP}	Gibb's free energy of ATP hydrolysis	ML^2T^{-2}
F_0	Baseline value of the fluorescence intensity	a.u.
$F(t)$	Fluorescence as a function of time	a.u.
F	Force exerted by the motors	MLT^{-2}
f_f	Friction forces per mass unit	LT^{-2}
$f_{r(t)}$	Random forces due to thermal agitation per mass unit	LT^{-2}
f_{el}	Elastic forces per mass unit	LT^{-2}
f_{mot}	Molecular motor force per mass unit	LT^{-2}
Fv	Power of the large-scale exocytosis	ML^2T^{-3}
J_{ves}	Current density of vesicles	$L^{-2}T^{-1}$
κ	Elastic constant of the cytoskeleton	MT^{-2}
m	Mass	M
η	Thermodynamic efficiency	–
n_o	Number of vesicles per cluster	–
r	Rate constant of ATP hydrolysis	T^{-1}
v	Average velocity of vesicle cluster transport	LT^{-1}
ω	Characteristic frequency of the elastic force	T^{-1}
W	Work of the large-scale exocytosis	ML^2T^{-2}

Improved Estimates of ATP Consumption

The work that moves the vesicle cluster-mitochondria complex along a certain distance equals the change in free energy:

$$W_{tot} = k(d^2 - dvt) = \Delta G_{process} \tag{5}$$

In our previous calculations, the elastic (k) constant value of the molecular motors was a free parameter in the model. For such reason there were variations in its predicted value from one release site to another (De-Miguel et al., 2012). In this study, we fed the model with a unique $k = 0.027$ pN/nm value measured experimentally by Bruno et al. (2011).

Equation (6) expresses the total amount of energy provided by the cleavage of ATP that is necessary under ideal conditions, to transport a vesicle cluster for a certain distance without dissipation. Due to the heterogeneity of the vesicle cluster sizes, the energy is expressed as the number of ATP molecules hydrolyzed per vesicle fused (ATP_{ves}) by dividing the numerator by the number of vesicles in the cluster n_0:

$$ATP_{ves} = \frac{\Delta G_{process}}{n_0 \Delta G_{ATP}} \tag{6}$$

TABLE 2 | Ranges of parameter values contributing to the vesicle transport.

Cluster	Peripheral	Internal
η_0	98–490	52–930
d (μm)	0.6–2.1	1.9–6.2
v (nm/s)	15.0–95.0	11.5–60.0
J_{ves} (ves/sec)	0.2–4.0	0.9–10.33
Elastic force (N × 10^{-11})	1.2–4.2 (0.6–4.1)	3.8–12.0 (2.2–24.2)
Motor force (N × 10^{-10})	1.2–6.0 (0.6–4.4)	1.8–4.7 (1.4–3.5)
ATP_{ves}	10.9–49.4 (3.4–73.0)	13.6–260 (0.4–25.1)
Efficiency (%)	0.2–6.4	0.1–1.9

Data in red are the estimates calculated in this study; data in parenthesis are from our previous study (De-Miguel et al., 2012).

The ΔG_{ATP} value was 5.4×10^{-20} Joules (Alberty and Goldberg, 1992), and n_0 is the number of vesicles that fused (see Equation 1). **Table 2** compares the data obtained for the elastic and motor forces, and for the ATP_{ves} expenses reported here and in our previous study (De-Miguel et al., 2012). **Table 2** shows that the ATP_{ves} values presented here remained within similar orders of magnitude than those previously reported.

Thermodynamic Efficiency

Since energy dissipation due to the presence of frictional forces is expected to occur in a non-ideal transport by living neurons, we used the classical definition of efficiency as the ratio between the ideal and the lost work and applied as in De Groot and Mazur (1969), later applied to analyze the efficiency of the calcium ATP_{ase} by Lervik et al. (2012).

$$\eta = \frac{W_{ideal} - W_{lost}}{W_{ideal}} \tag{7}$$

The W_{ideal} is the given by:

$$W_{ideal} = -r\Delta_r G \tag{8}$$

Where r is the force-related rate of ATP cleaved by the molecular motors. The kinetics of force generation of molecular motors are consistent with a two-step reaction (Higuchi et al., 1997). The binding of ATP has a rate constant that depends on the concentration and therefore its units are $\mu M^{-1} \cdot s^{-1}$; a second rate constant r accounts for the force generation used here, and has s^{-1} units (Higuchi et al., 1997). The r value related to the force generation is the one that matters for our estimates, since according to De Groot and Mazur (1969, Equation 10 of Chapter X), it relates the reaction rate to the production of entropy. This definition is adequate to calculate the efficiency since the entropy production related to thermal dissipation. As in our previous equation, $\Delta_r G$ is the Gibbs free energy of the ATP cleavage.

The work lost (W_{lost}) can be obtained from the Gouy-Stodola theorem in Equation (7) (see Kjelstrup et al., 2010):

$$W_{lost} = T\sigma \tag{9}$$

where T is the constant temperature of the surroundings of the system and σ is the production of entropy that accounts for the thermal dissipation. In our case, the energy is dissipated during the transport of vesicles and in the process of the ATP hydrolysis at a rate given by:

$$T\sigma = -r\Delta G - J_{ves}\Delta\mu_{ves} \tag{10}$$

This expression was derived according to energy conservation along the transport path; $\Delta\mu_{ves}$ in a previous paper was an electroneutral exchange of ions by the calcium ATP_{ase} (22), and here it relates to the force F of the motors. We also considered a negligible thermal driving force (Lervik et al., 2012). This expression was also used by Caplan and Essig (1999), who considered the isothermal case and the linear regime of proper pathways.

The efficiency η of vesicle exocytosis can be given in terms of measurable quantities as:

$$\eta = \frac{-r\Delta G - T\sigma}{-r\Delta G} = \frac{J_{ves}\Delta\mu_{ves}}{-r\Delta G} \tag{11}$$

The numerator of this fraction involves the flux of particles J_{ves} and the chemical potential difference $\Delta\mu_{ves}$ between the initial and the final position of the vesicles, which corresponds to a force. Since in the experiments we follow the trajectories of the vesicles, the numerator that corresponds to the work applied to the vesicles to move with a velocity v_{ves} is given by the product $F_{ves}v_{ves}$. The efficiency is then:

$$\eta = \frac{F_{ves}v_{ves}}{r|\Delta G|} \tag{12}$$

where F_{ves} is the sum of elastic and motor forces given in Equation (2).

The efficiency per vesicle was calculated by dividing by the number of vesicles (n_0) in the cluster.

$$\eta = \frac{F_{ves}v_{ves}}{n_0 r|\Delta G_{ATP}|} \tag{13}$$

The rate constant r of the force generated by the ATP hydrolysis for kinesin motors is <100–300 s^{-1} (Higuchi et al., 1997; Cross, 2004). A similar range of values has been measured for myosin motors (Johnson and Taylor, 1978; De La Cruz et al., 1999). Therefore, the 100 s^{-1} value used here may account for either motor type acting separately and with non-additive effects.

Curve Fitting and Statistical Analysis

The kinetics of exocytosis of 19 release sites obtained from six neurons were fitted to the mathematical model, as in De-Miguel et al. (2012; see **Figure 5**). The traveling distance and number of vesicles were limited by the ranges of values determined previously from electron microscopy (De-Miguel et al., 2012). In this way we reduced the possible combinations of values estimated by the model and reduced the error in the fittings. The data were fitted manually by using our own routines made in MATLAB software (MathWorks, Massachusetts, USA). This procedure was preferred over minimum square methods because sigmoidal functions with two crossovers became smoothed in abrupt parts of curves that had strong contributions by the motor activity. A previous account on the quality of the fittings and the effects of varying the values of the free parameters has been presented in De-Miguel et al. (2012).

The data sets relating the ATP_{ves} expenses and the efficiency vs. distance presented in **Figure 6** were fitted to empirical polynomial functions to underscore the W-shape of the charts. The order of the polynomials was adjusted to obtain the best R^2 correlation values. The polynomial functions in our previous study had better fittings; data of peripheral clusters were fitted by a third-order polynomial function with $R^2 = 0.92$. Likewise, the fitting quality of the internal cluster data was $R^2 = 0.83$. The reason for the lower quality of the fittings presented here is the absence of data in the distance ranges of the minimum peaks (see **Figure 6A**). However, the polynomial fittings had no other intention than to give numeric support to the clear W-shaped trend of the data. In any case, due to the calculation improvements already described, we consider that the data sets in this study are more precise.

Staining of the Actin Cortex

The actin cortex was measured from fluorescent stainings made by use of phalloidin coupled to a fluorescent probe. Neurons were fixed right after stimulation with CytoSkelFix (Cytoskeleton) for 4 min at −20°C and permeabilized for 30 min with phosphate-buffer saline (PBS) solution containing 0.3% Triton X-100. SFB (10%) was added as a blocker for 2 days, during which the preparations were maintained at 4°C. Actin was stained by incubation for 30 min at 37°C with phalloidin coupled to Alexa-fluor 488 (0.16 μM, Invitrogen). Controls incubated in parallel without phalloidin were devoid of any staining.

Observations of fluorescence made using an Olympus Fluoview FV1000 upright confocal scanning microscope equipped with a 60X oil immersion objective (1.45 NA). Images were stored digitally using Fluoview 3.1 software (Olympus). The thickness of the actin cortex was measured from digital images using ImageJ software (NIH, USA).

Electron Microscopy

Neurons in isolated ganglia were fixed right after stimulation with 10 trains of 10 impulses at 1 or 20 Hz, delivered at 10 s intervals. The procedure to obtain thin (70–100 nm) sections for electron micrographs of Retzius cells were as in Kuffler et al. (1987). Sections were photographed in a JEOL 1010 electron microscope (JEOL USA Inc.).

RESULTS

Kinetics of Somatic Exocytosis

Electrical stimulation of Retzius neurons with 20 Hz trains produced FM1-43 fluorescence spots at the neuronal surface (Trueta et al., 2003). In this experimental situation each release site develops a fluorescent spot upon the subsequent fusion of electrodense vesicles. A first sigmoidal fluorescence increase (**Figure 2A**) reflects the fusion of vesicles forming a cluster that

rested at distances <2.0 μm from the plasma membrane (De-Miguel et al., 2012). Such clusters are named "peripheral" and data are presented as green symbols (**Figure 2B**). A second sigmoidal increase in the same spot is due to fusion of vesicles in clusters that traveled from more internal sites (see De-Miguel et al., 2012). These clusters are called "internal," and data are represented with red symbols (**Figure 2B**).

The model fittings predicted that 52–930 vesicles per cluster became fused in the 19 clusters analyzed from 10 neurons. There was no correlation between the number of vesicles, the distance, or the velocity of pairs of clusters arriving subsequently at the same release site ($R^2 \leq 0.4$ for all cases). For example, in a release site the peripheral cluster contained 95 vesicles that traveled along 0.6 μm at 70 nm/s, whereas the internal cluster contained 262 vesicles that traveled along 4.1 μm at 12 nm/s; in other release site the peripheral cluster also had 95 vesicles that traveled along 0.6 μm at 59 nm/s, but the internal cluster contained 675 vesicles that traveled along 2.7 μm at 18 nm/s. In a third release site the peripheral cluster was larger than the internal, however both traveled at the same 30 nm/s velocity. Data of the pairs of clusters can be seen in **Figure 10**.

It was previously shown that uncoupling microtubules by addition of colchicine to the neurons abolishes somatic exocytosis, most likely by uncoupling the actin-mediated transport (De-Miguel et al., 2012). In addition, the actin cortex in neurons and secretory cells imposes a barrier for the transport at rest, but electrical activity in the presence of myosin turns the actin cortex to an active transporter (Vitale et al., 1995; Lang et al., 2000; Oheim and Stühmer, 2000; Giner et al., 2005; Tobin and Ludwig, 2007; Gutiérrez and Gil, 2011; Torregrosa-Hetland et al., 2011). For its potential friction-generating qualities, we uncoupled the actin cortex to test its contribution to the ATP expenses and efficiency of the transport. Pre-incubation of six neurons with cytochalasin D in the bathing solution produced that in all but one case ($n = 8$ clusters from 6 neurons), the latency to the onset of exocytosis was increased from 50–80 s to ∼300 s. In addition, the amplitude of the plateau fluorescence was reduced to values corresponding to 40–107 vesicles fused (**Figure 2B**). It can also be seen that in all but one case the fluorescence increase lacked the second sigmoidal. This experiment shows that the actin cortex has a sophisticated contribution to somatic exocytosis.

The Rate of Vesicle Fusion Reflects the Transport Conditions

The calculations of the efficiency depended on the correct measure of the flux of vesicles (J_{ves}; see Equations 1 and 4 in the Methods section), indirectly representing the rate of exocytosis. For this reason, it was necessary to demonstrate that the area of membrane did not limit exocytosis. This possibility was confirmed by correlating J_{ves} with the number of vesicles that fused. The J_{ves} values ranged from 0.2 to 5.2 vesicles per second in the 19 clusters studied and had a linear relationship ($R^2 = 0.85$) with the area of release (**Figure 3A**). For internal clusters the relation was sublinear with a 0.76 exponent ($R^2 = 0.88$). The deviation from linearity occurred when the number of vesicles per cluster was above 600. Such large clusters may have encountered major constrains in their traveling path, as will be confirmed below. However, the large clusters can extend over wide areas of membrane, as seen in electron micrographs (Trueta et al., 2004). Therefore, we consider that the J_{ves} values reflect accurately the transport velocity of the vesicle clusters. In support to this, **Figure 3B** shows that the efficiency of the ATP expenses was uncorrelated with the J_{ves} values.

ATP-Dependence of the Thermodynamic Efficiency

The efficiency of the ATP_{ves} expenses of peripheral clusters spanned within more than one logarithmic unit from values as low as 0.2% for the smallest 11 ATP_{ves} value. From there, the efficiency increased to its largest 6.4% value when the ATP_{ves} cost was 49 molecules (**Figure 4**). The intermediate data were described by a supralinear relationship. The 1.9 potency slope ($R^2 = 0.7$) is consistent with the possible incorporation of a second type of motor, presumably myosin coupled to the actin cortex. This addition could increase the efficiency of ATP_{ves} expenses by incorporating the characteristic longer steps per ATP molecule of myosin motors (Kohler and Rohrbach, 2015). The internal vesicle clusters were distributed within an efficiency range from 0.1 to 1.9% and a large range of ATP_{ves} cost of 14 to

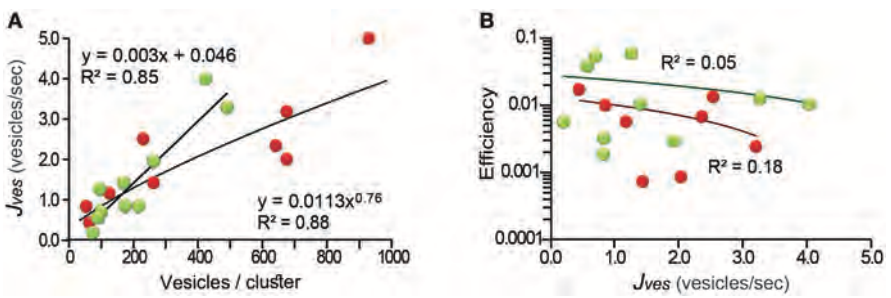

FIGURE 3 | The thermodynamic efficiency of the ATP per vesicle fused was independent from the rate of vesicle fusion (J_{ves}). **(A)** The J_{ves} values related linearly to the number of vesicles in peripheral clusters (green), and with a 0.76 exponent to the number of vesicles of internal clusters (red; for explanation see text). **(B)** The efficiency did not correlate with the rate of fusion of internal or external clusters (black lines), respectively. The equations giving the best fit to the data and the significance levels are presented.

260. The plot approximated a linear relationship ($R^2 = 0.6$) with a 0.9 exponent. This result is more consistent with the action of a single type of motor (kinesin) mediating the transport (Kohler and Rohrbach, 2015).

Uncoupling the actin cortex with cytochalasin D reduced the range of ATP_{ves} expenses to 1.3–19, and the efficiency to the lowest 0.06–0.4% range in the study (**Figure 4**). The small amount of exocytosis in this experimental situation suggests that only vesicles inside the cortex at the time of stimulation could fuse. This is in agreement with the 0.37–2.7 μm transport distances estimated for these clusters. The potency function that fitted these data, had again a slope of two ($R^2 = 0.90$). These data in addition with the short transport distances points to the possibility that short filaments of actin bound to myosin and contributed to move the proximal clusters that fused. Our conclusion from these sections is that the efficiency values are proportional to the ATP_{ves} expenses and may indicate additive effects on the vesicle transport.

Velocity as a Reporter of the Thermodynamic Efficiency

Figure 5 shows that the thermodynamic efficiency displayed a power law relationship with the transport velocity of the vesicles. This trend incorporated the whole population of data, although peripheral clusters traveled with a wider 15–95 nm/s range of velocities. The velocities above 60 nm/s were unreachable for internal clusters. As expected from Equation (12), the peripheral vesicles transported at higher velocities also displayed the largest -although yet low- thermodynamic efficiencies between 4.2 and 6.4%. This finding is not surprising from a different perspective: the peripheral clusters were small and had less mass to oppose to frictive obstacles. At velocities below 60 nm/s there was an extensive overlapping of both cluster populations in the chart, with the efficiencies of the internal clusters being ≤1.9%. Application of the actin depolymerizing agent cytochalasin D produced a reduction in the transport velocity to 1.5–17.0 nm/s that correlated with the lower 0.006–0.04% range of efficiency. This result seems more related to the lack of one motor system than to an increase in the frictive forces. Data from the internal and external clusters could be fitted independently to potency functions with equal 1.56 exponents and R^2 values of 0.69 and 0.41, respectively. However, the pooled data set, including those data collected in the presence of cytochalasin D were best described by a single function with a 1.63 slope ($R^2 = 0.86$). This property anticipates that the distribution of velocities expresses effects from other variables such as the size of the vesicle cluster and the cytoarchitecture of the pathway. To complement this scheme, we have also shown that the ATP_{ves} cost also increases with the velocity (De-Miguel et al., 2012).

Distance-Dependence of the ATP Expenses

The distance-dependence of the ATP_{ves} expenses reproduced the previously described W-shape (De-Miguel et al., 2012), with

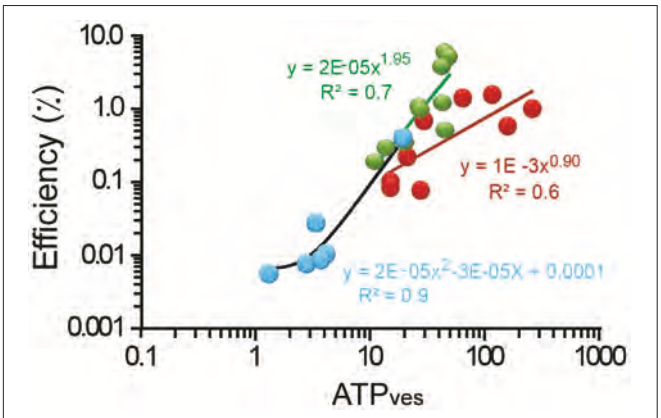

FIGURE 4 | Efficiency as a function of the ATP_{ves} expenses. Logarithmic plot of the efficiency as a function of the ATP_{ves}. The thermodynamic efficiency of exocytosis from peripheral clusters had a quadratic relationship with ATP_{ves} expenses (green line); internal clusters (red) the relationship had a 0.9 exponent (dark red line). Uncoupling the actin cortex with cytochalasin D (blue dots) reduced the range of the relationship by two logarithmic units. Data was fitted by a quadratic potency function (black line). The equations and their significance values are presented.

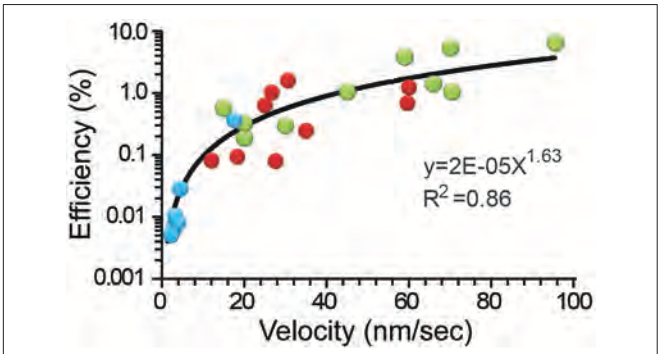

FIGURE 5 | The efficiency depended on the transport velocity. Data from internal (red), peripheral (green) clusters, and after addition of cytochalasin D (blue) were pooled together and fitted to a potency function (black line). The equation and significance level are presented.

certain differences in the ranges of ATP_{ves} values, that are presented in **Table 2**. The transport of external clusters along the shortest 0.6 μm resting distances had a high 52 ATP_{ves} cost. As the transport distance increased to 1.3 μm, the ATP_{ves} cost became gradually reduced to reach minimum of 13 ATP_{ves}. As the distance continued to increase, the trend of the energy cost reversed to reach 44 ATP_{ves} when the distance was 2.1 μm. This was the distance at which the high-energy barrier of the W curve appeared. This was also the site of convergence for external and internal clusters. The first internal cluster rested at 1.9 μm and release from its vesicles occurred at a high 118 ATP_{ves} cost (**Figure 6A**). From there, the ATP_{ves} expenses had a second decrease to reach the second minimum, which in this case was 14 ATP_{ves} in the segment between 2.3 and 4.3 μm. The last increase complemented the W shape by reaching the largest 260 ATP_{ves} value at 6.15 μm (**Figure 6A**). The polynomial

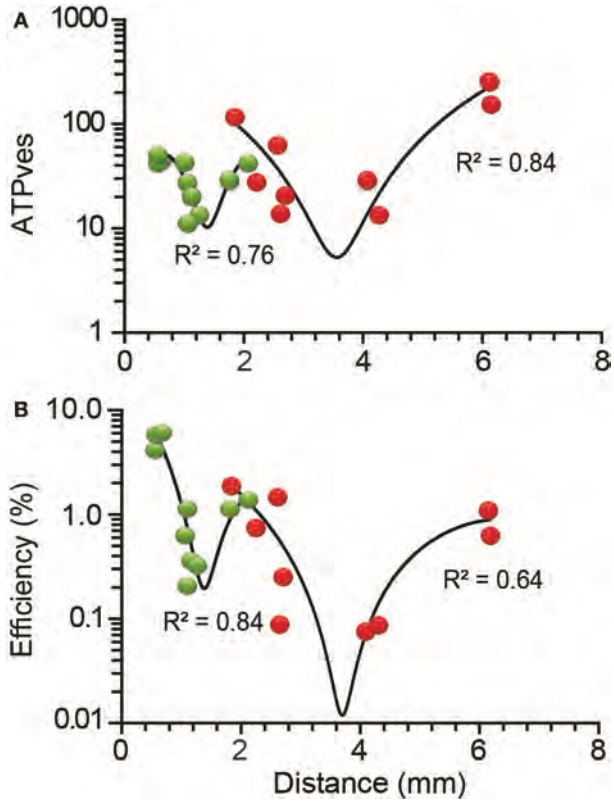

FIGURE 6 | Distance-dependence of the ATP_{ves} expenses and thermodynamic efficiency of exocytosis. **(A)** The ATP_{ves}-dependence on the distance had a W-shape. The short distance range of the plot contains information from peripheral (green) clusters, while distances above 1.9 μm contain information from internal (red) clusters. A maximum intermediate peak forming a high energy barrier appeared by 1.9 μm, with convergence of peripheral and internal clusters. **(B)** The distance-dependence of the thermodynamic efficiency of somatic exocytosis also was W-shaped, with each vesicle population separated by the intermediate maximum. The clusters that rested at the shortest distances had the largest efficiency values. The R^2 values are the significance of the polynomial functions fitted to the data (black lines).

fittings in the plots had the unique intention to underscore the W-shape distribution of the data without any use for the model calculations.

Distance-Dependence of the Thermodynamic Efficiency

As expected from the proportionality of the efficiency and the ATP_{ves} values in **Figure 4**, the thermodynamic efficiency also displayed a W-shape dependence on the transport distance (**Figure 6B**). The distance ranges of the efficiency plots were the same as for the ATP expenses. However, the efficiency of peripheral clusters covered a larger range of values than that of internal clusters. The first polynomial distribution in **Figure 6B** included the data from peripheral clusters ($R^2 = 0.84$). The low distance extreme had the higher 6.4% efficiency. At deeper distances the values first decreased to a 1.9% minimum and then increased to reach the intermediate 1.4% peak right where peripheral and internal clusters intersected. The second part of the chart had a sole contribution from internal clusters. This section could be approached by a polynomial function ($R^2 = 0.64$). The 0.08% second minimum efficiency occurred between 2.65 and 4.30 μm, although as discussed above, data with even lower values may be missing. At 6.15 μm the efficiency reached its internal maximum value of 1.1%. Our hypothesis to explain the W-distribution of the ATP_{ves} expenses and efficiency was that each component of the plot reflects a mechanical or ultrastructural interference on the vesicle pathway. An increase in the friction can be produced by a larger number of vesicles being transported or by obstacles in the pathway. It is worth to remark that the slopes of the W chart do not refer to the behavior of the vesicles within the range of distances covering that slope but indicate the amount of ATP expenses and efficiency over their whole trip to the membrane. Following this idea, those vesicles traveling the longest distances would have to overcome the obstacles that produce each of the four slopes of the chart. These possibilities were explored in the following parts of the study.

Ultrastructural Correlates of the Thermodynamic Efficiency

For its susceptibility to be affected by friction forces, the number of vesicles in the clusters was our first candidate to explain the components of the W chart. The plot in **Figure 6B** showed that the vesicle clusters near the plasma membrane had the largest efficiencies. **Figure 7** shows that those same clusters were small, as explained in **Figure 1**. Intuitively, the transport of small cargos occurs with higher efficiency owing to the smaller counteracting friction forces. However, the ATP_{ves} cost of the transport of these clusters was among the highest (**Figure 6A**). Moreover, the relationship between the size of the clusters and the efficiency did not follow the W shape. The number of vesicles per cluster increased as the clusters rested more internally, to reach 930 vesicles at 4.5 μm from the plasma membrane. Then the last cluster carried only 62 vesicles with a 1.1% efficiency. This small cluster was most likely being assembled near a Golgi apparatus (see Trueta et al., 2012). This result points to elements other than the vesicle numbers affecting the efficiency. Based on this reasoning we carried out a search for ultrastructural elements affecting the thermodynamic efficiency.

Ultrastructure of the Actin Cortex

The dual role of the actin cortex on the vesicle transport already described suggested its influence on the thermodynamic efficiency of the transport. The actin cortex of neurons stimulated with 1 Hz trains of impulses was stained with phalloidin coupled to Alexa fluorescent dye. The fluorescent label in equatorial images of the soma consisted of a thick 1.93 ± 0.74 μm (S.D.) array of radial bundles (**Figure 8**), as quantified from 46 counts of different parts of the cortex of five neurons. This thickness was similar to the distance at which we found the high energy barrier and high efficiency intermediate peak of the W distributions shown in **Figure 6**. Such value gives a possible explanation to the third slope of the W distributions in **Figure 6**. As internal clusters

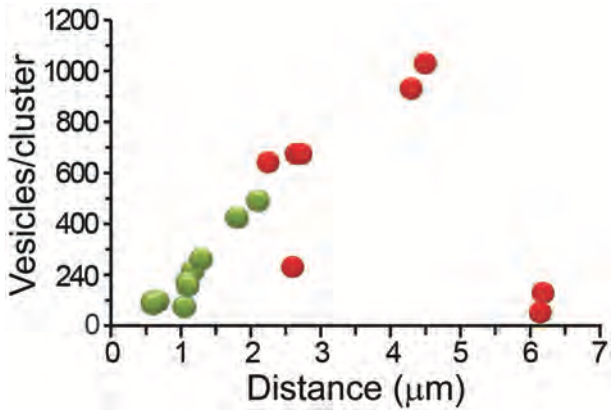

FIGURE 7 | Distance-dependence of the number of vesicles that fused per cluster. The number of vesicles in the clusters increased with the distance from the plasma membrane. The most internal clusters were small. Peripheral clusters are represented in green and internal in red.

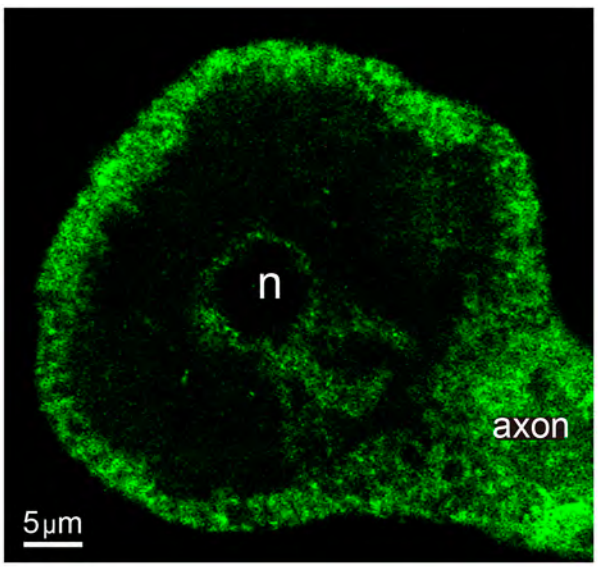

FIGURE 8 | Actin cortex of Retzius neurons. Confocal equatorial image of the soma of a Retzius neuron showing the fluorescence of Alexa dye coupled to phalloidin. The perinuclear region and primary axon also display a profuse staining. n indicates the position of the nucleus.

rested closer to the high energy barrier increasing amounts of vesicles were inside the actin cortex, where the myosin carried by the clusters assembles the actin-myosin transport with the actin filaments (Noguez et al., in preparation). As larger fraction of the clusters added the myosin-actin dymers to the kinesin-tubulin transport, the cost and efficiency of the transport would increase. However, this is a partial explanation. A fuller account comes from the origins of the two short distance slopes of the W charts, which are explained in the following paragraphs.

Distribution of Endoplasmic Reticulum

The search for alternative ultrastructural candidates to explain the ATP_{ves} expenses and thermodynamic efficiency of the first half of the W distributions took us to the endoplasmic reticulum. Electron micrographs showing release sites of neurons were obtained by fixing neurons right after 1 Hz stimulation ($n = 5$) to maintain the resting ultrastructure of the transport pathway (Trueta et al., 2004). The images in **Figure 9** contain structures immersed in the actin cortex, although the conventional fixation technique that we used to prepare the sections does not allow to resolve its structure. **Figure 9A** contains a cluster of electrodense vesicles resting distantly from the plasma membrane. Subsequent vesicles are bound by small fine filaments. The vesicle cluster was bound indirectly to the plasma membrane via a thick bundle of microtubules, according to the diameter of the individual fibers. Single vesicles appeared along the microtubules, presumably on their way to the plasma membrane (Leon-Pinzon et al., 2014; **Figure 1**). As explained in **Figure 1**, this vesicle migration explains the reduction of the number of vesicles as the peripheral clusters rest closer to the plasma membrane. An alignment of endoplasmic reticulum bags bordered the intracellular side of the plasma membrane; deeper and smaller bags of endoplasmic reticulum were scattered between the vesicles and the plasma membrane. One may wonder that vesicles being transported to the plasma membrane will find these bags on their way forming a bottleneck.

Electron micrographs obtained from neurons fixed after 20 Hz stimulation confirmed this idea. The image in **Figure 9B** shows vesicles from a large cluster reaching the plasma membrane by passing between endoplasmic reticulum. These obstacles bottlenecked the flux of vesicles and can be considered as sources of friction forces that reduce the thermodynamic efficiency of somatic exocytosis.

Countings of the distance between the plasma membrane and the center of mass of endoplasmic reticulum bags are presented in **Figure 9C**. The green and red lines fit the data distribution to two Gaussians, one with a mean $0.36 \pm 0.11\,\mu m$ (SD) distance from the plasma membrane, corresponding to the more external layer of endoplasmic reticulum. The red line fits the distribution of the scattered internal bags of endoplasmic reticulum, rendering a mean $0.93 \pm 0.12\,\mu m$ distance. This distribution supports that the endoplasmic reticulum is a source of friction forces that reduce the thermodynamic efficiency. Smaller vesicle clusters facing the plasma membrane seem to rest between the external layer of endoplasmic reticulum in absence of further obstacles to reach the plasma membrane.

Multiple Variables Affect the Thermodynamic Efficiency

The multivariable schemes in **Figure 10** integrate the data on the possible variables that determine the thermodynamic efficiency of somatic exocytosis. Each element of the transport pathway has been scaled based on the experimental evidence. The diameter of the circles representing each cluster was calculated from its number of vesicles. Peripheral clusters are organized in an

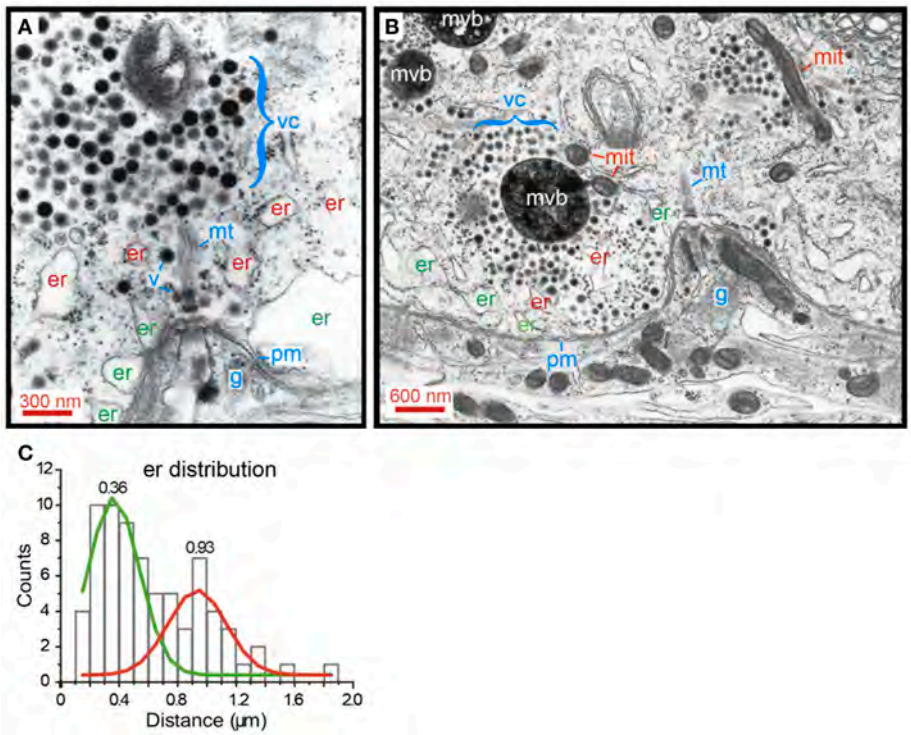

FIGURE 9 | Distribution of smooth endoplasmic reticulum in the soma shell. **(A)** Electron micrograph of a neuron that had been stimulated at 1 Hz. Vesicles remain at their resting states. A somatic vesicle cluster (vc) is bound to the membrane (pm) via a bundle of cytoskeletal fibers, most likely microtubules (mt). Peripheral endoplasmic bags (er) rest closely apposed to the plasma membrane. More internally, another layer of endoplasmic reticulum (er) contains smaller bags. Individual vesicles (v) can be seen in an apparent migration to the membrane, along the microtubule bundles (see also **Figure 1**). Glial cell processes (g) in an invagination of the Retzius neuron, right at the anchor site of microtubules to the plasma membrane. **(B)** Electron micrograph of a release site in a neuron that had been stimulated with 20 Hz trains. Vesicles in a large cluster are apposed to the membrane. Transport occurs through a bottleneck of endoplasmic reticulum. Mitochondria (mit) are common satellites of the clusters that travel with them. Multi-vesicular bodies (mvb) result from the incorporation of vesicles after exo/endocytosis (Trueta et al., 2012). Note that exocytosis occurs onto the glia. **(C)** Distribution of endoplasmic reticulum in the soma shell. The distances have the plasma membrane as reference. Peripheral (er) and internal (er) pools of endoplasmic reticulum were distinguished by Gaussian fittings to the histograms. The mean values for each distribution are indicated.

ascending order of efficiency. The distance from the plasma membrane to the center of mass of the clusters was determined by the model fittings. Pairs of clusters releasing in the same spot are associated by a black line representing the microtubule bundles. The efficiency of the ATP expenses per vesicle is indicated in the center of each cluster; the velocity of the transport is indicated on the right of each cluster. The actin cortex and endoplasmic reticulum are represented according to the morphometric analysis descried above. At first glance there is a good correlation between the size, the resting distance and the efficiency of peripheral clusters. The thermodynamic efficiency of the exocytosis process from vesicles in these peripheral clusters was inversely proportional to their resting distance. Similar correlations are unclear for the internal clusters in this representation, because although they were associated to a peripheral cluster, their biophysical properties were not correlated. The correlations between different variables of the clusters and the ultrastructure of the transport pathway are simplified in **Figure 10B**. The vesicle clusters were grouped from I to IV based on the distance, efficiency, size, velocity, and ultrastructural interactions. Both regions in which the ATP hydrolysis and efficiency had increasing slopes also had higher transport velocities. On the contrary, the regions in which the energy and efficiency had decreasing trends had slower velocity ranges. This result, which can be predicted from the formula of the thermodynamic efficiency in Equation (12), acquires a morphological correlate in **Figure 10**. **Table 3** summarizes the data according to the groups of vesicle clusters. For the small peripheral clusters in Group 1, the additive action of two motors and the clusters resting already between endoplasmic reticulum in the more peripheral layer may favor higher velocities and efficiencies at the expenses of the high ATP_{ves} cost. Group II has two friction barriers represented by the two layers of endoplasmic reticulum. As vesicles enter the barriers the thermodynamic efficiency decreases. This can be attributed to the friction exerted by the endoplasmic reticulum on the vesicle clusters. In group III, the large clusters are at least in part, immersed in the actin cortex. The assembly of two motors may increase the ATP expenses and efficiency. However, the effect of the endoplasmic reticulum barriers is

INFORME DE LABORES 2019

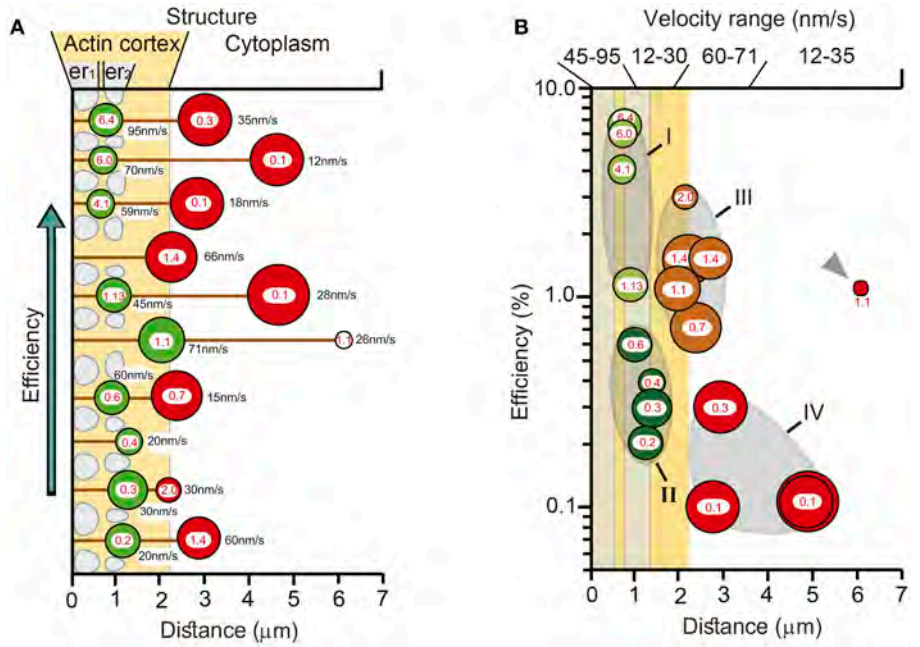

FIGURE 10 | Structural and biophysical correlations of the thermodynamic efficiency of the ATP_{ves} hydrolysis. **(A)** Pairs formed by peripheral (green circles) and internal (red circles) vesicle clusters that discharged in the same site are represented attached to microtubules (black lines). The distances were calculated by the model fittings from the mass center of the cluster to the plasma membrane. The diameter of the clusters corresponds to the number of vesicles in the cluster. For each cluster, the red numbers inside indicate the efficiency (%), and the black numbers on the right the transport velocity (nm/sec). The peripheral clusters are presented from bottom to top according to their increasingly efficiency values. Their paired internal clusters had independent efficiency values, velocities, sizes and traveling distances. The actin cortex is represented in pale orange. Both layers of endoplasmic reticulum, one immediately inside the plasma membrane (er_1) and the other ~1 μm inside (er_2) are represented as pale sacs. The number of vesicles decreased as the clusters approached the plasma membrane. The efficiency of the peripheral clusters decreased as the distance increased. The number of vesicles, the efficiency, the transport distance and velocity of their corresponding internal clusters were uncorrelated with those of their peripheral pairs. **(B)** Vesicle clusters were groped according to their efficiency, size, distance, and velocity. The thermodynamic efficiency of somatic exocytosis also correlated with the thickness of the actin cortex (pale orange) and both subsequent layers of endoplasmic reticulum (gray bars). Group I contains the smallest and more peripheral clusters, which also had the highest thermodynamic efficiency values. These clusters rested at the entrance of the submembrane barrier of endoplasmic reticulum (gray bar adjacent to the plasma membrane). Group II contained clusters embedded within the second layer of endoplasmic reticulum, (more internal gray bar). The transport velocities and efficiencies of these clusters were smaller than those of Group I. Group III (brown) rested in the limits of the actin cortex. These clusters were large, moved with high velocity and their efficiencies were above 1%. Group IV (red) contained large internal clusters that rested inside the actin cortex. Their velocities were smaller than those in Group III. The smaller cluster was the deeper (gray arrowhead). This cluster did not correlate with the rest of group IV for its size and for having a relatively large 1.1 efficiency, in spite of its low 26 nm/s velocity. Its size and position suggest that it was in the assembly process at the time of the stimulation series.

diminished. This can be explained if the flow of the peripheral clusters that precede the larger internal clusters has already diminished the friction forces by displacing the endoplasmic reticulum to the side, thus widening the spaces though which the internal clusters will flow. If so, the pairing of clusters in the same microtubule pathway would favor the transport of the internal larger vesicle clusters. The ATP expenses and thermodynamic efficiency of vesicles in Group IV may stem from their longer traveling distance, part of which is solely covered by the force of kinesin motors. In addition, entering the actin cortex may impose friction forces due to the accommodation of the vesicles within the entanglement of the actin fibers, before the coupling of the myosin motors. Another group that can be predicted contains the small clusters that are assembled and transported from the parikaryon (see Trueta et al., 2012). However, more evidence is required to strengthen this argument.

DISCUSSION

The application of thermodynamic theory to the study of somatic exocytosis predicts how the cytoarchitecture of the vesicle trafficking pathway influences the cost and thermodynamic efficiency of serotonin release. In spite of the common belief that biological systems operate with high efficiency levels, somatic exocytosis is far from an ideal system. Isolated myosin motors moving on actin fibers have efficiencies of 45% (Kjelstrup et al., 2013). Therefore, the low efficiency reported here shows the additive effects of the low efficiency of the motors and the frictive effects imposed by the ultrastructure of the transport pathway. Surprisingly, the thermodynamic efficiency of the simple calcium ATPase immersed in the plasma membrane, depends on the lipid composition of the membrane, with low efficiency values ≤12% (Lervik et al., 2012). Therefore, the values estimated here seem reasonable by considering the number of variables affecting the vesicle transport.

TABLE 3 | Variables contributing to the energy cost and efficiency of somatic exocytosis.

Cluster group	I	II	III	IV
Distance to membrane (μm)	0.6–1.1	1.0–2.3	1.8–2.6	2.7–6.1
Efficiency (0%)	1.0–6.4	0.2–0.6	0.7–2.0	1.1
ATP_{ves}	27–45	11–43	28–260	13–30
Velocity nm/s	45–95	12–30	60–71	35–12
Size of cluster	Small	Intermediate	Large	Larger
Vesicles per cluster	95–169	174–260	229–641 (65)	262–930 (52)
Intracellular structures	Actin cortex, Endoplasmic reticulum 1	Actin cortex, Endoplasmic reticulum 1+2	Actin cortex interface Endoplasmic reticulum 1+2	Cytoplasm Actin cortex interface Endoplasmic reticulum 1+2
Transport system	Kinesin Myosin	Kinesin Myosin	Kinesin Some Myosin	Kinesin Later Myosin

The red numbers correspond to the decreasing slopes of the W distributions of ATP_{ves} expenses and efficiency; the blue numbers correspond to the increasing slopes of the W distribution. Other colors underscore different structures; the tones indicate gradations. The number of vesicles in parenthesis are out of range. The value in Group IV corresponds to the most internal cluster, most likely under formation at the time of the stimulation of exocytosis. Endoplasmic reticulum 1 and 2 correspond to the external and internal layers in ***Figures 9****,* ***10****, respectively.*

It is pertinent to discuss a potential source of error in our measurements. The reports of the rate constant values of the ATP cleavage that fuels the actin and myosin motors have considerable variations depending on the subtype of motor and the experimental conditions of the measurements. Since these variations span over similar ranges 100–300 s^{-1}, we could choose one single value to represent both rate constants for our calculations. The choice for the low 100 s^{-1} value seemed the most accurate for our purposes, because the 18°C temperature at which our experiments were carried out—leeches are cold blooded animals—decreases the rate constants of chemical processes. We have no way to justify that this choice reflects the real values with which the vesicle transport operates in Retzius neurons since their motor subtypes are only superficially known. Antibodies against myosin type IV succeeded to bind myosin in other set of experiments and the contribution of each motor to somatic exocytosis has been blocked pharmacologically (Noguez et al., in preparation), but we still lack estimates of their rate constants. If the rate constant values were higher, the estimate of the efficiency would decrease linearly in proportion to the increase in the rate constant values, as predicted from Equation (12). For example, a 20% increase in the rate constant value from 100 to 125 s^{-1} would reduce the efficiency from 6.0 to 4.8%; likewise, a 200% increase in the rate constant value to 300 s^{-1} -which is near the largest estimate available (Johnson and Taylor, 1978; Apell et al., 1996; Higuchi et al., 1997; De La Cruz et al., 1999; Cross, 2004; De la Cruz and Ostap, 2009)- would reduce the efficiency to 0.2%. In any case, the values would move downwards linearly but not logarithmically. The additional possibility that each motor operates with a different rate constant value cannot be resolved with the tools of our study. The measures of the average velocity of the transport normalize these possible variations without sensitivity to separate them.

A duality has emerged between the structure/function relationship of the release sites and the thermodynamic efficiency of somatic exocytosis. Each slope of the W distribution of the efficiency vs. distance plot is influenced by the interaction of vesicles with a particular building block of the exocytosis process. The same structures that regulate the exocytosis machinery hamper the thermodynamic efficiency of the transport. For example, the endoplasmic reticulum is the fundamental source for intracellular calcium that first activates the vesicle transport in response to high frequency stimulation (Trueta et al., 2004), and later maintains the large-scale exocytosis in response to the activation of serotonin autoreceptors (Leon-Pinzon et al., 2014). In a previous study (Trueta et al., 2004) we have shown that very large vesicle clusters become apposed to the plasma membrane in response to electrical stimulation. This observation implies that they occupy positions that at rest contained endoplasmic reticulum. The endoplasmic reticulum may then be moved aside during transport of the peripheral vesicle cluster. As a positive consequence, the internal cluster that follows the same trajectory may find a cleared pathway to the plasma membrane, with a concomitant saving of energy and reduced heat dissipation.

The actin cortex adds another duality to neurons and excitable endocrine cells by preventing the entry of the vesicle clusters at rest and by propelling vesicles in response to electrical stimulation (Vitale et al., 1995; Lang et al., 2000; Oheim and Stühmer, 2000; Giner et al., 2005; Tobin and Ludwig, 2007; Gutiérrez and Gil, 2011; Torregrosa-Hetland et al., 2011). The third player is mitochondria, the fuel generator that in response to calcium produces ATP that activates the motors. Mitochondria travel along with the vesicle clusters, as suspected because both organelles appear together in electron micrographs after 1 or 20 Hz stimulation. The cargo imposed by the mitochondria may be as large as, or even larger than that imposed by the cluster of vesicles. Therefore, it is most likely that the mobilization of the energy generators along with the vesicle clusters increases the friction forces at the expenses of the thermodynamic efficiency.

A final question from our study concerns its general significance. Somatic exocytosis is part of a wider communication complex system that involves not only the soma, but every part

of the neuron. A remarkably similar mechanism for somato-dendritic exocytosis has been demonstrated in thalamic neurons releasing the peptides vasopressin and oxytocin (Ludwig and Stern, 2015). Moreover, the mobilization of serotonin-containing exocytosis structures in the isolated soma of Raphe neurons from mammals follow similar steps (Sarkar et al., 2012). The soma and dendrites of thalamic neurons releasing peptides contain an actin cortex whose activation promotes the vesicle transport and exocytosis (Tobin and Ludwig, 2007). The ATP expenses and efficiency of exocytosis have not been explored in those or in other types of neurons, but the highly conserved mechanism of somatic and in general extrasynaptic exocytosis (Trueta et al., 2012) suggest that the effects presented here may be of general interest. The dendrites and small axon varicosities, for example release of serotonin through a mechanism similar to that in the soma, although the transport distances of the vesicles are downscaled. The ATP expenses and the thermodynamic efficiency of the vesicle transport for their exocytosis may be scaled accordingly. Such smaller traveling distances may require less ATP and may operate with higher thermodynamic efficiencies.

The mechanism for somatic exocytosis seems to be highly conserved also for most signaling molecules in the central and peripheral nervous system (For review see Trueta and De-Miguel, 2012; Del-Bel and De-Miguel, 2018). Secretory cells follow similar mechanistic rules by transporting vesicles across an actin cortex in response to stimulation (Vitale et al., 1995; Lang et al., 2000; Oheim and Stühmer, 2000; Giner et al., 2005; Gutiérrez and Gil, 2011; Torregrosa-Hetland et al., 2011). These arguments suggest that our results represent general mechanisms in biology.

AUTHOR CONTRIBUTIONS

PN and FD-M designed and carried out the experiments, conducted the analysis and prepared the figures. MR designed the mathematical approach. FD-M wrote the manuscript.

FUNDING

Our work was funded by a Dirección General de Asuntos del Personal Académico (DGAPA) grant IN210317 from the Universidad Nacional Autónoma de México (UNAM) and grant 130031 from the Consejo Nacional de Ciencia y Tecnología (CONACyT) to FD-M. MR was supported by MINECO of the Spanish Government under grant Fis 2015-67837-P. PN is a doctoral student from Programa de Doctorado en Ciencias Biomédicas, Universidad Nacional Autónoma de México (UNAM) and received fellowship 193987 from CONACYT.

ACKNOWLEDGMENTS

We wish to express our gratitude to Mr. Bruno Mendez Ambrosio his excellent technical assistance during this study, and to Mrs. Sara Flores González for her invaluable assistance in the animal and laboratory care. We also express our gratitude to Mr. Francisco Perez for his continuous support in the computer unit and to Mr. Rodlfo Paredes and Dr. Fernando García Hernandez for their invaluable help in the preparation el the electron micrographs and fluorescence microscopy. The animal care facility at our Institute was fundamental for the good conditions of our animal colony. Professor J. G. Nicholls, Dr. Sharlen Moore, and Mrs. Sorel Achouna made critical readings of our manuscript.

Cannabidiol directly targets mitochondria and disturbs calcium homeostasis in acute lymphoblastic leukemia

Miguel Olivas-Aguirre[1], Liliana Torres-López[1], Juan Salvador Valle-Reyes[1], Arturo Hernández-Cruz[2], Igor Pottosin[1] and Oxana Dobrovinskaya[1]

Abstract

Anticancer properties of non-psychoactive cannabinoid cannabidiol (CBD) have been demonstrated on tumors of different histogenesis. Different molecular targets for CBD were proposed, including cannabinoid receptors and some plasma membrane ion channels. Here we have shown that cell lines derived from acute lymphoblastic leukemia of T lineage (T-ALL), but not resting healthy T cells, are highly sensitive to CBD treatment. CBD effect does not depend on cannabinoid receptors or plasma membrane Ca^{2+}-permeable channels. Instead, CBD directly targets mitochondria and alters their capacity to handle Ca^{2+}. At lethal concentrations, CBD causes mitochondrial Ca^{2+} overload, stable mitochondrial transition pore formation and cell death. Our results suggest that CBD is an attractive candidate to be included into chemotherapeutic protocols for T-ALL treatment.

Introduction

Acute lymphoblastic leukemia (ALL) of T lineage (T-ALL) represents a highly aggressive cancer, resistant to chemotherapy and with increased risk of relapse, which occurs in 15% of childhood and 25% of adult ALL cases. In T-ALL, a long-term remission fails in ~20% of children and 40% of adult patients. The prognosis for these groups remains poor, with a 5-year survival rate of <25%[1–5]. Thus, novel therapeutic strategies for the T-ALL treatment are needed.

Cannabinoids are a group of more than 60 structurally related terpenophenolic compounds. Most of them exert their effects through cannabinoid CB1 and CB2 receptors, which belong to the family of G protein-coupled receptors. Lymphocytes mainly express CB2, whereas CB1 are highly expressed in the central nervous system (CNS). Cannabinoids have been used for decades in the field of palliative care. Recently two phytocannabinoids, Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD), were found to possess antitumorigenic properties[6,7]. Contrary to THC, a well-known strong CB1 agonist with psychotropic effect, CBD has a low binding affinity for CB1/2 receptors and is considered as a "non-intoxicating drug"[8]. Molecular targets for CBD are uncertain. Among putative candidates, some members of the TRP channels´ family, orphan cannabinoid receptor GPR55, 5HT and PPARγ receptors have been proposed[6,9].

In the present study we addressed the immediate targets for CBD in leukemic cell lines, derived from T-ALL patients in relapse.

Results

CBD suppresses viability and impairs migration of leukemic T cells

Cytotoxic effect of CBD was first evaluated in leukemic cell lines of different lineages, including T-ALL, B lineage-

derived ALL (B-ALL), and chronic myelogenous leukemia (CML) by means of metabolic assay. T-ALL were the most CBD-sensitive among tested cell lines (Fig. 1a). However, there is an uncertainty in the interpretation of this result, which may be explained by mitochondrial metabolism inhibition, decreased proliferation rate, increased level of cell death, or combination of these effects. Then survival and proliferation of CBD- treated Jurkat cells were evaluated in long-lasting (72 h) cultures by counting live and dead cells CBD at 30–100 μM induced cell death, while at 10 μM the cells remained alive, but did not proliferate. Noteworthy, at low (1 μM) concentration, CBD stimulated the cell proliferation (Fig. 1b, left). Stimulation was also obtained in experiments with a sequential (1 μM every 24 h) CBD administration (Fig. 1b, right). Strikingly, dose dependence was very similar in both cases, irrespective to supposed CBD accumulation during sequential application. Apparently, cell fate was defined already by the first CBD administration.

In additional experiments, cervical and breast cancer cell lines were included for a comparison, because CBD effect on these types of cancer was reported earlier. Again, among 10 cell lines tested, cytotoxic effect of CBD was the most pronounced in T-ALL (Fig. 1c).

We also tested CBD toxicity in non-tumoral cells. Murine bone marrow-derived cell line OP9 displayed high resistance to CBD (Fig. 1d). Strikingly, in contrast to activated human $CD4^+$ T cells, resting $CD4^+$ T cells were relatively insensitive to CBD. Noteworthy, resting $CD4^+$ T cells pretreated with CBD (30 μM, 24 h) were able to respond to activating stimuli. At 72 h of activation their proliferative response was statistically indistinguishable from that of untreated $CD4^+$ cells (Fig. 1e).

The infiltration of lymph nodes and CNS by leukemic cells and formation of a mediastinal mass are tightly related to disease relapse and unfavorable prognosis in T-ALL[10]. Thus, the effect of CBD on the T-ALL cells migration was addressed. Since CXCL12/CXCR4 axis plays a significant role in the dissemination of leukemic cells[11,12], CXCL12 was used as a chemoattractant. Migration of T-ALL cells was shown to be significantly suppressed by 2 h preincubation with 30 μM CBD (Fig. 1f).

CBD (30–100 μM) triggered apoptosis in a part of the cell population (Annexin V - single positive cells). At the same time, loss of plasma membrane integrity was observed in a large cell population as early as at 4 h of treatment (Annexin V/ propidium iodide (PI) – double positive cells), indicating necrosis (Fig. 1g–i).

Transmission electron microscopy (TEM) imaging revealed multiple dramatic changes in cell morphology already after 2 h of CBD (30 μM) exposure (Fig. 2). Two of the most characteristic features were extensive cytoplasmic vacuolation and numerous swollen mitochondria, devoid of cristae. Golgi complex and endoplasmic reticulum (ER) were disassembled, which seems to be related to cytoplasmic vacuolation. Plasma membrane blebbing and apoptotic bodies (ApoBDs) formation were detected. The observed morphological changes pointed out to a complex mechanism, with both apoptotic and necrotic symptoms. In addition, double membrane vacuoles, containing degrading material (autophagosomes), were much more numerous in CBD-treated cells as compared to control.

Sublethal CBD concentrations activate autophagy in leukemic cells

Autophagy is a catabolic cellular process, representing an important strategy to ensure cell homeostasis by the elimination of defunct organelles in both physiological and pathological conditions[13]. Basal levels of autophagy serve a housekeeping function, whereas stress stimulates autophagy. CBD was shown to cause cell death by inducing a crosstalk between apoptosis and autophagy in breast cancer[14]. To reveal the ability of CBD to induce autophagy in T-ALL, LC3-I to LC3-II conversion and LC3-II turnover were monitored by immunoblotting. In the course of autophagy, microtubule-associated protein LC3-I first conjugates with phosphatidylethanolamine, forming LC3-II, followed by the LC3-II translocation to autophagosomes. An increased LC3-II level is considered as an indicator of the autophagy, but LC3-II is degraded by lysosomal proteases after autophagosome-lysosome fusion. Chloroquine (CQ) is known to prevent autophagosome-lysosome fusion and to inhibit the LC3-II degradation, thus LC3-II is accumulated in the presence of CQ[15,16]. Western blot analysis of LC3 variants demonstrated that sublethal CBD concentration (10 μM) effectively induced autophagy in Jurkat cells (Fig. 3a, b), since LC3-II level was higher in cells treated with both CBD (10 μM) and CQ (20 μM) when compared to either 20 μM CQ (basal autophagy) or 10 μM CBD treatment alone. Note that accumulation of LC3-II was diminished by its degradation during the autophagic flux in the samples without CQ.

Proceeding of the autophagic flux at the single-cell level was monitored using mCherry-GFP-LC3 expressing Jurkat cells. The mCherry-GFP-LC3 experimental strategy is based on the fact that GFP is quenched at acidic pH, found in the autophagolysosome, while mCherry is not. Accordingly, enhancement of the mCherry/GFP ratio sensitive to CQ indicates the autophagolysosome formation[17]. Figure 3c shows representative images from the experiment, in which Jurkat GFP-mCherry-LC3 cells were incubated with CBD (10 and 30 μM) and CQ, alone or in combination. High mCherry/GFP ratio, efficiently equalized by CQ, was observed in samples, treated with 10 μM CBD (Fig. 3d, e), evidencing a throughput of the autophagic pathway. In samples treated with 30 μM CBD this

Fig. 1 CBD effect on viability in different cancer cell lines. a Cell viability, evaluated by resazurin-based metabolic assay, as a function of CBD concentration in human leukemic cell lines of different lineages at 24 h of treatment. Cell lines derived from T-ALL (Jurkat, MOLT-3, and CEM), B-ALL (RS4;11 and Reh) and CML (K562) were tested. Data (resorufin fluorescence intensity, arbitrary units) were normalized to the vehicle-treated control and shown as mean ± SD ($n = 8$; *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$; ns, not significant; one-way ANOVA). **b** Live cell count (trypan blue exclusion test) in long-lasting Jurkat cells cultures exposed to different CBD concentrations (0–100 μM). Left: cell count at 72 h after single CBD administration; right: fresh CBD was added, 50% of medium volume was changed and cells were counted every 24 h. Data are normalized to the initial point (0 h) and shown as mean ± SD ($n = 3$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, one-way ANOVA test). **c** Cell viability was evaluated by resazurin-based metabolic assay at 24 h of treatment with CBD (30 μM) in human tumor cell lines of different histogenesis, including CML (K562), B-ALL (Reh and RS4;11), T-ALL (CEM, MOLT-3, and Jurkat), cervical cancer (SiHa and HeLa), and breast cancer (MCF7-7 and MDA-MB-231). Data (resorufin fluorescence intensity) were normalized to vehicle-treated control and reported as mean ± SD ($n = 8$ of four independent experiments; (*$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, Student's *t*-test). **d** Cell viability was evaluated by resazurin-based metabolic assay at 24 h of treatment with CBD (30 μM) in non-cancerous cells. Human $CD4^+$ cells were activated with anti-CD3/CD28 antibodies as described in Materials and Methods section. Data (resorufin fluorescence intensity) are normalized to the vehicle-treated control and reported as mean ± SD ($n = 8$ in at least three independent experiments; *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$; Student's *t*-test). **e** After preincubation with CBD (30 μM, 24 h), non-cancerous $CD4^+$ cells were activated by anti-CD3/antiCD28 antibodies. Cell viability was evaluated by resazurin-based metabolic assay every 24 h. Data (resorufin fluorescence intensity) were normalized to 0 h time point and shown as mean ± SD ($n = 8$ in at least three independent experiments). Statistical comparison between control and pretreated samples was undertaken at each time point (*$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, Student's *t*-test). **f** Migration capacity of Jurkat cells pretreated with CBD (10 or 30 μM, 2 h) was evaluated by chemotactic migration assay, using a Transwell system. Cells were allowed to migrate for 4 h, CXCL12 was used as a chemoattractant. The percentage of migrated cells was determined by cells count in the lower chamber. Data are mean ± SD ($n = 4$). Statistical comparison was made with respect to positive control (CXCL12) (*$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, one-way ANOVA test). **g**–**i** Cell death was evaluation by flow cytometry (**g**, **h**) and fluorescent microscopy (**I**) in Jurkat cells treated with different concentrations of CBD using Annexin V-AF488/PI double staining. Representative dot plots (2, 4, and 6 h) and images (12 h) are shown in **g** and **i**, correspondingly. Scale bar: 20 μm. In every dot plot lower left quadrant represents Annexin V^-PI^- (DN) live cells, in the lower right quadrant are Annexin V^+PI^- (early apoptotic) cells, Annexin V^-PI^+ (primary necrotic) cells are in the upper left quadrant, whereas the double-stained population Annexin V^+PI^+ (DP) in the upper right quadrant represents dead cells, which may include necrotic and late apoptotic ones. Statistical analysis of flow cytometry data is given in **h** ($n = 3$; *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, one-way ANOVA test)

ratio was low (Fig. 3d, e). However, the number of autophagosomes was increased at early times after CBD administration (30 μM), as it was revealed by an enhanced level of both GFP^+ and $mCherry^+$ puncta (Fig. 3f, g). These data may be explained by a truncation of basal, and, possibly, also CBD-induced autophagy at late phases in damaged cells.

CBD causes mitochondrial damage and induces cytochrome C release

Dissipation of the mitochondrial transmembrane potential (ΔΨm) is a hallmark of the mitochondrial permeability transition (MPT) - driven necrosis as well as of intrinsic apoptosis. It involves an irreversible mitochondrial outer membrane permeabilization and a release of various pro-apoptotic factors, including cytochrome C (Cyt-C), to the cytosol. In the cytosol, Cyt-C contributes to the apoptosome formation, with a consequent activation of the initiator caspase 9, which cleaves and activates executioner caspases[18].

We monitored ΔΨm in Jurkat cells double-stained with green fluorescent dye MtGreen, which covalently binds to mitochondrial matrix proteins, and tetramethylrhodamine ethyl ester (TMRE), a cationic fluorescent dye that is readily sequestered by energized mitochondria (Fig. 4a). When exposed to CBD (30 μM), the intensity of TMRE fluorescence, in contrast to that of MtGreen, was gradually decreased within the first 10 min of treatment, indicating a rapid ΔΨm loss (Fig. 4a, Supplementary Movie 1). The loss of TMRE fluorescence was dose-dependent (Fig. 4b). To monitor Cyt-C release from mitochondria in a response to CBD treatment, Jurkat cells were transfected with EYFP-Cyt-C. In untreated cells, Cyt-C localization was restricted to mitochondria, as confirmed by punctate distribution of EYFP-Cyt-C staining and its colocalization with TMRE (Fig. 4c, d). After treatment with CBD (30 μM), EYFP-Cyt-C distribution in the cytoplasm of treated cells became more diffuse (Fig. 4e), indicating Cyt-C release from mitochondria, observed as early as within the first 20 min of treatment (Fig. 4f). Concomitantly, cell volume was significantly reduced, as it was previously reported for CBD-treated Jurkat cells by others[19]. Jurkat cells, exposed to CBD, exhibited an enhanced activity of caspases 9 and 3, confirming the triggering of intrinsic apoptotic pathway (Fig. 4g).

Collapse of the ΔΨm is frequently associated with the induction of the mitochondrial permeability transition pore (mPTP), a wide channel formed through inner and outer mitochondrial membranes. The formation of mPTP is potently blocked by cyclosporine A (CsA)[20]. Two distinct mechanisms, leading to the Cyt-C release from mitochondria were suggested: one is related to the mPTP and inhibited by CsA and another is Bax-dependent but CsA-insensitive[21,22]. In our experiments both CBD-induced phenomena, Cyt-C release from mitochondria and cell shrinkage were inhibited by CsA (Fig. 4h). mPTP opening is associated with the oxidative stress[20]. CBD-induced reactive oxygen species (ROS) overproduction

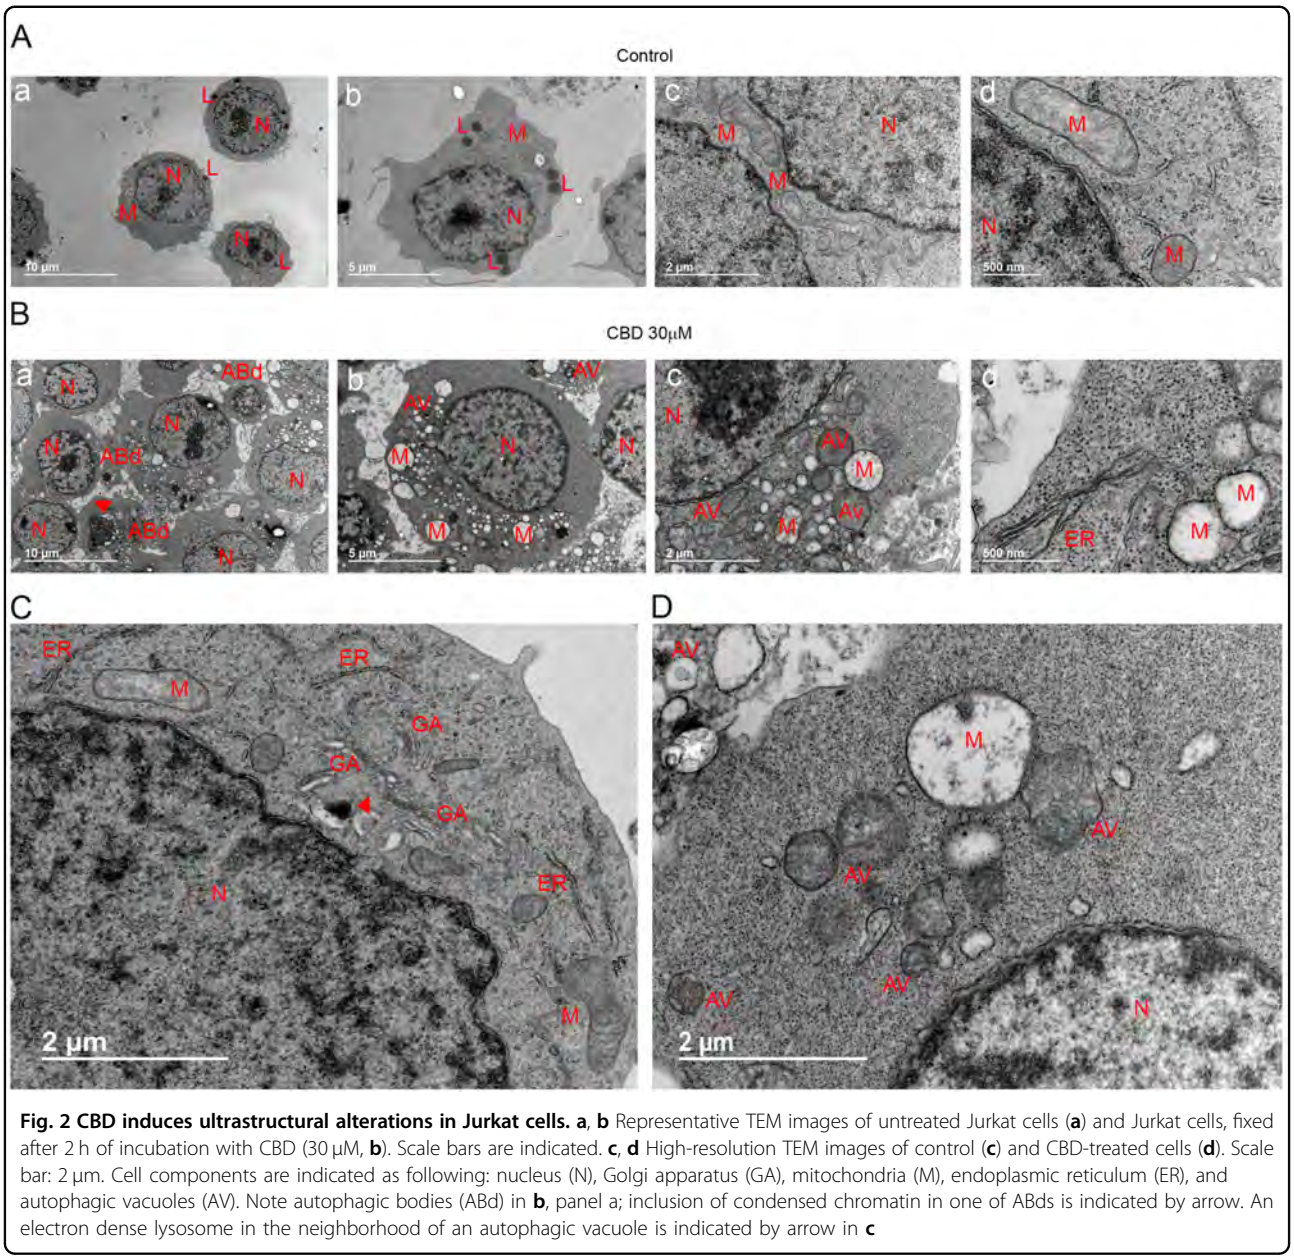

Fig. 2 CBD induces ultrastructural alterations in Jurkat cells. a, **b** Representative TEM images of untreated Jurkat cells (**a**) and Jurkat cells, fixed after 2 h of incubation with CBD (30 μM, **b**). Scale bars are indicated. **c**, **d** High-resolution TEM images of control (**c**) and CBD-treated cells (**d**). Scale bar: 2 μm. Cell components are indicated as following: nucleus (N), Golgi apparatus (GA), mitochondria (M), endoplasmic reticulum (ER), and autophagic vacuoles (AV). Note autophagic bodies (ABd) in **b**, panel a; inclusion of condensed chromatin in one of ABds is indicated by arrow. An electron dense lysosome in the neighborhood of an autophagic vacuole is indicated by arrow in **c**

was previously reported in different cell models[14,23]. As shown in the Fig. 4i, CBD within few minutes provoked a dose-dependent increase in ROS generation.

CBD-induced mitochondrial Ca^{2+} overload is responsible for the formation of mPTP

CBD-mediated elevation of the cytosolic free Ca^{2+} ($[Ca^{2+}]_i$) has been observed in several cancer and non-cancerous cells[24,25]. Calcium signal signature defines the cell fate, survival, or death scenarios[26]. Elevated intramitochondrial Ca^{2+} ($[Ca^{2+}]_m$) is a prerequisite for the mPTP formation[20]. It is generally assumed that $[Ca^{2+}]_m$ increase is triggered by an increase of $[Ca^{2+}]_i$. In many cases, Ca^{2+} source can be ER, whose membranes come to a very close proximity with the outer mitochondrial membrane (OMM)[27].

CBD promoted a dose-dependent elevation of $[Ca^{2+}]_i$ from the resting level of 100 nM up to 300 nM, both in T-ALL cells (Fig. 5a–d) and in healthy lymphocytes (Fig. 5e, f). Pharmacological analysis revealed that neither CB1/2 nor GPR55 receptors were involved in the CBD-induced $[Ca^{2+}]_i$ rise. Importantly, CBD-induced $[Ca^{2+}]_i$ rise was neither dependent on Ca^{2+} permeable channels in plasma membrane nor on extracellular Ca^{2+} (Fig. 5g–j). Thus, the source of CBD-induced $[Ca^{2+}]_i$ rise were intracellular Ca^{2+} stores. Blockage of plasma membrane

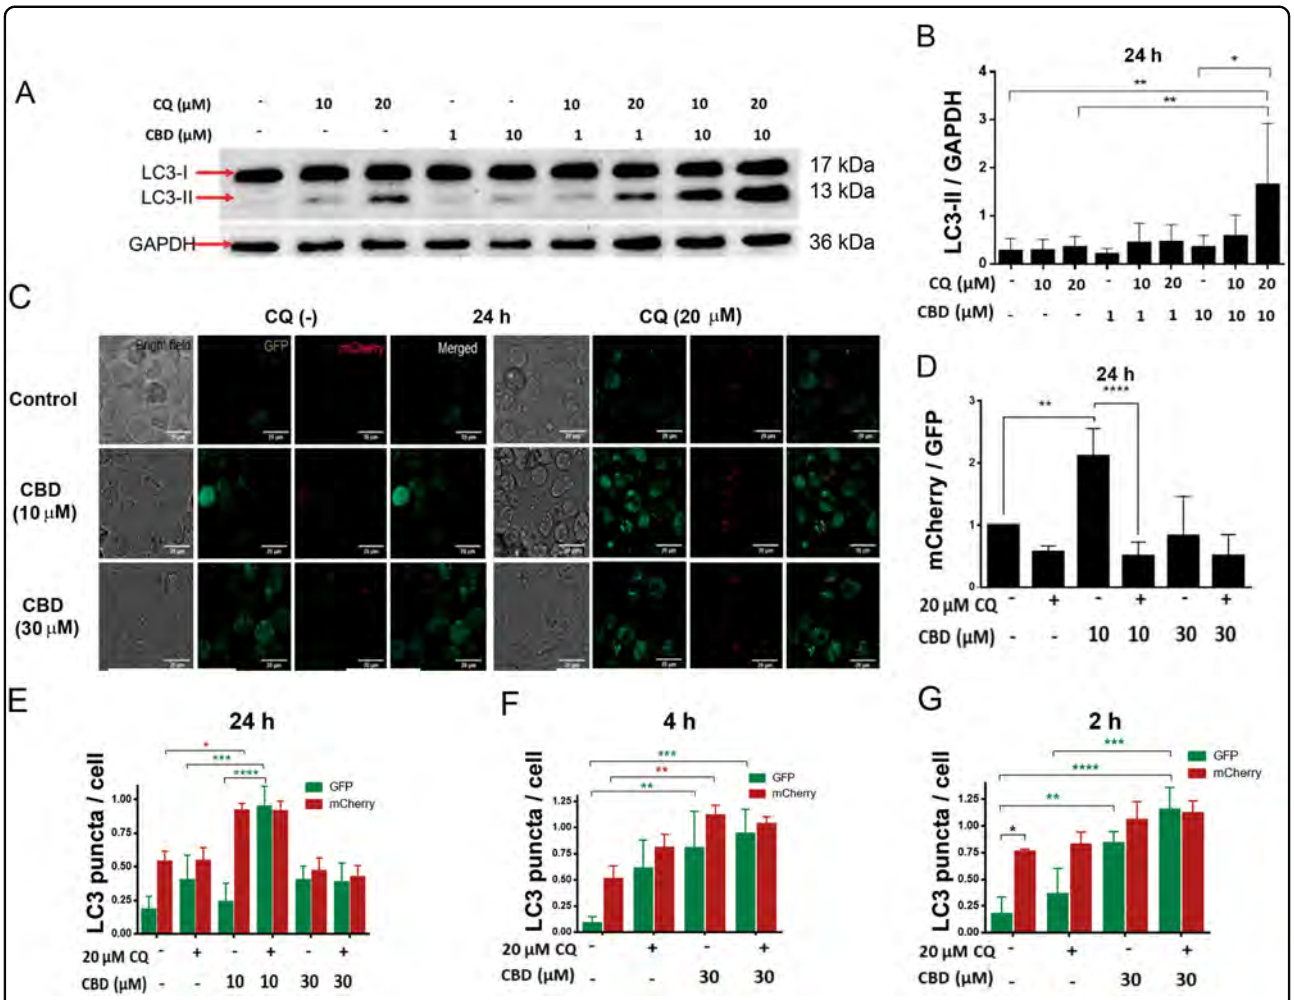

Fig. 3 CBD induces autophagy in Jurkat cells. a Representative Western blot of LC3-I/II protein expression in vehicle- or CBD- treated Jurkat cells (24 h). CQ was used to prevent the fusion of autophagosomes with lysosomes, where LC3-II is otherwise degraded. The concentrations of CQ and CBD are indicated. GAPDH was used as a loading control. Note that in absence of CQ the accumulation of LC3-II was observed neither in control (basal autophagy) nor in CBD-treated samples. In the presence of CQ LC3-II is accumulated and corresponding bands are more intense. **b** LC3-II/GAPDH density ratio in samples, obtained from Jurkat cells, grown in different conditions (as in example shown in **a**). Data are mean ± SD ($n \geq 4$; *$p < 0.05$; **$p < 0.01$). Control and different treatments were compared, using one-way ANOVA with Tukey's multiple comparisons tests. **c** Confocal microscopy images of mCherry-GFP Jurkat cells, incubated over 24 h at different conditions as indicated. CQ was used to prevent the fusion of autophagosomes with lysosomes during the autophagy flux. Note that the inhibition of autophagolysosomes formation by CQ results in prevention of GFP quenching in the acidic environment within a lysosome. **d** mCherry/GFP puncta ratio was calculated from confocal images of Jurkat cells as shown in **c**, incubated at different conditions. Quantification of the average number of mCherry and GFP puncta was performed using ImageJ "Particle analysis" tool. For each condition, 3 fields (10–20 cells/ field) were analyzed. Data from three independent experiments were averaged and are shown as mean ± SD. One-way ANOVA with Tukey's post-hoc tests were employed to compare statistical significance between groups (**$p < 0.01$; ****$p < 0.0001$). **e**–**g** LC3 puncta counts, where GFP and mCherry puncta were counted and analyzed separately in Jurkat cells in control samples or in samples treated with different combinations of CBD and CQ, and incubated during 24 h (**e**), 4 h (**f**) or 2 h (**g**). Quantification of the average number of mCherry and GFP puncta was performed using ImageJ "Particle analysis" tool. For each condition, 3 fields (10–20 cells/field) were analyzed. Data from four independent experiments were averaged and are shown as mean ± SD. Significance is depicted in green, when comparing GFP puncta between groups and in red for mCherry puncta comparison. Significance in black represents differences between GFP/mCherry puncta ($n \geq 4$, *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$; two-way ANOVA with Tukey's post-hoc tests)

Ca^{2+} permeable channels by Gd^{3+} and ruthenium red (RR) did not protect leukemic cells against CBD (Fig. 5i, j).

To monitor $[Ca^{2+}]_m$, Jurkat cells were transfected with a Ca^{2+}-sensitive, mitochondrial targeted indicator CEPIA3mt (Kd = 11 μM)[28]. Specific mitochondrial targeting of CEPIA3mt was confirmed by its colocalization with TMRE (Fig. 6a). Concurrent measurement of $[Ca^{2+}]_i$ were conducted with cells loaded with a conventional cytosolic ratiometric dye Fura-2. CBD-induced $[Ca^{2+}]_i$ increase was preceded by $[Ca^{2+}]_m$ transient (Fig. 6b). Peak value for

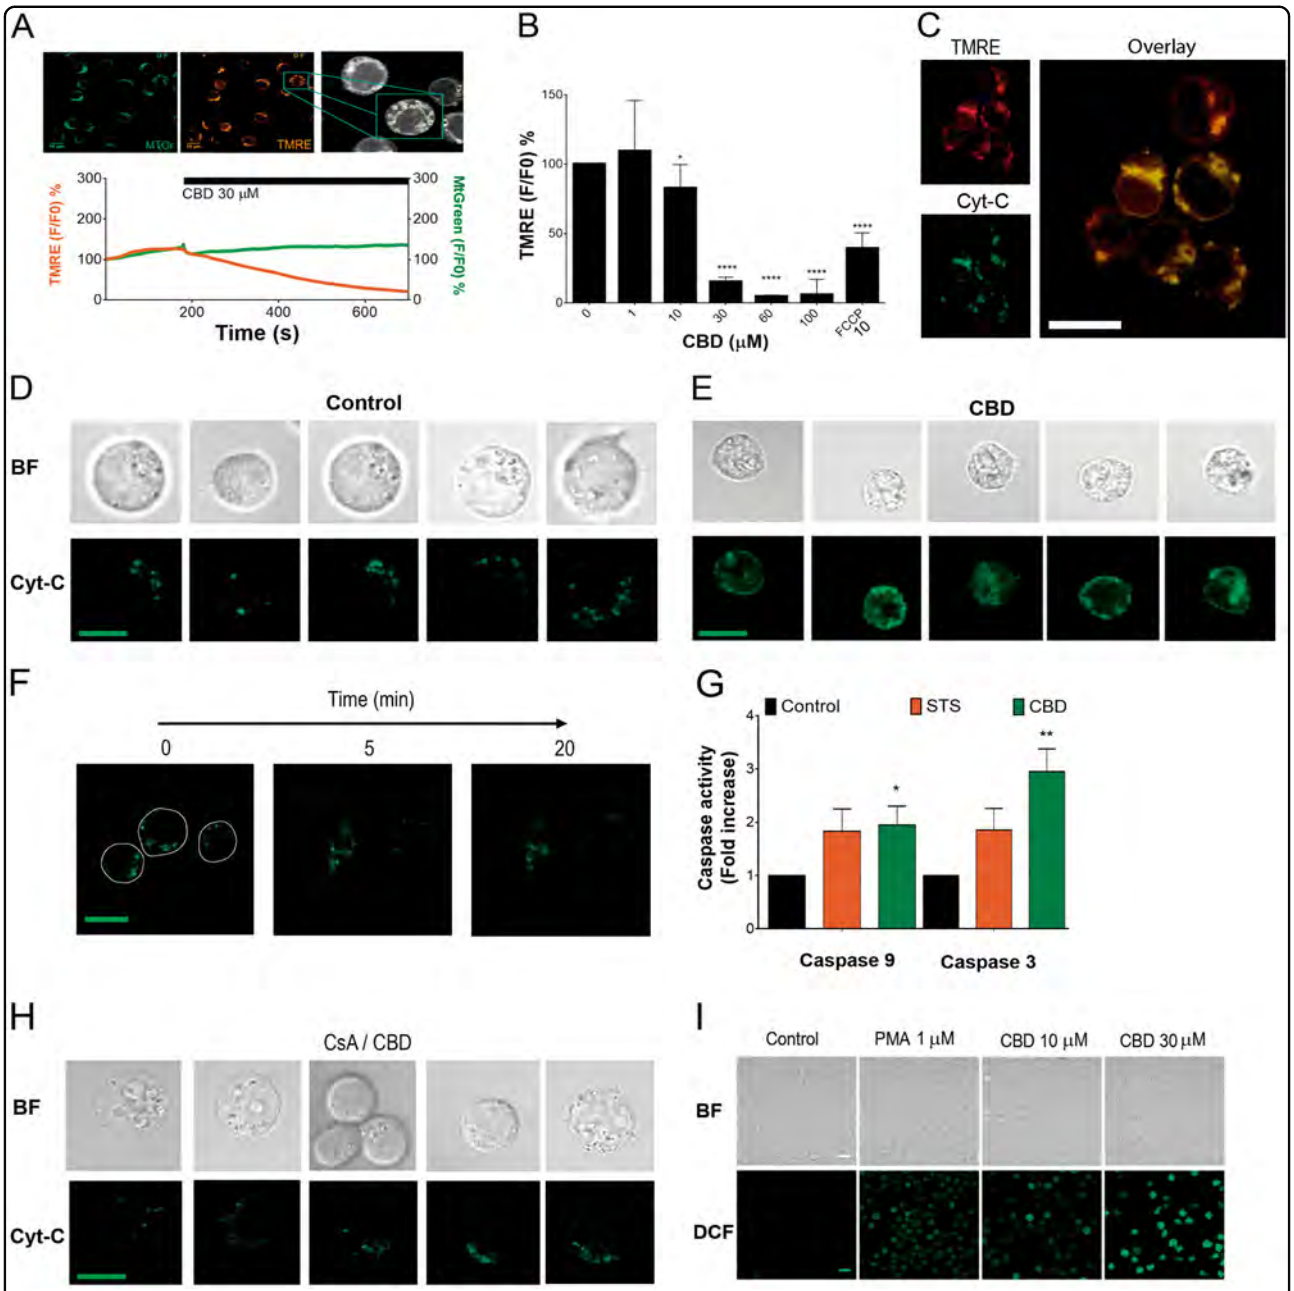

Fig. 4 CBD impairs mitochondrial function, induces Cyt-C liberation and ROS production. a Monitoring of Δψm loss in CBD-treated leukemic cells. Jurkat cells were double-stained with MtGreen and TMRE, mitochondria (ROI) were selected (upper panel) and intensity of fluorescence was monitored by confocal microscopy after CBD (30 μM) administration (lower panel, $n = 36$; see also Supplementary movie 1). **b** Intensity of TMRE fluorescence as an indicator of Δψm in Jurkat cells, treated with different concentrations of CBD (0–100 μM) during 10 min. FCCP (10 μM) was used as a positive control. Data are mean ± SD ($n = 8$ in three independent experiments). Statistical comparison with control was performed by means of one-way ANOVA test (*$p < 0.05$; ****$p < 0.0001$). **c** EYFP-Cyt-C is localized in mitochondria of Jurkat cells after 12 h of transfection. EYFP-Cyt-C and TMRE fluorescence are colocalized (200 nM TMRE, 200 ng EYFP-Cyt-C, pseudocolor). Images were acquired by confocal microscopy at 12 h after transfection, scale bar: 10 μm. **d** Representative images of five Jurkat cells, transfected with EYFP-Cyt-C (as in **c**). Dense green fluorescent puncta (pseudocolor) reflect Cyt-C localization in intact mitochondria. Scale bar: 10 μm. **e** Representative images of five Jurkat cells, transfected with EYFP-Cyt-C (as in **c**) and treated with CBD (30 μM, 1 h). Cyt-C was released from mitochondria as evidenced by a diffuse EYFP-CytC distribution. Scale bar: 10 μm. **f** EYFP-Cyt-C distribution in Jurkat cells, expressing EYFP-Cyt-C, at 0, 5, and 20 min with CBD (30 μM). Scale bar: 10 μm. **g** Caspase-9 and caspase-3 activity in vehicle- and CBD- treated (30 μM, 12 h) Jurkat cells. Staurosporine (STS, 5 μM) was used as a positive control. After incubation, cells were lysed, and caspase activity was determined by colorimetric assay (BioVision). Fold increase in activity compared to control was plotted as mean ± SE (four independent experiments). One-way ANOVA test was performed to compare CBD-treated to control group (*$p < 0.05$; **$p < 0.01$). **h** Pretreatment with mPTP inhibitor CsA (10 μM) prevents Cyt-C release, induced by CBD (30 μM; 1 h). Compare these images with Fig. 4d, e (vehicle- and CBD-treated cells) and note the protective effect of CsA. Scale bar: 10 μm. **i** ROS production as evaluated by fluorescent microscopy in DCF-loaded (2 μM) Jurkat cells. CBD effect on ROS production was monitored after 1 h of incubation. PMA (1 μM) was used as a positive control

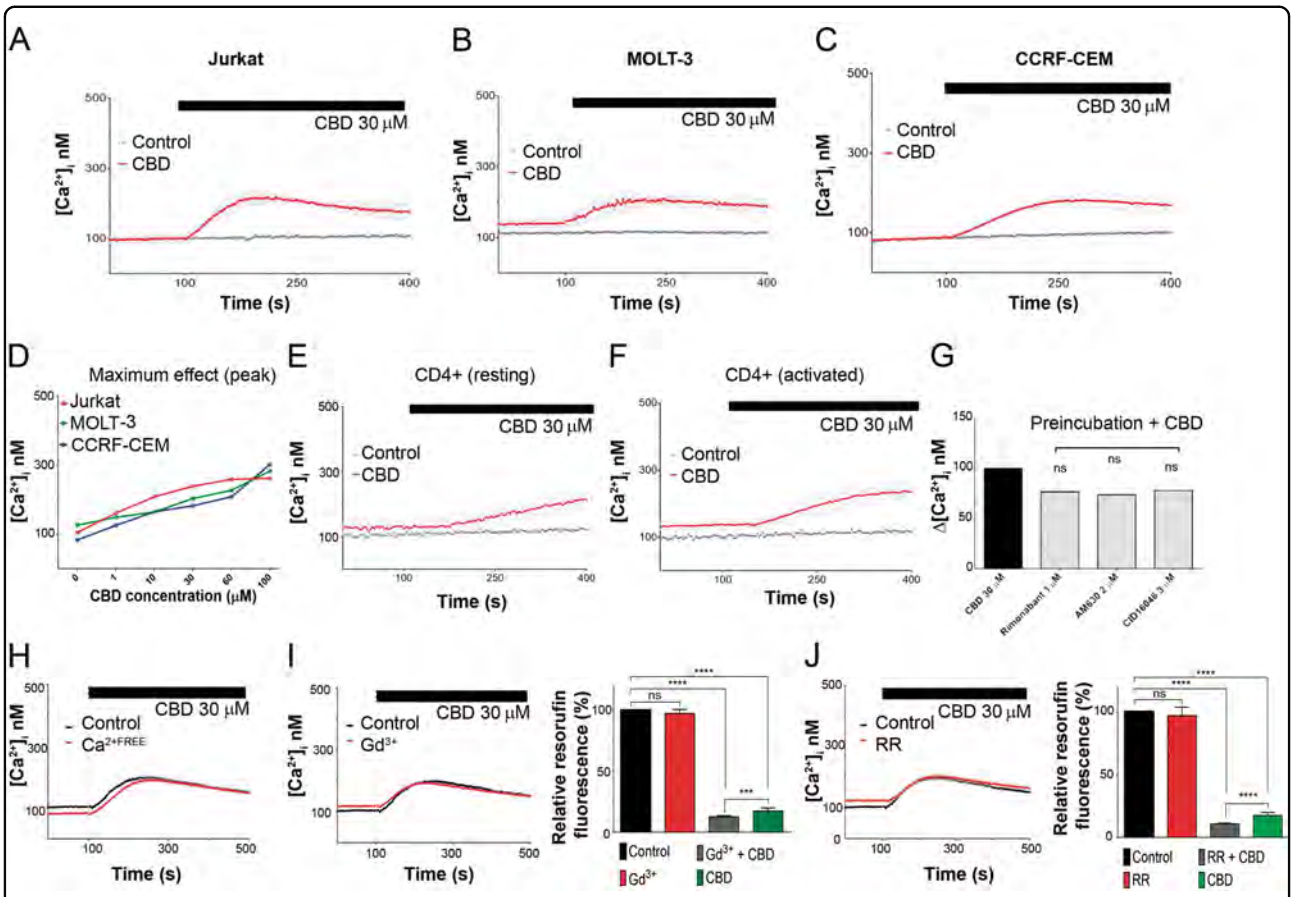

Fig. 5 CBD induces cytosolic Ca^{2+} rise in human T-ALL cell lines and non-cancerous T cells. a–c $[Ca^{2+}]_i$ monitoring in leukemic cells, treated with CBD. Traces represent the mean ± SD of at least six samples from independent experiments. **d** Dose dependence of peak $[Ca^{2+}]_i$ values in T-ALL cell lines, exposed to CBD. Data are mean ± SD for at least six samples from independent experiments. **e**, **f** $[Ca^{2+}]_i$ monitoring in non-cancerous T cells in resting (**e**) and activated (**f**) states. Traces represent the mean ± SD of at least six samples from independent experiments. **g** Pharmacological analysis of $[Ca^{2+}]_i$ rise in response to CBD. Before CBD treatment, cells were preincubated over 20 min with either CB1 antagonist, rimonabant (1 μM), CB2 inverse agonist, AM630 (2 μM), or GPR55 antagonist, CID16020046 (3 μM); values Δ $[Ca^{2+}]_i$ were obtained by subtracting the $[Ca^{2+}]_i$ baseline level from $[Ca^{2+}]_i$ maximum increase. Data are mean ± SD of at least 6 samples from independent experiments. **h** $[Ca^{2+}]_i$ monitoring in Jurkat cells, suspended in Ca^{2+}-free HBSS. Gd^{3+} (1 μM) or RR (1 μM) were added to Jurkat cells 20 min before the $[Ca^{2+}]_i$ measurement. **i**, **j** left: traces represent the mean ± SD of at least six samples from independent experiments. **i**, **j** right: data (resorufin fluorescence intensity) were normalized to vehicle-treated control and reported as mean ± SD ($n = 8$ of four independent experiments (****$p < 0.0001$, Student's *t*-test)

$[Ca^{2+}]_m$ signal was ~5 μM, basing on the titration curve for CEPIA3mt[28]. Notably, CBD-induced $[Ca^{2+}]_m$ transient occurred at time when $[Ca^{2+}]_i$ remained at the resting level. Thus, causal relation between CBD-induced $[Ca^{2+}]_m$ and $[Ca^{2+}]_i$ increases was further addressed. Jurkat cells highly express functional H1 histamine receptors and histamine treatment was proved to induce the inositol 1,4,5-trisphosphate receptor (IP_3R)-dependent Ca^{2+} release from the ER for this cell model[29]. Artificial depletion of the ER Ca^{2+} by histamine or thapsigargin and block of the ER Ca^{2+} release via IP_3R channels by 2-aminoethoxydiphenyl borate (2-APB) abolished the CBD-induced $[Ca^{2+}]_i$ increase. Thus, ER was the source of the CBD-induced $[Ca^{2+}]_i$ rise (Fig. 6c, d, f). CBD-induced $[Ca^{2+}]_m$ rise was potentiated by ER Ca^{2+} release (and concomitant cytosolic Ca^{2+} rise) and reduced upon the conditions, when ER Ca^{2+} release was blocked (Fig. 6c–e). Thus, ER Ca^{2+} release partly fuels the CBD-induced $[Ca^{2+}]_m$ rise. However, note that $[Ca^{2+}]_m$ rise was switched first upon CBD administration, not by Ca^{2+} release from the ER per se. Mitochondria act as a sink for Ca^{2+}, artificially released from the ER prior to CBD application as evidenced by an abrupt decrease of $[Ca^{2+}]_i$ in a response to CBD (Fig. 6c, f).

Ca^{2+} uptake from the cytosol to mitochondria is mediated by voltage-dependent anion channel (VDAC) in the OMM and the mitochondrial Ca^{2+} uniporter (MCU)

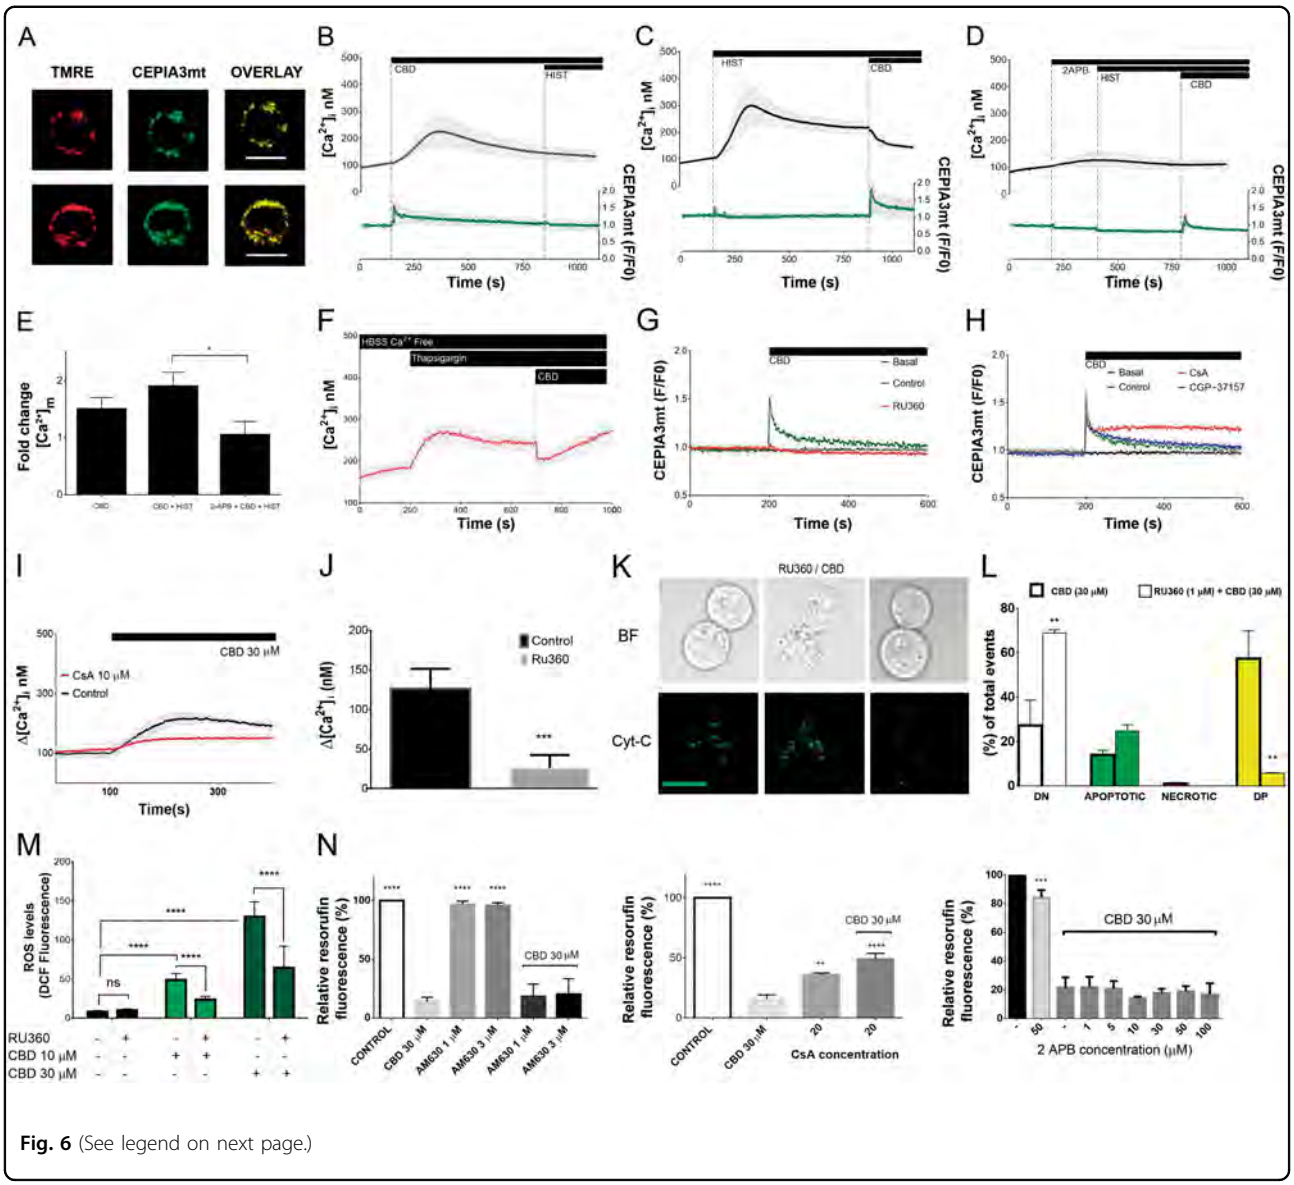

Fig. 6 (See legend on next page.)

in the inner mitochondrial membrane (IMM). In our experiments, CBD-induced $[Ca^{2+}]_m$ rise was completely suppressed by a permeable MCU blocker Ru360 (Fig. 6g), but not significantly affected by CGP-37157, the inhibitor of the inner membrane Na^+/Ca^{2+} exchanger, NCX (Fig. 6h). Specific inhibitor of mPTP, CsA, stabilized $[Ca^{2+}]_m$ at a high level (Fig. 6h). Of special note, the inhibition of mitochondrial Ca^{2+} overload and of mPTP by Ru360 and CsA, respectively, precluded the cytosolic Ca^{2+} rise (Fig. 6i–j). Thus, the ER Ca^{2+} release is causally dependent on the mitochondrial response. Collectively, our $[Ca^{2+}]_m$ data imply that CBD-induced Ca^{2+} uptake into the mitochondrial matrix via MCU caused a rapid $[Ca^{2+}]_m$ overload, which induced the mPTP opening and a subsequent $[Ca^{2+}]_m$ release. Thus, mitochondria appear to be a primary target for CBD and mPTP opening is required for the induction of Ca^{2+} release from the ER. MCU inhibitor Ru360 prevented CBD-induced ROS formation, Cyt-C release and cell death as revealed by Annexin V/PI assay (Fig. 6k–m). The last result is very essential, because it links mitochondrial Ca^{2+} overload to cell death. Remarkably, CsA, albeit per se possessing immunosuppressing activity, partially improved cell viability of CBD-treated cells, while CB2 inverse agonist AM630 and 2-APB were inefficient (Fig. 6n).

CBD interacts directly with mitochondria to promote the organelle dysfunction

To verify the conclusion that mitochondria are direct targets for CBD action, mitochondria were freshly isolated

(see figure on previous page)
Fig. 6 CBD directly induces mitochondrial Ca^{2+} overload and mPTP opening. a CEPIA3mt fluorescence is colocalized with mitochondrial marker TMRE in Jurkat cells. Scale bar: 10 µm. **b**–**d** Concurrent monitoring of $[Ca^{2+}]_i$ and $[Ca^{2+}]_m$ in Jurkat cells. $[Ca^{2+}]_i$ and $[Ca^{2+}]_m$ changes were evaluated with Fura-2 (2 µM) and CEPIA3mt, respectively. Note that cells were loaded either with Fura-2 or with CEPIA3mt; individual time courses for Fura-2 and CEPIA3mt, were synchronized with respect to the timepoint of CBD addition and averaged $[Ca^{2+}]_i$ and $[Ca^{2+}]_m$ responses were plotted at the upper and lower panels, respectively. CBD (30 µM), histamine (10 µM) and membrane-permeable IP_3R blocker 2 APB (50 µM µM) were added as indicated. Traces are mean ± SD of at least six samples from independent experiments. **e** Peak values for $[Ca^{2+}]_m$ changes, induced by CBD, from the experiments shown in **b**–**d**, with a variable level of $[Ca^{2+}]_i$ due to manipulations with Ca^{2+} release from the ER. Bars represent mean ± SD of at least six samples from independent experiments. One-way ANOVA test (*$p < 0.05$). **f** $[Ca^{2+}]_i$ monitoring in Jurkat cells, loaded with Fura-2 (2 µM). ER Ca^{2+} was depleted by thapsigargin (1 µM). Experiments were performed in Ca^{2+}-free medium (HBSS). Addition of CBD causes an abrupt decrease of $[Ca^{2+}]_i$ (*cf* with **c**). Traces are mean ± SD of at least three samples from independent experiments. **g**, **h** $[Ca^{2+}]_m$ monitoring in Jurkat cells, transfected with CEPIA3mt. CBD (30 µM) was added as indicated. When indicated, cells were preincubated over 20 min with either MCU blocker RU360 (1 µM), mPTP inhibitor CsA (10 µM), or inhibitor of mitochondrial Na^+/Ca^{2+} exchanger NCLX CGP37157 (1 µM). Traces are mean ± SD of at least six samples from independent experiments. **i** $[Ca^{2+}]_i$ monitoring in Jurkat cells, loaded with Fura-2 (2 µM). CBD (30 µM) was added as indicated. Cells were preincubated during 20 min with vehicle or CsA (10 µM), specific inhibitor of the mPTP. Values Δ $[Ca^{2+}]_i$ were obtained by subtracting the $[Ca^{2+}]_i$ baseline level from the peak $[Ca^{2+}]_i$. Traces are ±SD of at least six samples from independent experiments. **j** Cytosolic Ca^{2+} response to CBD (30 µM) in Jurkat cells was abolished by a preincubation with the MCU blocker Ru360 (1 µM) over 20 min. Values Δ $[Ca^{2+}]_i$ were obtained by subtracting the $[Ca^{2+}]_i$ baseline level from peak $[Ca^{2+}]_i$. Data are mean ± SD of a minimum of six independent experiments (**$p < 0.01$; ***$p < 0.001$; Student's *t*-test). **k** Representative images of Jurkat cells, transfected with EYFP-Cyt-C, pretreated with RU360 (1 µM, 20 min), and subsequently treated with CBD (30 µM, 1 h). Discrete green fluorescent puncta (pseudocolor) represent Cyt-C localization in intact mitochondria whereas Cyt-C release from mitochondria is evidenced by a more diffuse EYFP-Cyt-C distribution. Compare these images with Fig. 4d, **e** (vehicle- and CBD-treated cells) and note the protective effect of RU360. Scale bar: 10 µm. **l** MCU blocker RU360 effectively prevents CBD-induced cell death in Jurkat cells. Cell death was evaluated by flow cytometry, using Annexin V-AF488/PI double staining. Cells were preincubated with vehicle or RU360 (1 µM, 2 min), and then treated with CBD (30 µM, 6 h). Data of three independent experiments are present (**$p < 0.01$, one-way ANOVA test). **m** ROS levels were evaluated by DCF fluorescence intensity. Cells were either only treated with CBD (10 or 30 µM, 1 h, light and dark green bars, respectively) or additionally pretreated with RU360 (1 µM, 20 min). In all, 50 cells from at least three independent experiments were analyzed for each condition. Data are mean of ±SD. Statistic comparisons between control and CBD-treated samples, or between RU360-pretreated and non-pretreated samples were performed. ****$p < 0.0001$, one-way ANOVA. **n** Effects of the CB2 inverse agonist, AM630 ($n = 8$), mPTP inhibitor CsA ($n = 6$) and membrane-permeable IP_3R blocker 2APB ($n = 6$) on the viability of Jurkat cells, treated with CBD. Cell viability was evaluated by resazurin-based metabolic assay (24 h). Data are mean ± SD. Statistical comparison was made in relation to CBD-treated samples; *$p < 0.05$; **$p < 0.01$; ***$p < 0.001$; ****$p < 0.0001$, one-way ANOVA

from Jurkat cells. Mitochondria were stained with MtGreen and fluorescent Ca^{2+} indicator Rhod-2, and evaluated by flow cytometry. High percentage of double-stained particles evidenced high purity of mitochondria population (Fig. 7a). Upon exposure to 30 µM CBD isolated mitochondria exhibited $[Ca^{2+}]_m$ increase at external free Ca^{2+} of 100 nM, equal to the resting cytosolic Ca^{2+} level (Fig. 7b). The response of high affinity Ca^{2+} indicator Rhod-2 (Kd ~ 0.6 µM) was saturated, implying that free $[Ca^{2+}]_m$ level was above 1 µM for a long time. Incubation of isolated mitochondria with CBD over 10 min produced a strong dose-dependent decrease of ΔΨm (Fig. 7c), similar to that in whole cells (Fig. 4b).

CBD binding to VDAC: in silico evidences

In some cell models CBD can induce cell death via direct interaction with VDAC, promoting its closure to a conformational substate[30]. This substate possesses a reduced capacity to transport metabolites and increased Ca^{2+} permeability[31]. We performed in silico analysis of VDAC- CBD interactions. VDAC surface and N-terminus were tested for CBD binding. Among the main VDAC cavities, β9–12 and N-terminus regions exhibited the most suitable sites for the CBD binding, basing on respective free energy changes (docking score, see Supplementary Table 1). 3D analysis of the CBD-VDAC interaction revealed that more likely CBD interacts with 3 residues, Thr9, Asp12, and Leu13 at the N-terminus and neighboring pore residues Val146, Gln157, Gly175, Gln182, and His184 (Fig. 7d). Further analysis revealed that CBD binding is stabilized mainly by steric interactions and hydrogen bonds (Fig. 7e). Of putative CBD-interacting residues, Thr9, Asp 12, and Hist184 have a highest contribution to the overall binding energy (Supplementary Fig. 1, Supplementary Table 1).

Discussion

A crucial role of mitochondria in cell metabolism and bioenergetics, as well as in signaling pathways, regulation of transcriptional activity, proliferation, migration, and cell death is tightly related to their involvement into the intracellular Ca^{2+} dynamics[32]. In the present study, by means of concurrent monitoring of $[Ca^{2+}]_m$ and $[Ca^{2+}]_i$ in a response to the CBD treatment, we have provided the experimental evidences that mitochondria are primary CBD target in T-ALL. In the first place, acute transient $[Ca^{2+}]_m$ rise, preceding the $[Ca^{2+}]_i$ increase, was observed in a response to CBD (Fig. 6b). Furthermore, $[Ca^{2+}]_m$ increase together with a dissipation of ΔΨm was observed also in isolated mitochondria, treated with CBD (Fig. 7b, c). Ca^{2+} accumulation in mitochondrial matrix requires the crossing of both OMM and IMM. VDAC channel,

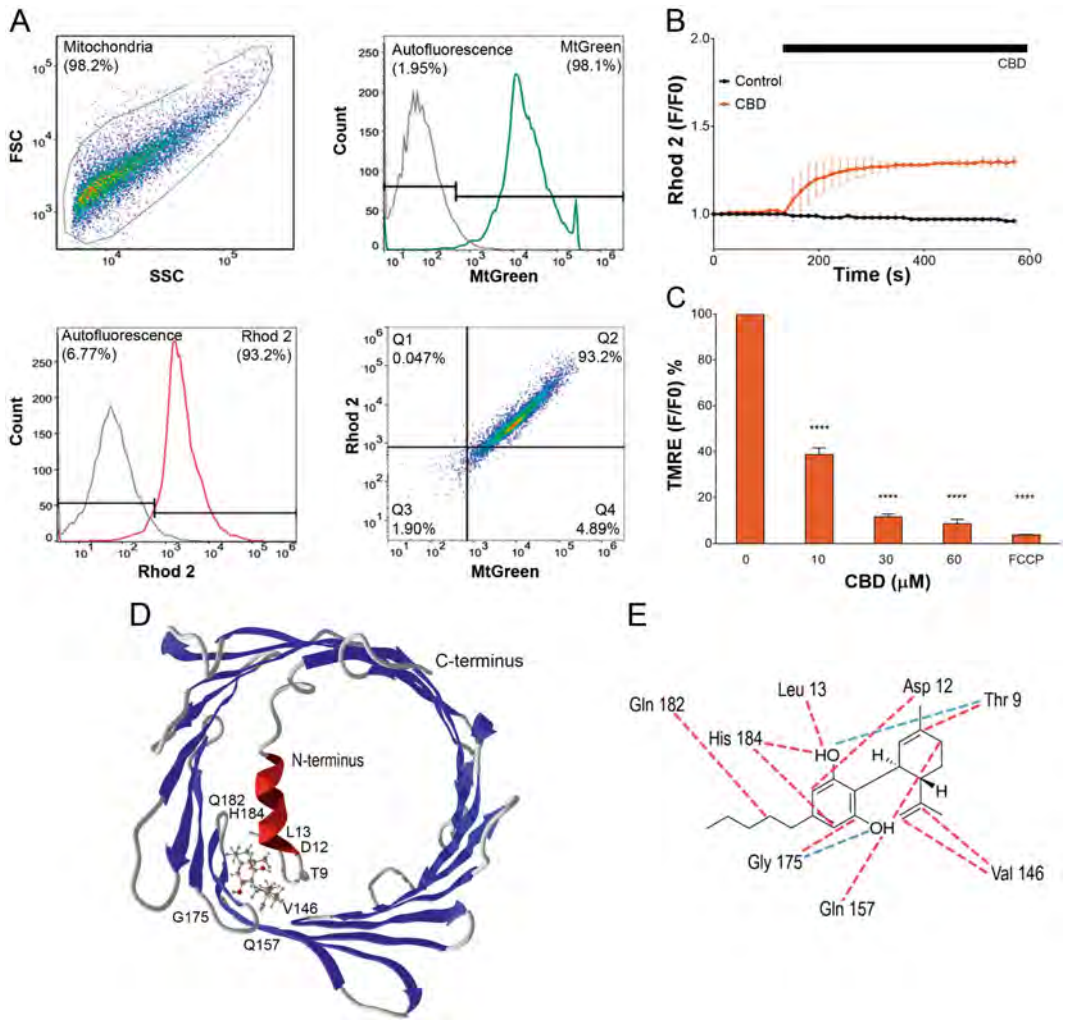

Fig. 7 CBD directly interacts with mitochondria. a Isolation of mitochondria from Jurkat cells was corroborated by flow cytometry analysis. Representative experiment is shown. The purity of mitochondria population was determined as a percentage of double positive particles after staining (20 min) with MtGreen (200 nM) and Rhod-2 (2 μM). First, the mitochondria population was visualized in FSC/SSC dot blot (upper left panel). Non-stained mitochondria were used to determine the autofluorescence interval (gray histograms and corresponding intervals in upper right and lower left panels). Accordingly, positive intervals for MtGreen (green histogram and corresponding interval in upper right panel) and Rhod-2 (red histogram and corresponding interval in lower left panel) were determined. More than 90% of freshly isolated mitochondria were double-positive (lower right panel). Freshly isolated mitochondria were assayed immediately. **b** $[Ca^{2+}]_m$ uptake by freshly isolated mitochondria in a response to vehicle or CBD (30 μM) treatments. Traces are mean ± SD for three independent experiments. **c** CBD effect on membrane potential (Δψm) in isolated mitochondria. Freshly isolated mitochondria were stained with TMRE (400 nM) and exposed to different CBD concentrations for 10 min. FCCP was used as a positive control. Data are mean ± SD of at least three independent experiments (****$p < 0.0001$, one-way ANOVA test). **d** In silico analysis predicts that CBD interacts with VDAC1 at N-terminus and β9–11 residues. **e** Residues, interacting with CBD are depicted; hydrogen bonding interactions are colored in red, whereas steric interactions are depicted in blue

ubiquitously expressed in OMM, is normally responsible for the OMM permeability to Ca^{2+}[33]. Under physiological conditions, VDAC permeability to Ca^{2+} at levels, required for an optimal function of TCA enzymes, is regulated by VDAC interaction with IP_3R in ER and chaperone 75 kDa glucose-regulated protein GRP75[34]. Our in silico analysis which demonstrated that CBD may interact directly with VDAC (Fig. 7) is in agreement with findings by others that CBD colocalizes with VDAC-rich mitochondrial membranes fraction from BV-2 microglia cell line and that purified VDAC, incorporated into lipid bilayers, is switched from fully open to major subconductance state by CBD[30]. Such "closed" channel state is known to be highly permeable for Ca^{2+}, due to the exposure of anionic groups within the channel pore[31].

Based on the available data, the following working model can be proposed (Fig. 8). Due to its direct interaction with CBD, VDAC1 is "fixed" in the Ca^{2+}-permeable state. This

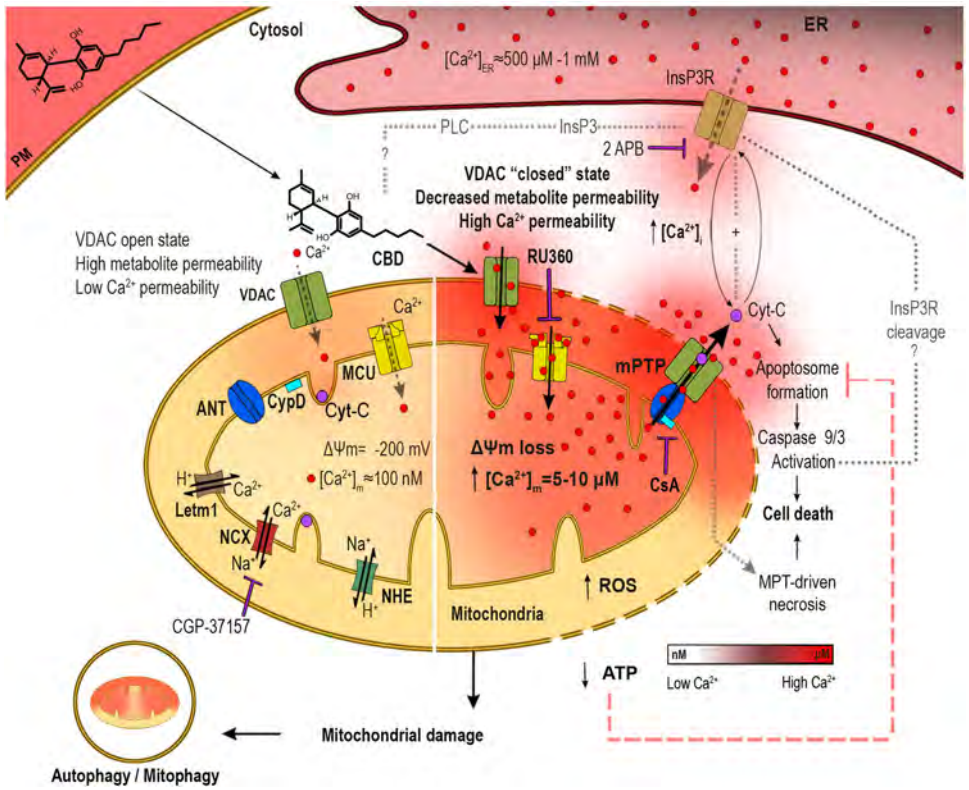

Fig. 8 Proposed mechanism for the CBD effect on T-ALL cells. Highly lipophilic CBD readily permeates plasma membrane and enters the cytosol, approaching mitochondria. Direct CBD interaction with VDAC favors the channel closed substate with increased Ca^{2+} permeability. It favors mitochondrial Ca^{2+} uptake through VDAC and MCU, leading to the mitochondrial Ca^{2+} overload that promotes the mPTP formation, Δψm loss, mitochondrial swelling, and cristae disruption. mPTP opening promotes the Cyt-C release from mitochondria. In cytoplasm, Cyt-C may orchestrate the apoptosome formation, caspases´ activation, and triggers the intrinsic apoptosis. mPTP rapidly triggers Ca^{2+} release from the ER, which tends to promote the mitochondrial Ca^{2+} overload in a feedforward manner. The CBD-induced dysfunction of mitochondria is accompanied by severe oxidative stress and rapid loss of ATP production, resulting in the MPT-driven necrosis. Autophagy occurs in T-ALL cells treated with sublethal CBD concentrations

causes Ca^{2+} entry into the intermembrane space. Ca^{2+} needs to concentrate to micromolar level there, to unlock and activate the MCU[35]. This is commonly believed to be induced by a substantial increase of extramitochondrial Ca^{2+}. Our data suggest that mitochondrial Ca^{2+} overload occurred already at resting 0.1 μM cytosolic Ca^{2+} (Figs. 6b, d and 7b). The driving force for Ca^{2+} accumulation within the intermembrane space could be a negative Donnan potential of −20 to −40 mV across the OMM[36]. This allows the concentration of Ca^{2+} in the intermembrane space up to 20-fold as compared to the cytosolic Ca^{2+} concentration, providing that the outer membrane is permeable for Ca^{2+}. The magnitude of the Donnan potential across the OMM depends on the accumulation of impermeable large anions within the intermembrane space. Such accumulation, e.g. of ATP, may be provoked by the same conformational shift within VDAC1, which not only increases its Ca^{2+} permeability, but also makes it adenine nucleotide-impermeable[36]. Activation of MCU along with a large negative potential across the IMM drives Ca^{2+} entry into the mitochondrial matrix, leading to a rapid $[Ca^{2+}]_m$ overload (Fig. 6). The latter triggers a stable mPTP formation, which causes depolarization of the IMM, mitochondrial dysfunction, severe oxidative stress, and Ca^{2+} and Cyt-C release into the cytosol.

Noteworthy, multiple leukemic phenotypes express higher levels of VDAC in a comparison to healthy cells and VDAC expression is increased upon chemotherapy. Moreover, the degree of overexpression is positively correlated with the cell death induction by anticancer agents[37–39].

We have observed different outcome of the CBD treatment depending on its concentration. At high CBD concentration, various scenarios of regulated cell death may be triggered in LLA-T (Fig. 8). In the present study, we reported apoptotic features such as Cyt-C release from mitochondria to cytosol, activation of caspases 9/3 and externalization of phosphatidylserine. On the other hand, appearance of the huge Annexin V^+PI^+ population in the early phases of CBD treatment evidenced MPT-driven

necrosis. One can hypothesize that development of MPT-driven apoptosis may be blocked due to energy penalty, a decreased ATP level caused by a cessation of oxidative phosphorylation by defunct mitochondria[40]. At sublethal (10 μM CBD) concentration, autophagy was induced and apparently efficiently prevented cell death (Fig. 1b, c, g, h; Fig. 3a–d). Low CBD concentrations even stimulated cell proliferation (Fig. 1b). This phenomenon may be explained in the frame of the same basic model, providing they promoted only limited $[Ca^{2+}]_m$ increase. Such moderate $[Ca^{2+}]_m$ accelerates metabolism due to Ca^{2+}-dependence of TCA cycle enzymes[41].

In conclusion, CBD directly targets mitochondria in T-ALL and changes their capacity to handle Ca^{2+}, which in turn affects multiple cellular functions, including ROS production and Ca^{2+} signaling, metabolic switch and the induction of autophagy and cell death. The latter is directly proved for our experimental model as the inhibitor of mitochondrial Ca^{2+} uptake Ru360 protected T-ALL cells from the CBD-induced cell death. Considering the pivotal role of mitochondria in oncogenic re-programming, CBD may be plausible candidate to be included into chemotherapeutic protocols. Importantly, resting T cells, representing major T lymphocyte population, were resistant to CBD and retained their ability to antigen activation. Healthy activated T cells were CBD-sensitive, but this population is small in T-ALL patients with a weakened immunologic system. However, contrasting effects of low and high CBD concentrations and possible differences in its tissue distribution and bioavailability requires further studies on animal models, with a focus on safety issues.

Materials/subjects and methods

Cell lines and culture conditions

Leukemic cell lines Jurkat (ATCC®TIB™, Clone E6-1, male, 14 years), MOLT-3 (ATCC®CRL-1552™, male, 19 years), CCFR-CEM (ATCC®CCL-119™, T-ALL, female, 4 years), K562 (ATCC®CCL-243™, female, 53 years), Reh (ATCC®CRL-8286™, female) and RS4;11 (ATCC®CRL-1873™, female, 32 years) purchased from ATCC® (Manassas, VA, USA) were grown in suspension in Advanced RPMI 1640 medium, supplemented with 5% (v/v) of heat-inactivated fetal bovine serum (FBS), 100 U/mL of penicillin, 100 μg/mL streptomycin and 1% of GlutaMAX™ (all from Invitrogene, Carlsbad, CA, USA). Tandem-labeled mCherry-GFP-LC3 Jurkat cells (gift from Dr. A. Thorburn, Colorado, USA) were maintained in complete growth medium (as for wild type Jurkat cells), additionally supplemented with 400 μg/mL of hygromycin B (Sigma, H3274) for selection. Suspension cells were maintained in the logarithmic growth phase by daily medium refreshment. Adherent cell lines MDA-MB-231 (ATCC®HTB-26™, female, 51 years), MCF7 (ATCC®HTB-22™, female, 69 years), SiHa (ATCC®HTB-35™, female, 55 years) and HeLa (ATCC®CCL-2™, female, 31 years) were maintained in DMEM medium supplemented with 10% (v/v) of heat-inactivated FBS, 100 U/mL of penicillin, 100 μg/mL streptomycin and 1% of GlutaMAX™. Adherent cells were passaged when they were in the logarithmic growth phase. All cells were cultured in a humidified incubator in 5% CO_2/95% air atmosphere at 37 °C.

Human samples

Blood samples (10 mL) from non-cancerous, apparently healthy volunteers (6 males and 6 females, younger than 35 years) were collected by capacitated personal under aseptic conditions. A written informed consent was obtained from all persons, prior to sample collection, according to the Declaration of Helsinki. Sample acquisition protocol was evaluated and approved by the Bioethics and Biosecurity Committee of the Biomedical Research Centre and the Faculty of Medicine of the University of Colima, in agreement with the federal laws (Artículo 100, Ley General de Salud).

Cannabidiol

CBD solution in methanol (10 mg/mL, equivalent to 32 mM) was purchased from Cayman Chemical (90081) and stored at −20 °C. Working solutions in complete growth medium were prepared daily. Methanol (154903, Merck) was used in vehicle-treated controls. Reference methanol concentration for a vehicle control was 0.3% v/v, which corresponds to that applied with the highest tested CBD concentration (100 μM).

Purification and activation of $CD4^+$ lymphocytes

Heparinized freshly isolated blood samples were diluted 1:1 with cold PBS. Peripheral blood mononuclear cells (PBMC) were separated by centrifugation in Ficoll (17-144002, Ficoll-Paque 1.073, GE Healthcare) gradient (1:1.5 blood/Ficoll ratio, 1000 × *g*, 30 min, RT). PBMC were collected from the interphase and carefully washed in PBS. Finally, cells were resuspended in a fresh RPMI 1640 medium, supplemented with 10% of FBS and incubated overnight for cell recovery. Next day, PBMC were subjected to negative selection (to avoid activation) with human $CD4^+$ T cell isolation kit (130-096-533, Miltenyi Biotec Miltenyi Biotec), following manufacturers' specifications. Briefly, PBMC were collected, washed (400 × *g*, 5 min) and the pellet was resuspended in cold MACS buffer. Live cells were counted (trypan blue exclusion test) and incubated with $CD4^+$ T cell biotin-antibody cocktail (1 μL/1 × 10^6 cells) against CD8a, CD11b, CD11c, CD19, CD45R (B220), CD49b (DX5), CD105, Anti-MHC Class II, Ter-119, and TCRγ/δ, for 20 min at 4 °C with agitation, followed by incubation with microbeads, conjugated to monoclonal anti- biotin antibodies (2 μL/1 × 10^6 cells)

over 20 min at 4 °C. Next, 1 mL of MACS buffer was added, cells were centrifuged (400 × *g*, 5 min), supernatant was discarded to remove the excess of antibodies and cells were resuspended in 1 mL of cold MACS buffer. $CD4^+$ T cell population was separated using a MACS separator. LS column was placed in the MAC separator, rinsed with 3 mL of MACS buffer and cell suspension was added. Enriched $CD4^+$ T (negative) cells were collected and column was washed three times with MACS buffer for a complete $CD4^+$ harvesting. Enriched $CD4^+$ T cell population was centrifuged (400 × *g*, 5 min), resuspended in complete Advanced RPMI 1640 medium and incubated at 37 °C in a humidified atmosphere (5% CO_2, 95% air) prior to the experiments. The population purity was more than 95% as verified by flow cytometry (FACSCanto II, BD Biosciences), using antiCD4 antibodies (BioLegend 357404).

For polyclonal activation, resting $CD4^+$ lymphocytes were pretreated in 96-well plates with antiCD3 monoclonal antibodies (5 µg/mL) (BD, 555336) for 2 h at 37 °C. Medium excess was removed and cells were further incubated with antiCD28 monoclonal antibodies (2 µg/mL) (BD, 555725) for 4 days. Ligation of CD3/CD28 provides an antigen-independent activation stimulus by cross-linking T cell receptor (TCR), resulting in transit from quiescent to proliferation state.

Resazurin-based metabolic assay

To estimate cell drug toxicity, resazurin-based metabolic assay was used. Bioreduction of resazurin reagent (Tox 8, Sigma-Aldrich) by viable cells reduces the amount of its oxidized form and concomitantly increases the amount of its fluorescent intermediate resorufin. The amount of dye conversion in solution was measured fluorometrically, using a fluorescence plate reader GloMax Discover (PROMEGA). Cells (10^6/mL) were seeded into 96-well plates in 180 µL of complete RPMI medium per well. Cells were incubated 24 h without or with CBD (1–100 µM). For assay, 20 µL aliquots of resazurin reagent were added to each well to a final volume of 200 µL and cells were further incubated for 4 h (37 °C). Samples' fluorescence was measured by excitation at 520 nm and emission was collected at 580–640 nm. RPMI fluorescence was subtracted for each condition. Samples were run in triplicate, in at least three independent experiments. Data obtained from resorufin fluorescence were averaged, normalized to their controls and expressed as cell viability.

Sequential CBD administration

Jurkat cells (2.5×10^5/mL per well) were seeded into a 48-well plate in complete Advanced RPMI medium. Cells were exposed to CBD (1–100 µM, dissolved in 500 µL of RPMI) and incubated for 24 h. After incubation, cell culture was gently resuspended, and 10 µL of suspension was taken for cell counting, using a hemocytometer and trypan blue exclusion test, to determine the number of viable cells. A second dose of CBD was administered, and cells were incubated for the next 24 h. The procedure was repeated one more time, so that total assay was completed in 72 h. Initial cell number was taken as 100%, and daily cell count was normalized to this point. Three cell counts ($n = 3$) from three independent experiments were averaged and expressed as percentage of viability.

$CD4^+$ T cell recovery test

Non-cancerous $CD4^+$ T-cells from healthy donors were cultured (1×10^6 cells/mL) in complete Advanced RPMI 1640 medium. Cells were preincubated with CBD (30 µM) or vehicle over 24 h. After CBD treatment, cells were washed and resuspended in a CBD-free medium and used for activation with antiCD3 and antiCD28 antibodies, as described earlier. Cell viability was determined by resazurin-based metabolic assay (Tox8, Sigma-Aldrich) as previously described, using a fluorescence plate reader (GloMax Discover, PROMEGA). Samples were excited at 520 nm and emission was collected at 580–640 nm. RPMI fluorescence was subtracted for each condition and data was generated in triplicate, in at least three independent experiments. Data obtained from resorufin fluorescence were averaged, normalized to their control values and expressed as cell viability.

Migration assay

Leukemic cells were seeded in 12-well plates (3422, Transwell system, Corning Inc.) and preincubated for 1 h with CBD. Pretreated cells (2×10^5) were placed in 400 µL of serum-free medium in the upper chamber of Transwell inserts (8 µM pore size). Recombinant human CXCL12 (Sigma-Aldrich) was used as a chemoattractant (100 ng/mL) in the lower chamber, filled with complete RPMI (10% FBS) medium. Cells were allowed to migrate over 4 hours. After incubation, insert was removed and cells from the lower chamber were counted, using hemocytometer. Migration was expressed as a percentage of migrated cells in relation to the total cell number.

Cell death analysis

For this assay, Alexa Fluor® 488 Annexin V/Dead Cell Apoptosis Kit (V13241, Thermo Fisher Scientific) was used, following manufacturer specifications. Kit provides a nucleophilic marker (propidium iodide, PI, Ex/Em max = 535/617 nm) as an indicator of plasma membrane damage and Annexin V-Alexa Fluor 488 (Ex/Em max = 488/510 nm), binding to externalized phosphatidylserine (a hallmark of apoptosis). Jurkat cells (10^6/mL) were seeded in a 24 well plate and incubated with or without CBD (0–100 µM) for determined period (2, 4, 6, or 12 h).

After the incubation period, cells were centrifuged (400 × *g*) and washed with cold PBS. Then cells (1×10^6) were resuspended in 100 µL of 1X Annexin V-binding buffer and 5 µL of Annexin V conjugate with 1 µL of PI working solution (200 µg/mL) were added. The mixture was incubated for 20 min at room temperature (protected from light), 200 µL of Annexin V - binding buffer was added and cells were analyzed either by confocal microscopy (LSM 700, Carl Zeiss) or by flow cytometry (FACSCanto II, BD Biosciences).

For confocal microscopy, cells were placed into home-made coverslips-bottomed chambers (poly-L-lysine-coated coverslips were fixed at the bottom of chamber using Dow corning® high vacuum grease). 40×/63x oil-immersion objectives were used. For excitation, 488 nm laser was used for both Alexa Fluor 488 and PI. Raw data were further processed, and images were generated using Zen software (Zeiss).

For flow cytometry analysis, color compensation (Alexa Fluor 488 vs PI) was performed previously to data acquisition. 488 nm laser was used for excitation. PI fluorescence was measured using 556LP mirror and 585/42 filter, Alexa Fluor 488 fluorescence was measured using 502LP mirror and 530/30 filter. Debris and doublets were gated out, and 10,000 events of single cells per sample were collected. Autofluorescence control was used to determine the positive fluorescence threshold. Annexin V^-PI^- populations were classified as healthy, Annexin V^+PI^- as early apoptotic, Annexin V^-PI^+ as primary necrotic, and Annexin V^+PI^+ as necrotic/late apoptotic. Data analysis was performed with FlowJo 10.2 software.

Determination of mitochondrial membrane potential

Jurkat cells (10^6/mL) were double-labeled with MitoTracker™ Green (100 nM, Ex/Em max = 490/518 nm; M7514, Thermo Fisher Scientific) and TMRE (200 nM, Ex/Em max = 555/582 nm; T669, Thermo Fisher Scientific), both from Thermo Fisher Scientific, by incubating over 30 min. After incubation period, cells were centrifuged (400 × *g*, 10 min) and washed with Hanks Balanced Salt Solution (HBSS; NaCl 143 mM, KCl 6 mM, $MgSO_4$ 5 mM, $CaCl_2$ 1 mM, HEPES 20 mM, BSA 0.1%, glucose 5 mM, pH 7.4, ≈300 mOsm) to remove excessive dye. For imaging, cells were placed in home-made coverslips-bottomed chambers and analyzed by confocal microscopy (LSM 700, Carl Zeiss) in a time series mode. Images were acquired every second and raw data were further processed by ImageJ program, where regions of interest (ROI) were defined, based on MitoTracker Green distribution. The fluorescence of each ROI for both dyes (TMRE/MtGr) was then averaged and expressed as a temporal ratio between the fluorescence of each frame and the initial fluorescence (F/F0). To evaluate drugs' effect, CBD (0–100 µM) or FCCP (10 µM; C2920, Merck) were administered, and cells were incubated for 10 min, centrifuged (400 × *g*, 10 min), resuspended in HBSS, and transferred to a 96-well plate. TMRE retention was assessed by measurement of fluorescence intensity, using a GloMax Discover plate reader, by exciting the sample at 549 nm and collecting the emission signal at 575 nm. Data from independent experiments were averaged and the effect of CBD/FCCP was expressed as percentage of TMRE signal in comparison to control.

EYFP-Cyt c transfection

DH5α competent bacteria (18258012, Thermo Fisher Scientific) were transformed by heat shock and EYFP-Cyt-C construct[42] was added and incubated for 14 h at 37 °C in LB agar (22700025, Thermo Fisher Scientific), supplemented with 100 µg/µL of ampicillin (11593027, Thermo Fisher Scientific). Colonies were selected and transferred to supplemented media for further incubation during 14 h for bacterial growth. Plasmid DNA was purified by NucleoBond XtraMidi (740410.10, Macherey-Nagel) kit, and DNA purity and concentration were evaluated spectrophotometrically by absorption at 260/280 nm. For transfection, 10^5 Jurkat cells were starved in Optimem reduced media for 12 h, then exposed to complexes composed by lipofectamine 3000 (L3000015, Thermo Fisher Scientific) and plasmidic DNA (500 ng) and centrifuged (400 × *g*) for 30 min to promote interaction. Transfected cells were incubated at 37 °C, with 5% CO_2 overnight, whereas FBS (10%) was added at the next day. Protein expression was monitored, and experiments were performed 12 h after transfection. Images were acquired using a confocal microscope (LSM 700, Carl Zeiss) equipped with ×40/×63 oil-immersion objectives.

Cyt-C release microscopic assay

Jurkat cells transfected with EYFP-Cyt-C (Ex/Em max = 514/526 nm) were labeled with TMRE (200 nM, 30 min) to confirm mitochondrial EYFP-Cyt-C localization. EYFP-Cyt-C expression and distribution were evaluated in Jurkat cells 12 h after transfection by confocal microscopy. The effect of CBD (30 µM) was monitored in transfected cells incubated for indicated period with the drug. To evaluate the effects of CsA and Ru360, cells were preincubated with one of these drugs for 10 min, followed by treatment with CBD. For data acquisition, cells were placed in home-made coverslips-bottomed chambers. The images were acquired using a confocal microscope (LSM 700, Carl Zeiss), equipped with ×40/×63 oil-immersion objectives.

ROS production

To evaluate ROS production, 2′,7′-Dichlorofluorescin diacetate (DCFDA, D6883, Merck) was used following manufacturer's recommendations. Jurkat cells (10^6/mL)

were loaded with permeable DCFDA (2 μM) for 30 min in HBSS. After this, cells were washed to remove extracellular dye. Cells were resuspended in RPMI1640 medium and allowed to recover and to hydrolyze the AM groups, producing the insoluble form. Culture media was removed, and cells were resuspended in HBSS and treated either with PMA (1 μM, P8139, Merck) as a positive control or with CBD (10 and 30 μM). For data acquisition, cells were placed in home-made coverslips-bottomed chambers. Images were acquired by confocal microscopy (LSM 700, Carl Zeiss), equipped with ×40/×63 oil-immersion objectives and analyzed by ZEN imaging software.

Caspase 3/9 assay

Caspase 3/9 colorimetric assays (K106/119, BioVision) were used following manufacturer's recommendations. Jurkat cells were grown in the presence of vehicle, staurosporine (positive control) or CBD during 12 h. After this period, 10^6 cells from each sample were washed, resuspended in lysis buffer and incubated over 10 min on ice. Then samples were centrifuged (10,000 × *g*, 15 min) and supernatants (cytosolic fraction) were transferred into new tubes. For caspase activity assays, 100 μg of protein (as estimated by BCA protein quantification kit, Merck) from every sample were mixed with 50 μL of reaction buffer (containing 10 mM DTT) and 5 μL (4 mM) of the caspases´ substrates (DEVD-*p*NA for caspase 3, LEHD-*p*NA for caspase 9). Mixtures were incubated for 2 h at 37 °C and placed into a 96-well plate. Absorbance was measured at 405 nm, using a GloMax Discover plate reader. Data from three independent experiments were averaged and normalized in relation to non-treated cells, yielding fold increase in caspase activity.

Transmission electron microscopy

Jurkat cells were treated with CBD (30 μM) for 2 h. Next, control or treated cells were centrifuged (400 × *g*), supernatants were discarded and the pellets were fixed with 2.5% glutaraldehyde and post-fixed in 1% OsO_4 and 0.8% $K_4Fe(CN)_6 \cdot 3H_2O$, and 5 mM Ca^{2+}. Post-fixed cells were dehydrated in acetone and embedded in Epon. Ultrathin sections were stained with uranyl acetate and lead citrate and examined under a JEOL JEM 12 000 EII transmission electron microscope at the Unidad de Imagenología, Instituto de Fisiología Celular (IFC), UNAM, Mexico City.

CEPIA3mt transfection

DH5α competent bacteria (18258012, Thermo Fisher Scientific) were transformed by heat shock and CEPIA3mt/pCMV construct (58219, Addgene) was added[27]. Samples were incubated for 14 h at 37 °C in LB agar (22700025, Thermo Fisher Scientific), supplemented with 100 μg/μl of ampicillin (11593027, Gibco). Colonies were selected and transferred to supplemented media for further incubation during 14 h for bacterial growth. Plasmid DNA was purified by NucleoBond XtraMidi (740410.10, Macherey-Nagel) kit and purity and DNA concentration were determined by spectrophotometry (absorption at 260/280 nm). For the transfection, 10^5 Jurkat cells were starved in Optimem reduced media over 12 h, collected, exposed to complexes of lipofectamine 3000 (L3000015, Thermo Fisher Scientific) and plasmidic DNA (1 μg), and centrifuged (400 × *g*) for 30 min to promote interaction. Cells were incubated at 37 °C with 5% CO_2 overnight, whereas FBS (10%) was added at the next day. Protein expression was monitored, and experiments were performed 24 h after transfection. For confocal imaging, cells were placed in home-made coverslips-bottomed chambers. Images were acquired using a confocal microscope (LSM 700, Carl Zeiss) equipped with ×40/×63 oil-immersion objectives.

Determination of the intracellular free Ca^{2+} concentration

For free $[Ca^{2+}]_i$ measurements, cells were loaded with ratiometric Ca^{2+} indicator Fura-2 (F1201, Thermo Fisher Scientific). Cells were twice washed with PBS and resuspended in a loading solution (HBSS, 0.01% pluronic acid, 2 μM Fura-2/AM), incubated for 30 min at room temperature protected from light, washed, and resuspended in HBSS. Changes in fluorescence were recorded with a F7000 spectrophotometer (Hitachi High-Technologies). Measurements were realized in quartz cuvettes, containing 1.5×10^6 cells/mL. Loaded cells were excited alternately at 340/380 nm and the fluorescence emission was collected every 2 s at 510 nm. Fluorescence was recorded by means of the FL-solutions software. Maximum and minimum free $[Ca^{2+}]$ levels were determined at the end of each experiment by adding 0.3% Triton X-100 and consequent addition of EGTA to a final concentration of 35 mM, respectively. Free $[Ca^{2+}]_i$ was calculated by using the following equation:

$$\left[Ca^{2+}\right]_i = K_d(R - R_{MIN})/(R_{MAX} - R)$$

where R stays for the ratio of fluorescence intensity upon excitation at 340 to that at 380 nm and R_{MIN} and R_{MAX} correspond to maximal and minimal values of this ratio, determined as described above[43].

In some experiments Ca^{2+}-free HBSS was used (NaCl 143 mM, KCl 6 mM, $MgSO_4$ 5 mM, HEPES 20 mM, BSA 0.1%, glucose 5 mM, EGTA 1 mM, pH 7.4, ≈300 mOsm).

Mitochondrial Ca^{2+} measurements

CEPIA3mt (Ex/Em max = 488/510 nm) expression and its mitochondrial localization were confirmed in transfected Jurkat cells, loaded with TMRE, by confocal microscopy (LSM700, Carl Zeiss). For $[Ca^{2+}]_m$

measurements, 10^5 cells (24 h after transfection) were placed in a quartz cuvette and fluorescence was evaluated by spectrofluorometry, using a F7000 HITACHI spectrofluorometer (FL solution software). Samples were excited at 488 nm and fluorescence was measured at 510 nm. $[Ca^{2+}]_m$ was evaluated as fluorescence intensity in relation to the initial fluorescence intensity (F/F0).

Mitochondria isolation

Mitochondria were isolated as reported earlier[39], with some modifications. Jurkat cells were harvested and centrifuged (400 × *g*) at 4 °C for 10 min, washed twice with PBS (pH 7.4) and resuspended in 10x of volume of isolation buffer (IB, HEPES-KOH 20 mM, PMSF 1 mM, sucrose 250 mM, mercaptoethanol 1 mM, EGTA 1 mM, EDTA 1 mM, $MgCl_2$ 1.5 mM, KCl 10 mM). Cells were incubated on ice for 10 min and homogenized with a Dounce homogenizer. Homogenate was then centrifuged at 650 × *g* for 10 min at 4 °C, pellet, containing nuclei, was discarded and the supernatant was collected for a further 12500 × *g* centrifugation for 30 min at 4 °C. Pellet containing the heavy membrane fractions (HMF) was collected and the supernatant was discarded. HMF were washed with IB and resuspended in isotonic sucrose buffer (sucrose 250 mM, EDTA 1 mM, Tris-HCl pH 7.4 10 mM). Homogenate was placed in a discontinuous sucrose gradient (sucrose 1/1.5 M, EDTA 1 mM, Tris-HCl pH 7.4 10 mM) and centrifuged for 25 min at 60,000 × *g*, 4 °C. Mitochondria were collected from the interphase, washed and resuspended in the experimental buffer (KCl 125 mM, KH_2PO_4 1 mM, Tris-HCl 10 mM, glutamate 5 mM, malate 2.5 mM, EGTA 1 mM, $CaCl_2$ 0.7 mM). Isolated mitochondria were suspended in the lysis buffer (Nonidet P-40 0.5% w/v, Tris-HCL 50 mM, NaCl 150 mM, EDTA 1 mM, and PMSM 1 mM) for 1 h and centrifuged at 15000 × *g* for 5 min. The supernatant was collected, and isolation yield was estimated by the protein content (BCA quantification assay). Finally, mitochondrial samples, containing 50 µg of protein, were used in the experiments. To evaluate the purity and integrity of isolated mitochondria, a small fraction was stained with MtGreen (200 nM, Ex/Em max = 490/510 nm; M7514, Thermo Fisher Scientific) as mitochondrial marker, followed by staining with Rhod (2 µM, Ex/Em max = 552/581 nm; R1244, Thermo Fisher Scientific) or TMRE (200 nM, Ex/Em max = 549/575 nm; T669, Thermo Fisher Scientific). Samples were acquired by flow cytometry (FACSCantoII, BD Biosciences) and data were analyzed by FlowJo software.

Ca^{2+} measurement in isolated mitochondria

Freshly isolated mitochondrial samples (50 µg of protein per sample) were incubated with Rhod2 (2 µM) over 30 min, washed by centrifugation (12500 × *g*, 5 min) and resuspended in experimental buffer (KCl 125 mM, KH_2PO_4 1 mM, TrisHCl 10 mM, glutamate 5 mM, malate 2.5 mM, EGTA 1 mM, $CaCl_2$ 0.7 mM). Samples were placed in a quartz cuvette, and fluorescence was evaluated by F7000 spectrophotometer (Hitachi High-Technologies), using excitation at 552 nm and collecting the fluorescence at 581 nm. Data was recorded using the FL-Solution software (Hitachi). $[Ca^{2+}]_m$ change was evaluated by taking fluorescence for each acquisition in relation to the initial fluorescence value, F/F0.

Membrane potential measurements on isolated mitochondria

Isolated mitochondria (50 µg of protein/sample) were stained with TMRE (200 nM; 30 min), treated with CBD (0–60 µM) or FCCP (10 µM) for 10 min, washed, resuspended in experimental buffer (KCl 125 mM, KH_2PO_4 1 mM, TrisHCl 10 mM, glutamate 5 mM, malate 2.5 mM, EGTA 1 mM, $CaCl_2$ 0.7 mM) and placed in a 96-well plate. Fluorescence was assayed using a GloMax Discover plate reader, by exciting the sample at 549 nm and collecting the emission at 575 nm. Data from independent experiments were averaged and the effect of CBD or FCCP on membrane potential value is defined as % of TMRE fluorescence with respect to control.

Detection of autophagic flux by LC3 immunoblotting

During autophagy, the amount of LC3-I decreases and that of LC3-II increases. But at the late phase after autophagolysosome formation LC3-II disappears being degraded by lysosomal proteases. If cells are treated with lysosomal protease inhibitors or with drugs inhibiting autophagosome-lysosome fusion, LC3-II degradation is prevented. Thus, LC3-II amount at a certain time point does *per se* serve a measure of the total autophagic flux. This flux should be more accurately evaluated by comparison of the amount of LC3-II between samples in the presence and absence of lysosomal protease inhibitors or compounds preventing autophagosome-lysosome fusion[15,44]. CQ was shown to prevent autophagosome-lysosome fusion[16] and was used therefore in the present work.

For Western blot analysis, cells after corresponding treatments (CQ, CBD, or CQ and CBD combination) were harvested and lysed with RIPA buffer (Tris-HCl 25 mM, pH 7.6, NaCl 150 mM, EDTA 5 mM, NP-40 1%, sodium deoxycholate 1%, SDS 0.1%), supplemented with protease inhibitors (11697498001, Complete, Roche). For protein quantification, BCA Protein Assay Kit (Sigma) was used. For each sample, 15 µg/line of protein were loaded on a 15% SDS-PAGE gel. After electrophoresis (100 V, ~2 h), proteins were transferred onto PVDF membranes. Membranes were blocked for 1 hour with 5% BSA in TBS Tween-20 buffer (TBS-T) and incubated overnight at 4 °C with anti-human LC3 rabbit antibodies

(Novus-Biologicals, NB100-2220, dilution 1:3000) and mouse monoclonal anti-human GAPDH antibodies (SCBT, sc-47724, dilution 1:1000) as a loading control. As secondary
antibodies, HRP-conjugated goat anti-rabbit IgG (Novus-Biologicals, NBP2-30348H, dilution 1:3000) and HRP-conjugated anti-mouse IgGκ (SCBT, sc-516102, dilution 1:1000) were used for LC3 and GAPDH, respectively. Membranes were incubated with secondary antibodies over 1 h at room temperature, followed by incubation with the ECL detection reagent (Bio-Rad, 170-5061). Protein bands were visualized with Bio-Rad Universal Hood II system and analyzed with Image Lab 5.0 software.

Autophagic flux measurement with mCherry-GFP-LC3

To measure autophagic flux at the single cell level, Jurkat cells, stably expressing tandem mCherry-GFP-LC3, were used[45]. Cells were cultured in the presence of CBD, CQ or their combination for 2, 4, and 24 h. After these periods, cells were collected by centrifugation ($100 \times g$), suspended in PBS and placed in a in home-made coverslips-bottomed chambers for microscopy imaging. Double positive mCherry + /GFP + puncta represented autophagosomes, whereas fusion with the lysosome (autophagolysosomes) caused quenching of the pH-sensitive GFP, resulting in appearance of mCherry + GFP- puncta. CQ prevents GFP quenching by inhibiting autophagosome-lysosome fusion[16]. Samples were analyzed by confocal microscopy (LSM700, Carl Zeiss). Alternatively, custom-made confocal microscope (Solamere Technology Group, Salt Lake City, USA) based on a Yakogawa spindisk confocal scan head (CSUX1M1, Yokogawa Electronic Co., Tokio, Japan), equipped with solid state Coherent Obis lasers (405, 488, 561 and 640 nm) was used. Autophagy flux was evaluated by counting red (mCherry+) and green (GFP+) puncta (0.5–3 μm^2) in the cells. Data analysis was performed using "Particle analysis" tool of ImageJ software, as reported by others[46–48]. Three fields for each condition (10–20 cells/ field) in at least three independent experiments were analyzed. Data are presented as mean of LC3 puncta/ cell or as mean of mCherry/GFP ratio.

Protein-ligand docking

To explore binding sites for CBD within human VDAC1 channel, molecular docking analysis was performed, using Molegro virtual docker 6.0 software. Chemical structure of CBD was obtained from Pubchem (NIH, 644019), whereas hVDAC1 channel structure was downloaded from the protein data bank (PDB, 2JK4). For the beginning, three main cavities for hVDAC1 were defined and explored as possible CBD-interacting sites. MolDock Optimizer was selected as a search algorithm, 20 runs (number of times that the docking is repeated for each ligand) was chosen, and 1000 ligand binding conformations were established. From them, the best 5, based on their docking score (MolDock Score), were selected for each cavity. For all 15 selected binding conformations the contribution of each participating residue in the CBD binding was evaluated (Ligand map > Ligand Energy Inspector). Finally, basing on Total energy/MolDock Score, the best binding conformation was revealed and plotted by creating backbone visualization in the workspace.

Acknowledgements

This study was funded by CONACyT grants 220793 to I.P., FC2015/1-140 to O.D., and PAPIIT IG200119 (DGAPA-UNAM) to A.H.C.; doctoral fellowships (M.O. A., L.T.L. and J.SV.R). We thank Dr. Boehning and Dr. Methner for providing EYFP-Cyt C and CEPIA3mt plasmids, Dr. Thorburn for gifting mCherry-GFP-LC3 expressing Jurkat cells, Dr. Rincón-Heredia and Dr. Díaz for sample preparation and data acquisition by TEM, and Dr. Gómez and Mr. Reyes for their assistance in the docking simulations. Memory induction

ABSTRACT

The association between a taste and gastric malaise allows animals to avoid the ingestion of potentially toxic food. This association has been termed conditioned taste aversion (CTA) and relies on the activity of key brain structures such as the amygdala and the insular cortex.

The establishment of this gustatory-avoidance memory is related to glutamatergic and noradrenergic activity within the amygdala during two crucial events: gastric malaise (unconditioned stimulus, US) and the post-acquisition spontaneous activity related to the association of both stimuli. To understand the functional implications of these neurochemical changes on avoidance memory formation, we assessed the effects of pharmacological stimulation of β-adrenergic and glutamatergic NMDA receptors through the administration of a mixture of L-homocysteic acid and isoproterenol into the amygdala after saccharin exposure on specific times to emulate the US and post-acquisition local signals that would be occurring naturally under CTA training. Our results show that activation of NMDA and β-adrenergic receptors generated a long-term avoidance response to saccharin, like a naturally induced rejection with LiCl. Moreover, the behavioral outcome was accompanied by changes in glutamate, norepinephrine and dopamine levels within the insular cortex, analogous to those displayed during memory retrieval of taste aversion memory. Therefore, we suggest that taste avoidance memory can be induced artificially through the emulation of specific amygdalar neurochemical signals, promoting changes in the amygdala-insular cortex circuit enabling memory establishment.

1. Introduction

Classical conditioning has been used as a model to study how neurotransmitters are involved in the acquisition and storage of information [1,2]. The neurochemical basis of memory formation emerged through pharmacological manipulations of receptors' activity before or after the learning phase. However, there is scarce information on how specific neurotransmitters participate in the encoding of both the conditioned stimulus (CS) and the unconditioned stimulus (US), triggering the mechanisms associated with the establishment of memory [3–7].

Taste aversion memory has been widely used as an associative learning paradigm in the search of the neurobiological mechanisms involved in memory processes. Animals' survival depends on their capacity to adapt to the environment by efficiently store the consequences of the ingestion of a specific food; specially the ones that might be toxic, this way, the animal will be able to display an avoidance response to evade aversive outcomes. In order to associate and store these memory traces, appropriate neurochemical representations on key brain structures have been described. Exposure to a novel taste produces increments of dopamine and norepinephrine in both the amygdala and the insular cortex (IC) [3–6]. Conversely, a malaise-inducing agent such as LiCl generates an elevation of glutamate [3,5,8] and norepinephrine [3] within the amygdala, suggesting that these neurotransmitters are related to the signaling of the aversive outcome. Furthermore, taste aversion memory can be enhanced by intra-amygdalar administration of glutamate when a weak US is given (low concentration of LiCl) [9,5]. Blockade of either noradrenergic [10] or glutamatergic [11] receptors within the amygdala before the induction of gastric malaise impairs aversive taste memory establishment. Altogether, this evidence suggests

INFORME DE LABORES 2019

that glutamatergic and noradrenergic activity within the amygdala could be related to the encoding of the necessary signals to generate an aversive taste memory trace.

Memory consolidation involves post-acquisition processes whereby newly acquired information is maintained and established into long-term memory [12,13]. As part of these consolidation mechanisms, data suggest that electrical or neurochemical patterns of activity occur during post-acquisition wakefulness and during sleep in the absence of sensory information [3,4,14–17]. In this regard, it has been reported an increase in norepinephrine levels within the amygdala that remained elevated 2 h after inhibitory avoidance training [18]. Particularly, we demonstrated an increase of the extracellular levels of glutamate and norepinephrine within the amygdala [3], and dopamine and glutamate within the IC [4] about 45 min after taste and gastric malaise pairing. These changes of neurotransmitters levels are related to taste aversion consolidation, since amygdalar blockade of N-methyl-D-aspartate (NMDA) and β-adrenergic receptors during the timeframe of reactivation disrupts long-term memory consolidation [3]. Moreover, reversible inactivation of the amygdala at the time of reactivation impedes the release of glutamate and dopamine within the IC and impairs stabilization of conditioned taste aversion (CTA) [4]. These results strongly suggest that the amygdala modulates post-acquisition events within the IC required for CTA memory consolidation [19–21].

The aim of this study was to evaluate the effects of local amygdalar stimulation of noradrenergic β-receptors and glutamatergic NMDA receptors, in pursuance of emulating the neurochemical signals related to the US and to the post-acquisition spontaneous activity; that has been described within this structure during CTA formation and long-term stabilization. Thereby, we administrated a mixture of a NMDA receptor agonist (L-homocysteic acid) and a β-adrenergic receptor agonist (isoproterenol) into the amygdala to mimic the neurochemical signals triggered at different times. In addition, we monitored the neurochemical levels within the IC during memory retrieval as a result of the artificially induced taste avoidance and compared it with a naturally-induced taste aversion retrieval as previously reported [21].

2. Material and methods

2.1. Animals

Two-months old male Wistar rats, weighing 260–280 g at the time of surgery, were used in this study. Animals were obtained from the Instituto de Fisiología Celular animals production facility. Rats were housed individually and maintained on a 12 h light/12 h dark cycle with water and food ad libitum except when noted on the behavioral procedures. All procedures were completed during the light period and were approved by the Animal Care and Ethics Committee of the Instituto de Fisiología Celular (FBR 30-14) in accordance with the National Institutes of Health guidelines.

2.2. Intra-amygdalar drugs administration and taste avoidance assessment

Rats were implanted bilaterally with 12 mm long stainless-steel guide cannulae (23 gauges) directed to the central and basolateral amygdalar nuclei using standard stereotaxic procedures (AP-2.8 mm, L ± 4.8 mm, DV-6.5 mm relative to Bregma, [22]. After six days of surgery recovery, animals were deprived of water for 24 h; rats were allowed to drink 15 mL of tap water from two graded bottles for 15 min between 10:00 and 11:00 in their home cage to obtain a baseline water consumption over 6 days. Additional water access was allowed for 15 min in the afternoon (around 5 pm) to ensure proper hydration of the animals. To diminish handling-associated stress, daily handling was performed during 3 min every day prior to the infusion protocol. All drugs were dissolved in saline solution (0.9% wt/vol). We administered isoproterenol (2 μg/μL, Sigma Aldrich), L-homocysteic acid (18.315 μg/μL, Sigma Aldrich, [23]) or a mixture of isoproterenol and L-homocysteic acid (2 μg/μL; 18.315 μg/μL final concentrations respectively). There is evidence of central and basolateral nuclei participation in taste aversion formation, especially during LiCl administration [3,5,24,25]. Therefore, a total volume of 1 μL was injected per hemisphere in the amygdala (0.5 μL/min); the injector was left for another minute to allow diffusion into the tissue. Drug administration was made through 30-gauge dental needles that protruded 1 mm from the tip of the guide cannulae. Injection needles were connected via polyethylene tubing to two 10-mL Hamilton syringes, driven by an automated micro infusion pump (Carnegie Medicine).

On the acquisition day, rats were divided in 7 groups counterbalanced according to their mean baseline consumption of tap water. Two graded bottles were presented, one with 15 mL of a 0.1% (wt/vol) saccharin solution (Sigma Aldrich) and the other with 15 mL of tap water. Rats were allowed to drink for 15 min. After a 15 min delay, rats received an intra-amygdalar injection and 30 min later rats were infused again according to the administration protocol. Experimental groups were separated as follows (final number of animals on each group is shown): saline solution - saline solution (SS-SS, n = 6); isoproterenol - isoproterenol (ISO - ISO, n = 6); L-homocysteic acid - L-homocysteic acid (LHa-LHa, n = 6); saline solution-mix of isoproterenol and L-homocysteic acid (SS-MIX, n = 6); mix of isoproterenol and L-homocysteic acid-saline solution (MIX-SS, n = 6) and mix of isoproterenol and L-homocysteic acid-mix of isoproterenol and L-homocysteic acid (MIX-MIX, n = 7). We compared the behavioral response of an artificially induced taste avoidance to a naturally induced rejection through gastric malaise caused by LiCl; hence a positive control group received an i.p. injection of LiCl (0.15 M, 7.5 mL/kg) (LiCl 0.15 M, n = 5) 15 min after saccharin acquisition consumption during acquisition. Seventy-two hours after training, all animals could drink from two graded bottles, one with saccharin solution (0.1% (wt/vol) and the other with tap water for 15 min; the consumption measurements of each bottle were obtained. Data is presented as Preference index (Preference index = Saccharin mL / Saccharin mL + tap water mL).

2.3. Collection of cortical neurotransmitters related to an artificially-induced taste avoidance

Unilateral microdialysis cannula (22-gauge, shaft length 14 mm. CMA Microdialysis) aiming the insular cortex (AP + 1.2 mm; L + 5.5 mm; DV -4.5 mm, [22]) and bilateral steel cannulas (12 mm length and 23 gauge) aiming the amygdala (AP -2.8 mm, L ± 4.8 mm, DV −6.5, [22]) were implanted using standard stereotaxic protocols. Six days after surgery, animals were deprived of water for 24 h and placed in the microdialysis chamber during 3 h for six days to let them habituate to the context and constant manipulation. Rats were allowed to drink 30 mL of tap water from a graded bottle for 15 min to obtain a water baseline consumption intake. Microinfused drugs were dissolved in saline solution (0.9% wt/vol) and a total volume of 1 μL was injected per hemisphere in the amygdala (0.5 μL/min) as described above. On the acquisition day, rats were divided into 3 groups counterbalanced according to their mean baseline tap water consumption and were exposed for 15 min to a graded bottle with 30 mL of a 0.1% (wt/vol) saccharin solution. After a 15 min delay, rats received a first intra-amygdalar injection and 30 min later rats were infused again according to the administration protocol. Experimental groups were separated as follows: one group received saline solution-saline solution (SS-SS, n = 8); a second group received a mix of isoproterenol and L-homocysteic acid-mix of isoproterenol and L-homocysteic acid (MIX-MIX, n = 8) and a third group (positive control) that received a LiCl i.p. injection (0.15 M, 7.5 mL/kg) (LiCl 0.15 M, n = 6) 15 min after saccharin consumption.

Seventy-two hours after training, a dialysis probe with a 3 mm membrane (CMA 12 MD Probe, CMA Microdialysis) was connected to the microinfusion pump system (CMA Microdialysis), which infused

artificial cerebrospinal fluid (NaCl 125 mM, KCl 5 mM, $NaH_2PO_4H_2O$ 1.25 mM, $MgSO_4$ •$7H_2O$ 1.5 mM, $NaHCO_3$ 26 mM, $CaCl_2$ 2.5 mM, glucose 10 mM) at a rate of 1 μL/min. After insertion of the probe, 1 h of fluid stabilization was allowed; samples were collected every 4 min in vials containing 1 μL of an antioxidant mixture (0.25 mM ascorbic acid, Na_2EDTA 0.27 mM, 0.1 M acetic acid) and immediately frozen at −80 °C. Three fractions were collected as baseline samples, afterward, a 0.1% (wt/vol) saccharin solution was presented for 15 min. We obtained five more fractions after CS exposure onset. The saccharin consumption was measured during retrieval and it was reported as percentage of consumption of saccharin during the acquisition intake (acquisition consumption percentage = saccharin solution intake during retrieval × 100/saccharin intake during acquisition). During microdialysis experiments, animals were trained and evaluated with one bottle of saccharin to avoid changes in neurotransmitter levels associated with water preference.

2.4. Analysis of glutamate, norepinephrine and dopamine in microdialysis samples

Neurotransmitters levels were determined by capillary electrophoresis. Briefly, microdialysis samples were derivatized with 6 μL of 16.58 mM 3-(2-furoyl) quinoline-2-carboxaldehyde (Molecular Probes, Eugene, OR, USA) in the presence of 2 μL of KCN 25 mM in 10 mM borate buffer (pH 9.2) and 1 μL of internal standard (0.075 mM O-methyl-L-threonine). The mixture was allowed to react in the dark at 65 °C for 15 min. Separation and analysis were conducted in a capillary electrophoresis system (Beckman-Coulter PACE/MDQ, Glycoprotein System, Beckman Coulter, Brea, CA, USA) with laser-induced fluorescence detection; light at 488 nm from an argon ion laser was used to excite the 3-(2-furoyl) quinoline-2-carboxaldehyde-labeled analytes. A micellar electrokinetic chromatography buffer system was used to separate the dialyzed compounds. The borate buffer included 35 mM borates, sodium dodecylsulphate 25 mM, 13% (vol/vol) methanol HPLC grade, final pH 9.6. The samples were injected hydro-dynamically at 0.5 psi for 5 s in a 75 μm i.d. capillary (Beckman Coulter); then the separation was performed at 25 kV. After each sample, the capillary was flushed with 0.1 M NaOH, water and running buffer. The glutamate, norepinephrine and dopamine peaks were identified by matching the migration pattern with those in a spiked sample and corrected by relating the area under the curve of the unknown sample with the area under the curve of the internal standard. Data were analyzed using Karat System Gold (Beckman Coulter). Results are expressed as percentage of basal concentration (percentage of basal concentration = analyte concentration × 100/mean of the three first samples).

2.5. Histology

Cannulae placement was verified at the end of behavioral procedures, animals were sacrificed with an overdose of sodium pentobarbital and transcardially perfused with a physiological saline solution. Brains were removed and stored in paraformaldehyde (4% solution in phosphate buffered saline) for 24 h. After a sucrose gradient treatment, coronal sections of 40 μm were cut and stained with cresyl violet. Samples were then examined under a light microscope to corroborate the correct placement of cannulas; those tips that were not located in the aimed area were removed from the statistical analysis (Fig. 3).

2.6. Statistical analysis

For all experiments, animals were assigned to each treatment group after balancing their average consumption of tap water. Preference consumption indexes were calculated as follows: mL saccharin consumption/mL saccharin + mL tap water consumption. A preference consumption index equal to 0.5 reflects a random choice for saccharin. Preference consumption indexes were analyzed using One-sample Student's *t*-tests compared to a hypothetical value of 0.5 (chance level) to determine taste preference. Additionally, we used a One-way ANOVA with Dunnet's post hoc test to compare preference consumption indexes of the different groups in comparison to the control group and effect size was calculated with Cohen's d. In order to assure that treatments did not cause adipsia or a general reduction in consumption, we compared total fluid intake (mL saccharin + mL tap water) among groups with One-way ANOVA (Fig. 2).

Changes in the extracellular levels of neurotransmitters within the insular cortex were analyzed using Repeated measures ANOVA with Bonferroni post hoc test. For the behavioral response during microdialysis protocol, one-way ANOVA with Dunnet's post hoc test was used to compare avoidance response during test in contrast with the control group. The accepted level of significance was p-value ≤ 0.05. Data are presented as mean ± SEM. Statistical analysis was performed using StatView version 4.57 and graphs were obtained with GraphPad Prism version 6.00, GraphPad software.

3. Results

3.1. Emulation of amygdalar representation of the US and reactivation signals by pharmacological activation of NMDA and β-receptors elicits taste avoidance

From the histological analysis the following rats with cannulae misplacement were removed from results and statistical analysis: ISO-ISO n = 1; MIX-SS n = 2; MIX-MIX n = 1. Fig. 1A represents the behavioral protocol previously described in the methodology. The two-bottle protocol was used because is considered more sensitive since the animals have access to saccharin and water at the same time, enhancing the detection of the avoidance. The animals got accustomed to having two-bottles available for drinking during the baseline monitoring and they alternate between bottles throughout the experiment (Table 1). Table 2 shows the mean consumption of liquid during acquisition and test; no difference on total volume consumption (water + saccharin) was observed among groups during long-term memory test ($F_{6,35}$) = 1.376, p = 0.253). Table 3 shows the raw consumption of the different groups during the long-term memory test; statistical analysis showed significant differences in the saccharin preference among groups ($F_{6,35}$) = 6.629, $p < 0.001$), post hoc analysis revealed that both naturally (LiCl 0.15 M) and artificially induced (MIX-MIX) taste avoidance are reflected as a significantly lower saccharin preference when compared to the SS-SS group ($p < 0.001$, d = 4.721 and p = 0.003, d = 3.461, respectively). The ISO-ISO, LHa-LHa, MIX-SS and SS-MIX groups exhibited a similar saccharin preference compared to SS-SS groups and did not have significant differences (SS-SS vs ISO-ISO p = 0.970, d = 0.367; SS-SS vs Lha-Lha p = 0.269, d = 0.901; SS-SS vs MIX-SS p = 0.995, d = 0.245; SS-SS vs SS-MIX p = 0.854, d = 0.879). Moreover, no differences were observed in saccharin preference between LiCl 0.15 M and MIX-MIX groups (p = 0.807 d = 1.4). The groups LiCl 0.15 M (p = 0.004) and MIX-MIX (p = 0.017) showed preference indexes below chance, indicating a clear avoidance of saccharin, whereas the SS-SS (p = 0.003) and SS-MIX (p = 0.018) groups showed a preference index above chance, demonstrating a predilection for saccharin, hence no avoidance. Therefore, only double intra-amygdalar infusions of a mixture of isoproterenol and L-homocysteic acid, which resemble the US encoding and reactivation signaling, induced a long-term avoidance memory, which is like a naturally developed response after taste and malaise pairing (Fig. 1B).

3.2. Artificially and naturally induced taste avoidance elicit similar neurochemical representations within the insular cortex

During microdialysis experiments (protocol representation in Fig. 2A), regarding extracellular levels of glutamate, repeated measures

INFORME DE LABORES 2019

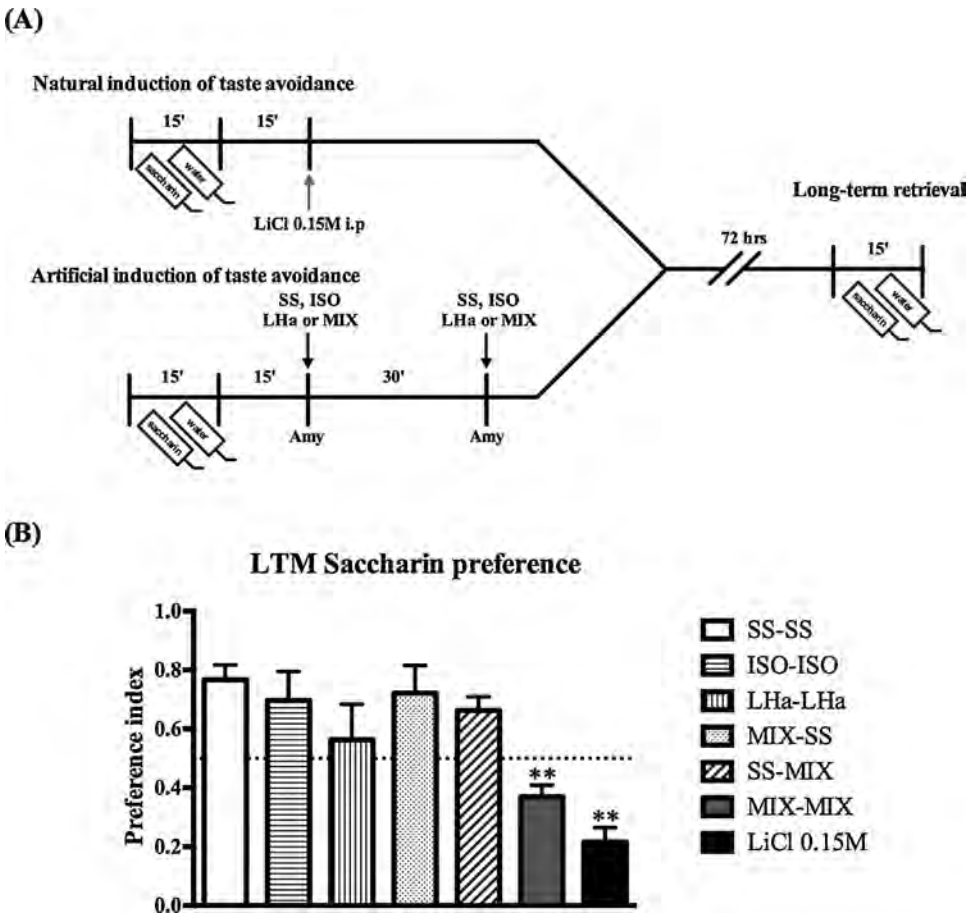

Fig. 1. Effect of pharmacological manipulation in the amygdala over saccharin preference during taste avoidance retrieval. (A) Schematic representation of the behavioral and micro-infusion protocols used. (B) Long-term memory (LTM) for saccharin preference, MIX-MIX and LiCl 0.15 M groups showed reduced preference for saccharin during taste avoidance retrieval, whereas SS-SS, ISO-ISO, LHa-LHa, MIX-SS, and SS-MIX did not. Dark arrows represent micro-infusions into the amygdala (Amy); gray arrow represent LiCl i.p. administration. The graphic is expressed as means of saccharin preference index ± SEM. Dotted line represents consumption on chance level (0.5); ** $p < 0.01$ versus SS-SS group. LHa: L-homocysteic acid; ISO: isoproterenol; MIX: L-homocysteic acid + isoproterenol; SS: saline solution; LTM: Long-term memory.

ANOVA analysis revealed significant differences among fractions ($F_{8,190}$) = 2.232, p = 0.030) and an interaction effect ($F_{16,190}$) = 1.777, p = 0.044) with no groups differences ($F_{2,190}$) = 1.058, p = 0.349). Bonferroni's post hoc test showed that artificially induced avoidance (MIX-MIX) and LiCl 0.15 M groups were different in comparison to SS-SS group at fraction 6 (p = 0.006 and p = 0.028, respectively), i.e., when animals were exposed to the conditioned stimulus during retrieval. Our data demonstrated that a naturally or artificially induced taste avoidance caused a significant augmentation in the extracellular levels of glutamate within the IC during memory retrieval (Fig. 2B).

For norepinephrine release, statistical analysis showed significant differences among fractions ($F_{8,167}$) = 2.117, p = 0.041) with an interaction effect ($F_{16,167}$) = 1.770, p = 0.043), without group effect ($F_{2,167}$) = 0.477, p = 0.621). Bonferroni's post hoc analysis revealed that MIX-MIX ($p < 0.001$) and LiCl 0.15 M ($p < 0.001$) groups were different in comparison to SS-SS group at fraction 6 (saccharin exposure). Therefore, memory retrieval produces an elevation of norepinephrine levels in the IC during both artificial and natural-induced avoidance (Fig. 2C).

Regarding the dopamine release (Fig. 2D), two-way ANOVA revealed differences in dopamine levels among fractions ($F_{8,185}$) = 3.345, p = 0.015) with no group effect ($F_{2,185}$) = 0.414, p = 0.668) and no interaction effect ($F_{16,185}$) = 1.187, p = 0.288). Post-hoc analysis showed that MIX-MIX ($p < 0.001$) and LiCl 0.15 M (p = 0.01) groups were different in comparison to SS-SS group at fraction 6 when the animals were exposed to the conditioned stimulus. We observed a clear increase in dopamine extracellular levels within the IC when animals were exposed to the saccharin after artificial or natural induced avoidance.

In the behavioral assessment of these animals we observed significant differences in saccharin consumption during taste avoidance retrieval among groups ($F_{2,18}$) = 6.017, p = 0.039), post hoc analysis showed that saccharin consumption in LiCl 0.15 M (p = 0.021, d = 1.89) and MIX-MIX (p = 0.044, d = 1.046) groups were different from SS-SS group, whereas no difference was observed between LiCl 0.15 M and MIX-MIX groups (p = 0.588, d = 0.290) (Fig. 2E).

4. Discussion

During the last decades, memory research has focused on how cellular and molecular mechanisms are involved in the codification and consolidation of memory. In CTA memory establishment, the amygdalar glutamatergic activity has been related to visceral signaling of the US [3,5,8,11,25]; whereas noradrenergic transmission is probably implicated with a stress response due to the administration of the malaise-inducing agent [3]. Specifically, β-adrenergic and NMDA receptors within the amygdala play an essential role in the US processing [5,9–11]. However, it has been reported that microinfusions of glutamate into the amygdala did not generate taste aversion or avoidance, unless it was paired with a subthreshold dose of LiCl [10,5]. Our experiments confirm that concomitant activation of β-adrenergic and NMDA receptors at 15 min post-intake is not enough to induce an avoidance response during retrieval, and subsequent reactivation of these receptors appears to prompt the long-term memory.

Long-term memory stabilization involves post-acquisition reactivation patterns of activity [17] that can be reflected as extracellular changes in neurotransmitters after the CS-US pairing [3,4]. Coactivation of NMDA and β-adrenergic receptors during the post-acquisition reactivation timeframe has demonstrated to be necessary for taste aversion memory consolidation within the amygdala [3]. The present results further support the idea that glutamatergic and noradrenergic activities during the post-acquisition period are part of the

neurobiological mechanisms involved in the consolidation of taste aversive memory. According to our observations, it is indispensable to generate both the US signaling and the post-acquisition signaling in the amygdala to induce a reliable taste avoidance response reflecting or representing the establishment of a taste memory trace. Therefore, it is possible that US signaling through the activation of NMDA and β-adrenergic receptors initiates molecular pathways involved in synaptic modifications, whereas post-learning reactivation activity patterns underlies long-term memory persistence.

Although the period between administrations was calculated according to the US and post-acquisition events reported previously, it is possible that kinetics of drug's action may be altered by the co-administration of isoproterenol and LHa. It has been reported that isoproterenol promotes LHa release from astrocytes, as it is an endogenous excitatory aminoacid [26]. Therefore, it is possible that β-adrenergic activation leads to a higher concentration of LHa within the amygdala altering the kinetics of NMDA activation.

The activation of β-adrenergic and NMDA receptors leads to a synergistic effect for the establishment of taste avoidance memory. It has been demonstrated that synaptic plasticity is facilitated by β-adrenergic activation, probably as a result of the enhancement of P/Q type calcium currents in amygdalar neurons, generating an increase in intracellular calcium levels [27]. In addition, isoproterenol enhances synaptic transmission through an increase in presynaptic Ca^{2+} influx in the amygdala [28], producing a higher response mediated by AMPA [27] and NMDA currents [29]. Activation of β-adrenergic receptors

promotes the stimulation of adenylate cyclase that triggers cAMP formation and subsequent activation of cyclic-AMP-dependent kinase (PKA) and mitogen-activated protein kinase (MAPK) [30]. The activated PKA phosphorylates many synaptic and intracellular targets including cAMP response element binding pathway (CREB) [31,32]. The β-adrenergic activation causes the strengthening of intracellular

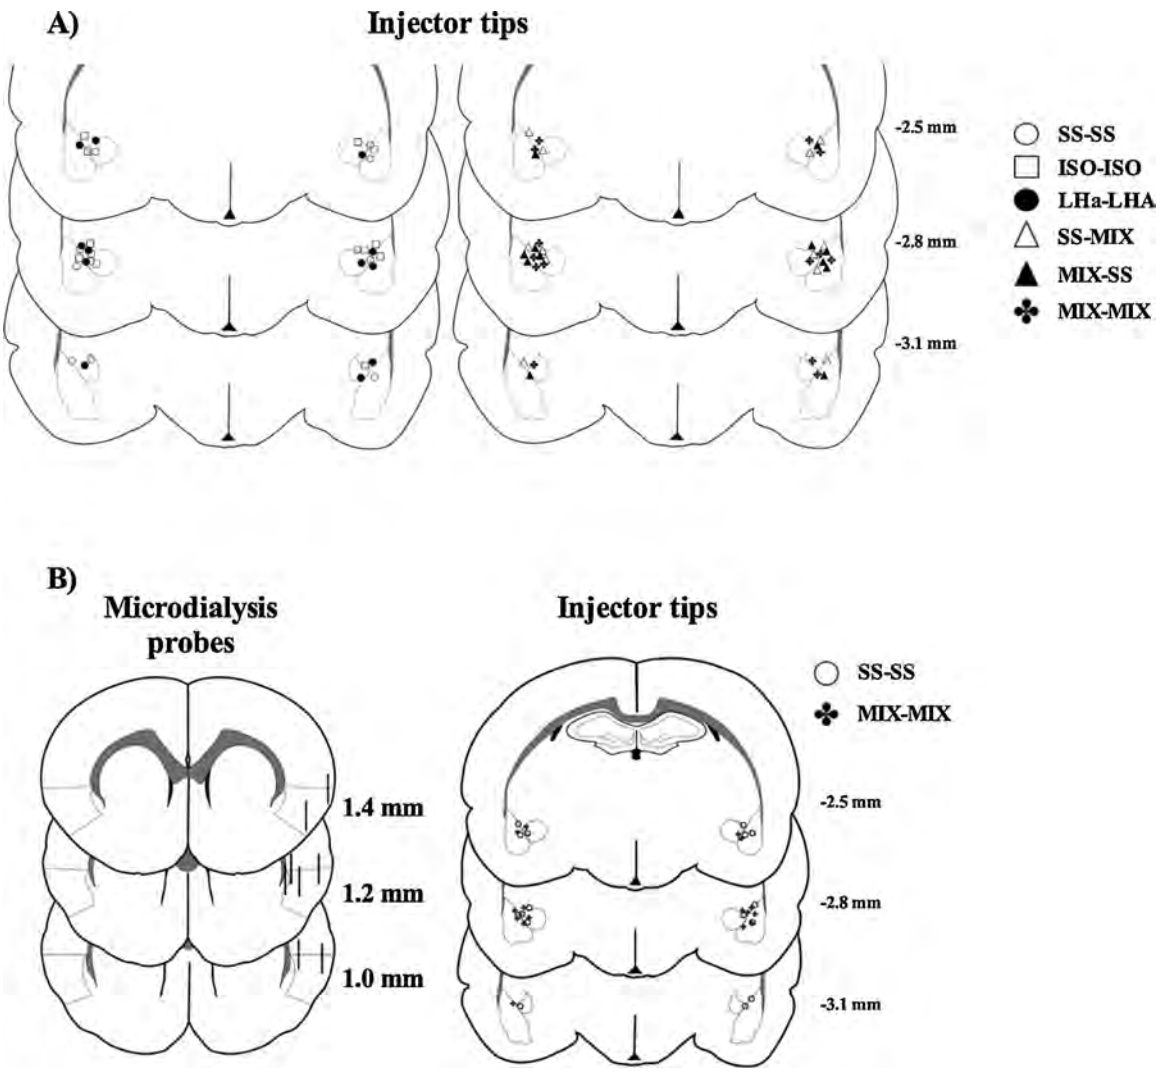

Fig. 3. Summary of injector tips and microdialysis probes. (A) Representation of the tips of the injectors aiming the amygdala in the pharmacological activation experiment. (B) Representation of the tips of the injectors aiming the amygdala and the microdialysis probes within the insular cortex.

processes, resulting in a greater response to a given input, in this case the activation of glutamatergic receptors. PKA also facilitates AMPA receptors trafficking [33] and phosphorylation of NMDA receptors by PKA enhances Ca^{2+} conductivity [34,35]. The increased intracellular flow of Ca^{2+} promotes the activation of adenylate cyclase through calcium / calmodulin kinase by improving cAMP production [36] and the subsequent intracellular events described before. Therefore, the synergistic activation of adenylate cyclase, as a consequence of the activation of β-adrenergic receptors and NMDA, improves the activity of MAPK, CREB and transcription factors; that determine in a coordinated way the transcription and translation of genes. All these processes culminate in the increase in protein synthesis required for neuronal remodeling within the neural networks necessary to acquire and consolidate taste avoidance memories [37].

In this regard, it has been proposed that a single molecular event triggered during acquisition may not be sufficient to maintain long-term memory; and the persistence of memory requires rounds of consolidation-like processes during different time windows [38–41]. Therefore, we suggest that emulation of US amygdalar events is necessary to initiate the molecular pathways involved in modifications of the amygdala-insular network and the coactivation of NMDA and β-adrenergic receptors during the post-learning period facilitates the taste avoidance memory consolidation through protein synthesis-dependent mechanisms.

Although unspecific modifications between the amygdala and different brain structures could be induced by our pharmacological manipulations, we focused on the response in the IC considering that taste aversion memory involves the functional integrity of this structure [42–46]; it is also possible that the communication of the amygdala-insular cortex had been modified affecting the trace of the taste in a way that an avoidance response is displayed in a second encounter.

The amygdala has afferents to the IC [47,48] and receives feedback information from the insula [49]. The functional connectivity between the amygdala and the IC has been demonstrated by the tetanic stimulation of the amygdala that generates a long-term potentiation in the IC, promoting an improved retention of CTA [19,50]. Although the amygdala-IC pathway appears to be predominantly glutamatergic [9,43,50], it can also be modulated by dopaminergic activity from the ventral area tegmental [51], and norepinephrine from the locus coeruleus [52]. During the time frame following the acquisition of CTA, levels of dopamine and glutamate involved in the maintenance of long-term memory also increase within the IC. Interestingly, when the amygdala is transiently inactivated, there is an impairment of the reactivation signaling within the IC and CTA memory consolidation [4]. All these results suggest that the interaction of the amygdala-IC plays an important role in the formation and stabilization of taste memories where an aversive outcome is avoided.

Recently, it has been demonstrated that during the taste aversion

INFORME DE LABORES 2019

retrieval, the presentation of a CS stored as aversive induces an elevation of glutamate, dopamine and norepinephrine levels within the IC [21]. As shown, the artificial induction of taste avoidance promoted a similar increase in glutamate during memory retrieval. Glutamatergic neurotransmission seems to be relevant for the retrieval and maintenance of CTA since the infusions of α-amino-3-hidroxi-5-metilo-4-isoxazolpropionic (AMPA) receptor antagonists in the IC hinders taste aversion retrieval [21,53]. Moreover, the presentation of an aversive or stressful stimulus causes an increase in norepinephrine levels in the forebrain [54], including the IC [55]. Similarly, injections of the malaise-inducing agent (the US) induce an increase in norepinephrine levels within the IC [4]. Thus, exposure to an aversively-conditioned taste stimulus generates an elevation of norepinephrine within the IC as reported previously [56]. In relation to dopamine release, a novel or salient stimulus cause activation of dopaminergic neurons [57,58]. Hence, consumption of an aversively conditioned taste stimulus promotes an increase in dopamine levels within the IC. This elevation of dopamine probably reflects the response to the salient stimulus generated by the relevance of the aversive taste. Therefore, the consumption of a taste stimulus associated with aversive signals, artificially stimulated or naturally associated with gastric malaise, produces an elevation of the extracellular levels of glutamate, norepinephrine and dopamine inside the IC. Our results demonstrate that the pharmacological activation of NMDA and β-adrenergic receptors in the amygdala could induce behavioral and neurochemical responses like a naturally-induced taste avoidance memory.

Even though other neurotransmitter systems are involved in CTA formation, such as acetylcholine [59,60], cortical extracellular changes of this neurotransmitter have been related mostly to the novelty of the stimulus [6] and apparently is not required during CTA retrieval [59,61]. Other monoamines, such as serotonin participate in the CTA formation within the IC or the amygdala, but have been less studied during the retrieval phase in the amygdala [62] or the insular cortex [63].

5. Conclusion

The confirmation of the functional role of the neurochemical signals that have been described during and after the acquisition of an aversive taste memory allow us to better understand the mechanisms that underly memory formation. We suggest that the induction of an artificial taste aversion memory, through pharmacological activation of NMDA and β-adrenergic receptors within the amygdala, promotes changes in the amygdala-insular cortex circuit enabling aversive memory establishment. It is important to note that during memory retrieval, behavioral and neurotransmitters patterns response within the IC are indistinguishable from an artificially induced or true avoidance memory.

HIGHLIGHTS

- Anisomycin induces state-dependent recognition memory.
- DRB, an elongation RNA inhibitor, induces state-dependent recognition memory.
- The duration of drug action is a boundary condition for the induction of state-dependent recognition memory.
- Drugs induce state-dependent memory only when infused at early consolidation window.

Recognition memory

ABSTRACT

It is well established that newly acquired information is stabilized over time by processes underlying memory consolidation, these events can be impaired by many drug treatments administered shortly after learning. The consolidation hypothesis has been challenged by a memory integration hypothesis, which suggests that the processes underlying new memories are vulnerable to incorporation of the neurobiological alterations induced by amnesic drugs generating a state-dependent memory. The present experiments investigated the effects of amnesic drugs infused into the insular cortex of male Wistar rats on memory for object recognition training. The findings provide evidence that infusions of several amnesic agents including a protein synthesis inhibitor, an RNA synthesis inhibitor, or an NMDA receptor antagonist administered both after a specific period of time and before retrieval induce state-dependent recognition memory. Additionally, when amnesic drugs were infused outside the early consolidation window, there was amnesia, but the amnesia was not state-dependent. Data suggest that amnesic agents can induce state-dependent memory when administered during the early consolidation window and only if the duration of the drug effect is long enough to become integrated to the memory trace. In consequence, there are boundary conditions in order to induce state-dependent memory.

1. Introduction

Memory consolidation refers to the post-learning processes by which recently acquired information is stabilized and strengthened into long-term memory (Müller and Pilzecker, 1900; McGaugh, 1966, 2000). There is extensive evidence that memory consolidation can be either impaired or enhanced by post-learning administration of treatments that affect neuronal functioning. Many kinds of treatments, including electroconvulsive shock (Duncan, 1949) and protein synthesis inhibitors impair consolidation when administered shortly after learning but not when administered several hours after learning (Agranoff, 1967; Davis and Squire, 1984; Packard and Teather, 1997; Lechner et al., 1999; Roullet et al., 2001). Some evidence suggests that memory consolidation may consist of multiple stages, at least during two sensitive windows in which amnesic agents can induce amnesia, one early phase immediately after memory acquisition and a second period of time between 120 and 240 min later (Bourtchouladze et al., 1998; Roullet et al., 2001; Igaz et al., 2002). Such findings indicate that there are different post-learning time-windows when memories are labile and vulnerable to amnesic events.

Early studies reported that administration of protein-synthesis inhibitors immediately after acquisition impairs long-term memory (Flexner et al., 1963; Agranoff et al., 1965). These findings, and those of many subsequent experiments using protein synthesis inhibitors, suggested that memory consolidation depends on *de novo* protein synthesis, in which newly synthesized proteins modify functional connectivity between neurons that were involved in learning (Dudai, 2004). Subsequent experiments investigated the effects of many different protein synthesis inhibitors, including anisomycin, acetoxycycloheximide, cycloheximide and puromycin. Each of these drugs blocks the translation of proteins by a different mechanism of action (see Davis and Squire, 1984; Rao and Grollman, 1967; Barbacid and Vazquez, 1975; Hazzalin et al., 1998; Alberini, 2008).

The findings of these and many other studies appear to provide compelling evidence that protein synthesis inhibitors impair memory by blocking memory consolidation. However, a recent study reported evidence that memory impairment induced by injections of cycloheximide after training was reversed by the re-administration of cycloheximide before retrieval. These findings suggest that under some conditions the amnesia induced by protein-synthesis inhibitors is due to a difference in the brain state induced by the protein synthesis inhibitor shortly after learning, i.e., during the consolidation process, and the brain state during subsequent testing. That is, the brain state occurring after learning, during consolidation, may be required for subsequent memory retrieval (Gisquet-Verrier and Riccio, 2012; Gisquet-Verrier et al., 2015).

Memory consolidation impairment has also been found in experiments using the RNA elongation inhibitor 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) (Sherry et al., 2010; Prado-Alcalá et al., 2017; Ozawa et al., 2017; Steinmetz et al., 2017). Also, NMDA receptor antagonists impair memory consolidation based on aversive (Ferreira et al., 2002; Guzmán-Ramos et al, 2010; Guzmán-Ramos et al., 2012), as well as non-aversive training experiences (Baker and Kim, 2002; Winters and Bussey, 2005). The possibility that memory consolidation impairments induced by treatments affecting RNA elongation and NMDA receptors might also be the consequence of state-dependent memory induction, as suggested by the memory integration hypothesis), has not, as yet been investigated (Gisquet-Verrier et al., 2015). To investigate this issue the present experiments examined the effects of several amnesic agents to determine whether integration hypothesis might account for their influences on memory.

The experiments investigated drug influences on the consolidation of object recognition memory (ORM) (Brown and Aggleton, 2001). ORM is assessed by a single brief training session and a testing session and does not use aversive or rewarded training. Rodents have a natural tendency to explore novel objects rather than previously encountered ones. Consolidation of ORM involves several brain areas including the insular cortex (Bermudez-Rattoni et al., 2005; Balderas et al., 2008). The insular cortex has been proposed as a dynamic center in the salience network (Menon, 2015) that is critical to process novel-familiar information in recognition memory (Bermudez-Rattoni et al., 2005; Balderas et al., 2008; Bermudez-Rattoni, 2014; Schmahmann et al., 2007). The aim of this study was to determine whether amnesic treatments other than protein synthesis inhibitors also induce state-dependent recognition memory when infused into the insular cortex and provide additional understanding of dissociation between memory consolidation impairments and state-dependent memory.

2. Material and methods

2.1. Animals

A total amount of 210 adult male Wistar rats weighing 260–280 g were used in this study. Animals were obtained from the Instituto de Fisiología Celular and were housed individually at 22 °C in a 12 h light/12 h dark cycle starting at 7 a.m. All procedures were performed during the light cycle and were approved by the animal care and ethics committee of the institute (IFC-FBR 30–14). Rats had *ad libitum* access to water and food.

2.2. Guide cannulae implantation

Rats were implanted bilaterally with 9 mm (23G) steel cannulae aiming at the insular cortex using standard stereotaxic procedures. The coordinates for the insular cortex were AP + 1.2 mm; L ± 5.5 mm; DV -3 mm from Bregma (Paxinos and Watson, 1998). Cannulae were fixed to the skull using two screws with dental acrylic cement. Stylets were inserted to prevent clogging. Animals were allowed to recover from surgery for six days before behavioral protocols.

2.3. Object recognition memory protocol

The apparatus and general protocol used have been reported previously (Balderas et al., 2008, 2012). Briefly, all procedures were conducted in the experimental room where animals were left for 1 h before and 1 h after each session. During three consecutive days, animals were introduced into the open-field arena without any objects for 10 min and afterwards, rats were handled for 3 min to avoid handling-stress effects at the infusion sessions. During the sample session, rats were placed in the arena facing to the wall opposite the objects and were allowed to freely explore two identical objects (O1 and O2) for 5 min. Memory recognition test session was conducted 24 h later. At memory test, rats were allowed to explore freely one copy of the previously presented object (Familiar object, FO) together with a new one (Novel object, NO) for 5 min. The objects to be discriminated were white glass bulbs (6 cm in diameter and 11 cm in length) and transparent glass jars (5.5 cm in diameter and 5 cm in height). All objects were fixed to the floor at the back corners of the arena (10 cm from walls) with Velcro to prevent them from being displaced by the rats. To avoid olfactory cues, objects were thoroughly cleaned with 70% ethanol and the sawdust was stirred after each trial. Object exploration was defined as directing the nose at a distance of less than 1 cm from the object or touching the object with the nose. Object exploration was not scored when animals sat on the object or when the rats used the object to move backwards with the rat's nose facing the ceiling (Balderas et al., 2008; Albasser et al., 2010).

2.4. General microinfusion procedure

During infusion session, stylets were removed, and injectors were inserted into cannulae aiming at the insular cortex extending 2 mm bellow the tip. Injection needles were connected via polyethylene tubing to 10 μL Hamilton syringes, driven by an automated micro-infusion pump (Carnegie Medicine, Stockholm, SE). A volume of 1 μL (0.5 μL/min) was injected per hemisphere in the insular cortex (Balderas et al., 2008; García de la Torre et al., 2009), the volume and site of infusion have been demonstrated to be restricted to the insular cortex (Adaikkan and Ronseblum, 2015; Merhav and RosenblumK, 2008; Levitan et al., 2016); the injectors were left for another minute to allow diffusion into the tissue. Stylets were inserted again to prevent clogging. Infusion times are described later.

2.5. Drugs

Protein synthesis inhibitor anisomycin (ANI 120 mg/mL, Sigma-Aldrich, Missouri, US) was dissolved in an equimolar HCl-Ringer solution (NaCl 118 mM, KCl 4.7 mM, $NaH_2PO_4H_2O$ 1.2 mM, $MgSO_47H_2O$ 1.2 mM, $NaHCO_3$ 19 mM, $CaCl_2$ 2.5 mM, glucose 3.3 mM; pH was adjusted to 7.4). Vehicle solution was Ringer solution with HCl and adjusted pH to 7.4 (VEH). The RNA elongation inhibitor 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB 40 ng/μL, Sigma-Aldrich, Missouri, US) was dissolved in 1 M PBS and 8% of dimethyl sulfoxide (DMSO,

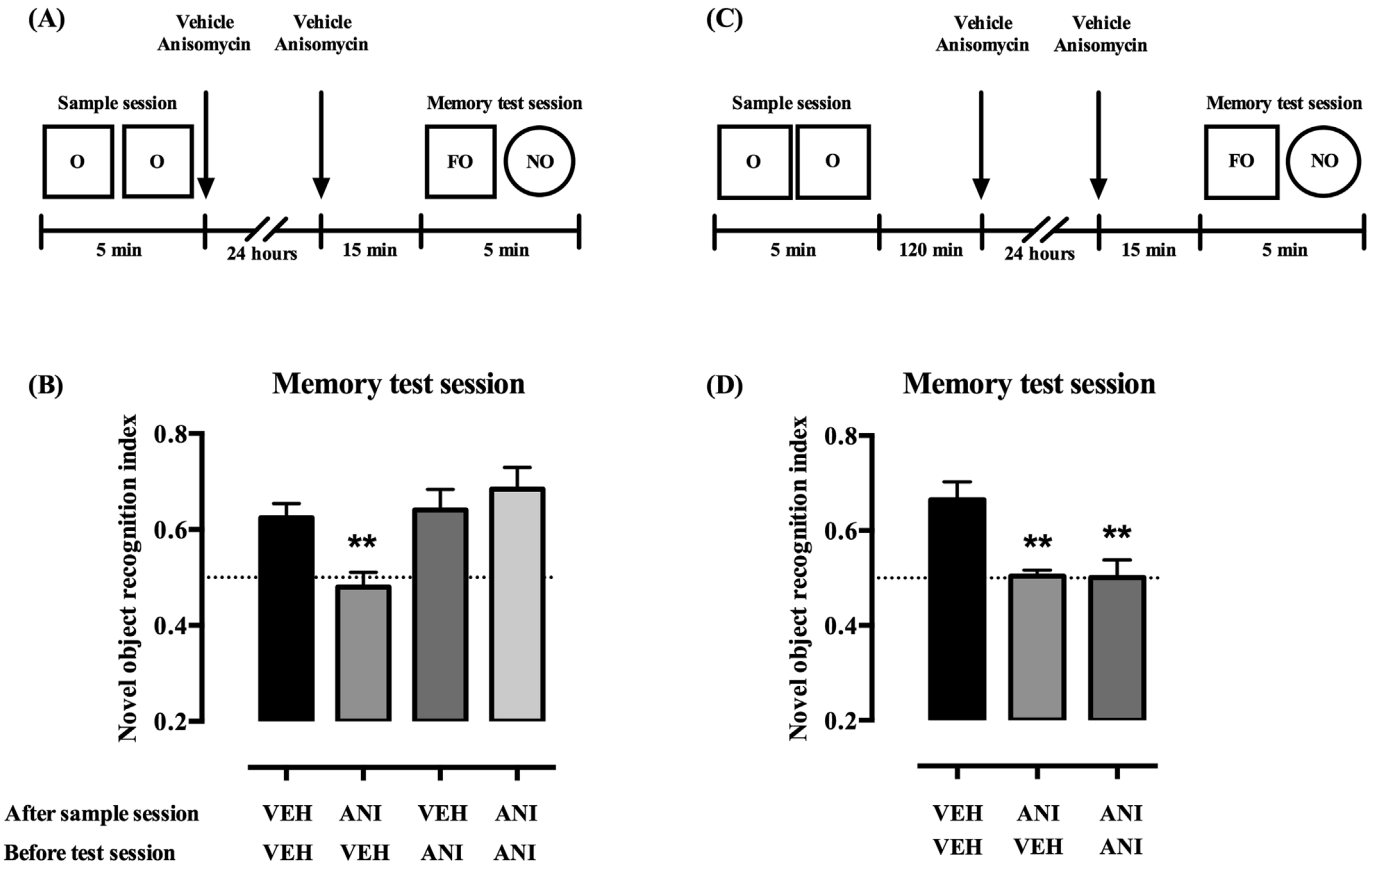

Fig. 1. Protein-synthesis inhibitor induces state-dependent memory when infused into the insular cortex during early consolidation window. (A) Schematic representation of the behavioral and intra-cortical infusion protocol used. (B) Novel object recognition index during memory recognition test session, VEH-VEH, VEH-ANI, and ANI-ANI groups showed preference for the novel object; whereas the group ANI-VEH did not. (C) Schematic representation of the behavioral and intra-cortical infusion protocol used in anisomycin administration at 120 min. (D) Novel object recognition index during memory recognition test session, the group VEH-VEH (120 min) showed preference for the novel object; whereas the groups ANI-VEH (120 min) and ANI-ANI (120 min) did not show preference for any object. Object (O), Familiar Object (FO) and Novel object (NO). Arrows represent micro-infusions into the insular cortex. Graphics are expressed as means of recognition index ± SEM. Dotted line represents exploration chance (0.5); **p < 0.01 versus VEH-VEH.

Sigma-Aldrich, Missouri, US). Vehicle solution was PBS 1 M with 8% DMSO (VEH). The NMDA receptor antagonist, DL-2-amino-5-phosphonovaleric acid (APV 10 mg/mL, Tocris Bioscience; Bristol, UK) was dissolved in saline solution (0.9% wt/vol). Saline solution was used as vehicle (VEH). We have administered the doses that have been shown to induce amnesia in various tasks and brain structures (Tronel and Sara, 2003; Guzmán-Ramos et al., 2010; Igaz et al., 2002; Prado-Alcalá et al., 2017; Balderas et al., 2008), since higher doses could cause nonspecific reactions masking state-dependent memory.

2.6. Drug injection protocol

In order to determine whether the infusion of anisomycin, DRB or APV induces state-dependent recognition memory, we used the following administration protocol. All drugs or vehicle were infused into the insular cortex immediately after ORM sample phase and 15 min before ORM retrieval. This yielded VEH-VEH, ANI-VEH, VEH-ANI, ANI-ANI, DRB-VEH, VEH-DRB, DRB-DRB, APV-VEH, VEH-APV and APV-APV groups (Please see, Fig. 1A, Fig. 2A, and Fig. 3A).

It has been suggested that amnesic drugs generate amnesia during the early stages of consolidation (Tronel and Sara, 2003). Thus, it is possible that induction of state-dependent memory occurs during the same sensitive window. To determine whether infusion of anisomycin or DRB outside the early consolidation window (120 min, Bourtchouladze et al., 1998; Igaz et al., 2002; Roullet et al., 2001) induces state-dependent recognition memory. We administrated vehicle, anisomycin or DRB into the insular cortex 120 min after ORM sample phase and 15 min before ORM retrieval. In order to reduce animal testing, we focused only on the groups VEH-VEH, ANI-VEH, ANI-ANI, DRB-VEH and DRB-DRB (see, Figs. 1C and 2C); since we have previously shown that administration of ANI before ORM retrieval did not affect memory expression (VEH-ANI), and DRB infusion before test (VEH-DRB) disrupts memory retrieval.

As anisomycin and DRB inhibit protein synthesis by different mechanisms, it is important to determine what anisomycin and DRB might have in common that underlies induction of state-dependent memory in comparison to APV. A possible explanation for this effect is the half-life of these drugs, as it has been reported that anisomycin (Wanisch and Wotjak, 2008) and DRB (Nguyen et al., 1994) induce sustained protein synthesis inhibition effect (hours), whereas the APV plasticity inhibition lasted ~60 min (Ji et al., 2005). Therefore, we investigated whether a prolonged exposure to APV, by a double administration into the insular cortex, could induce a state-dependent recognition memory. In brief, vehicle or APV were administrated after ORM sample phase, 60 min after ORM sample phase and 15 min before ORM retrieval. We aimed to evaluate VEH-VEH-VEH, VEH-APV-VEH, VEH-APV-APV, APV-APV-VEH and APV-APV-APV groups considering that administration of APV immediately after ORM sample phase induced recognition amnesia (APV-VEH), memory impairment could not be reversed by the administration of APV before retrieval (APV-APV) and APV infusion did not affect memory retrieval (VEH-APV); hence the APV-VEH-VEH, APV-VEH-APV and VEH-VEH-APV groups were omitted in the study due to the above-mentioned reasons (Please see Fig. 3C).

Considering that early consolidation phase is vulnerable to

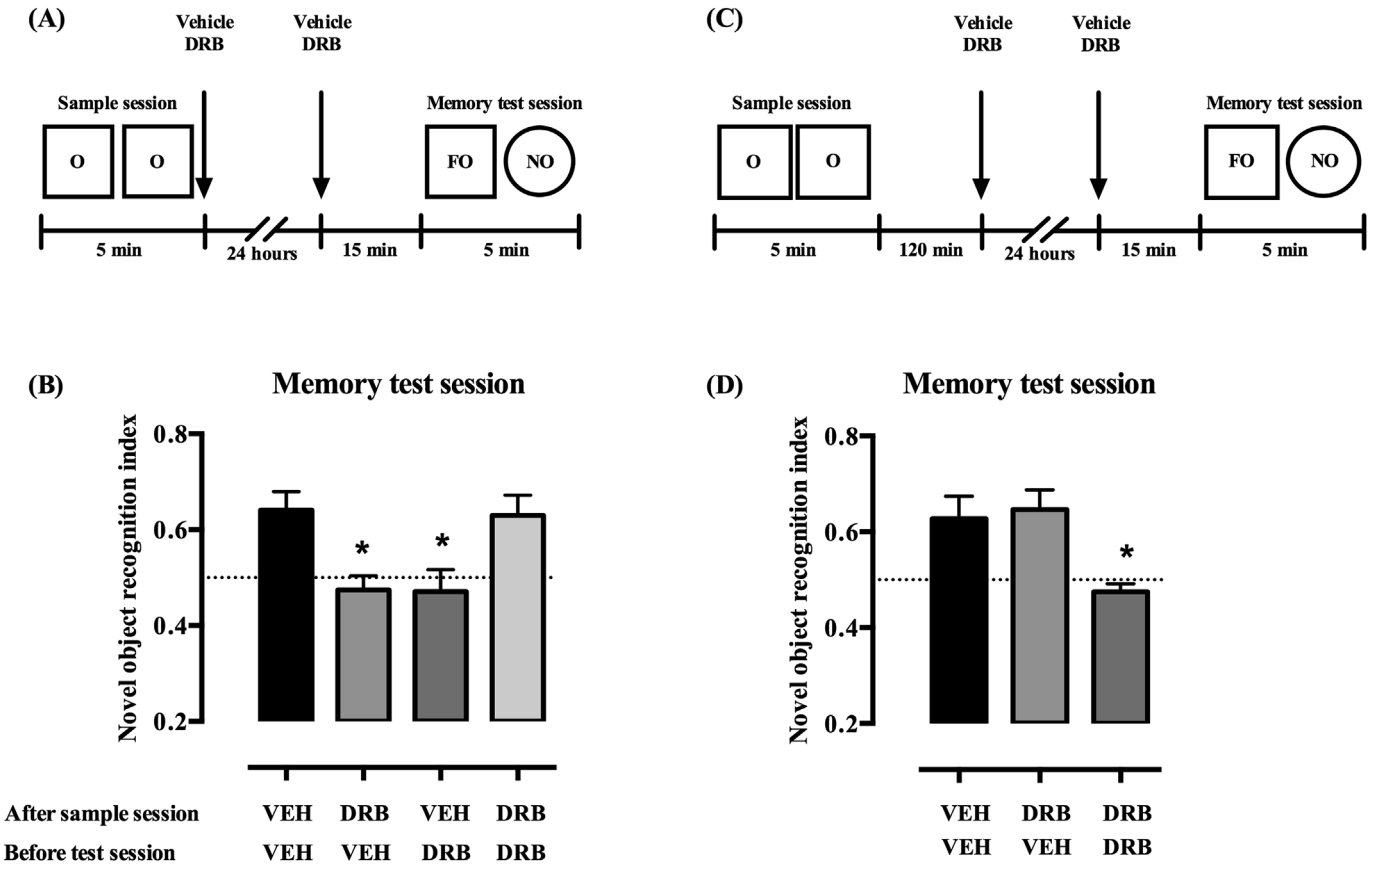

Fig. 2. RNA elongation inhibitor induces state-dependent memory when infused into the insular cortex during early consolidation window. (A) Schematic representation of the behavioral and intra-cortical infusion protocol used. (B) Novel object recognition index during memory recognition test session, the groups VEH-VEH and DRB-DRB showed preference for the novel object; whereas VEH-DRB and DRB-VEH groups did not. (C) Schematic representation of the behavioral and intra-cortical infusion protocol used in DRB administration at 120 min. (D) Novel object recognition index during memory recognition test session, VEH-VEH and DRB-VEH groups (120 min) showed preference for the novel object; whereas DRB-DRB (120 min) group did not. Object (O), Familiar Object (FO) and Novel object (NO). Arrows represent micro-infusions into the insular cortex. Graphics are expressed as means of recognition index ± SEM. Dotted line represents exploration chance (0.5); *p < 0.05 versus VEH-VEH.

induction of state-dependent recognition memory, we evaluated whether state-dependent recognition memory can occur when APV administrations are separated by a longer time window (120 min). We infused vehicle or APV into the insular cortex immediately after ORM sample phase, 120 min after ORM sample phase and 15 min before ORM retrieval. We determined the following groups: VEH-VEH′-VEH, VEH-APV′-VEH, VEH-APV′-APV, APV-VEH′-APV, APV-APV′-VEH and APV-APV′-APV (Please see Fig. 4A). VEH-VEH′-APV and APV-VEH′-VEH groups were excluded because we have observed that APV spared recognition memory retrieval (VEH-APV) and APV impaired memory recognition establishment (APV-VEH) (See, Fig. 3B).

2.7. Histology

At the end of the experiments, animals were injected i.p. with an overdose of sodium pentobarbital, and perfused intracardially with 0.9% saline solution. The brains were removed and stored at 4 °C in 4% paraformaldehyde in phosphate buffered saline. After treatment with sucrose gradient, 40 μm coronal sections were cut and stained with cresyl violet. Samples were examined by light microscopy to corroborate placement of the cannulae.

2.8. Experimental design and statistical analysis

For all experiments, objects and open-fields arenas were counterbalanced. Animals were randomly assigned to each treatment group. Timing and video analysis were conducted by an experimenter who was blind to the treatment condition. Recognition indexes for each object were calculated as follows: time of exploration of the object/total time of exploration during test. Also, we calculated the percentage of exploration time in comparison to vehicle group. Percentage of vehicle exploration time = (Total exploration time of experimental group/Total exploration time of vehicle group) * 100. We compared the novel object recognition indexes to a hypothetical value of 0.5 (chance level) using One-sample Student's *t*-test in order to determine preference for an object. Additionally, we used One-way ANOVA with Dunnett's *post hoc* test to compare the mean novel object exploration indexes versus the mean exploration index of control group. We compared the mean percentage of exploration time during ORM test amongst groups with One-way ANOVA with Dunnett's *post hoc* test. The accepted level of significance was p value ≤ 0.05. Data are presented as mean ± SEM. Effect size was determined by calculating Cohen's *d* statistic. Statistical analysis was performed using GraphPad Prism version 6.00, GraphPad software.

3. Results

3.1. Verification of cannula placements

Coronal sections (40 μm) were cut and stained with cresyl violet. The location sites of the cannulae for the micro-infusions were observed in the insular cortex region (Please see Fig. 5). Twelve animals with misplaced cannulae were not included in further analyses.

INFORME DE LABORES 2019

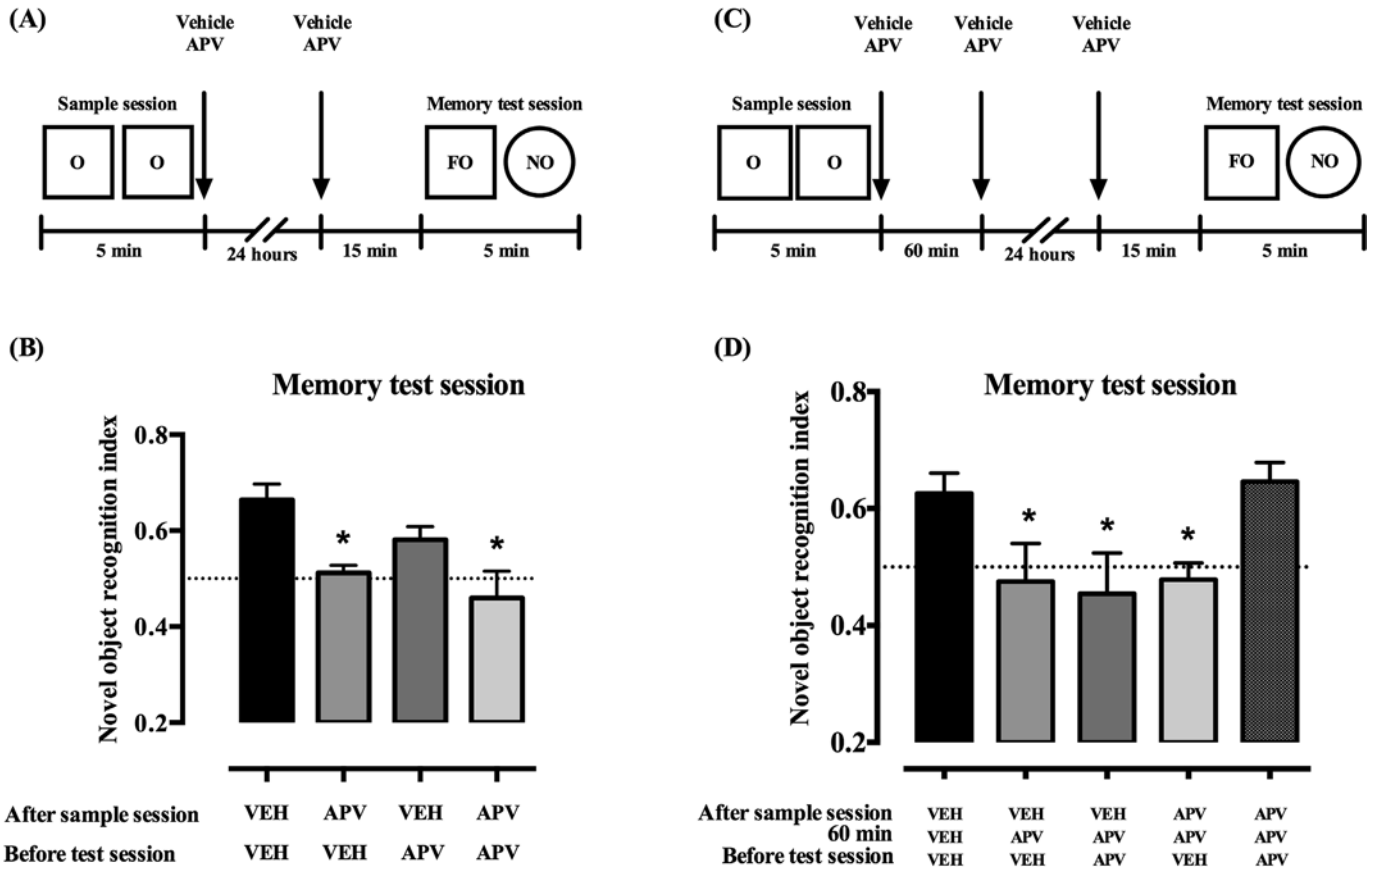

Fig. 3. Prolonged exposure to APV generates state dependent recognition memory. (A) Schematic representation of the behavioral and intra-cortical infusion protocol used. (B) Novel object recognition index during memory recognition test session, VEH-VEH and VEH-APV groups showed preference for the novel object; whereas APV-VEH, and APV-APV groups did not show preference for novel object. (C) Schematic representation of the behavioral and intra-cortical infusion protocol used in prolonged exposure to APV experiments. (D) Novel object recognition index during memory recognition test session, VEH-VEH-VEH and APV-APV-APV groups showed preference for the novel object; whereas VEH-APV-VEH, VEH-APV-APV and APV-APV-VEH groups did not show preference. Object (O), Familiar Object (FO) and Novel object (NO). Arrows represent micro-infusions within the insular cortex. Graphics are expressed as means of recognition index ± SEM. Dotted line represents exploration chance (0.5); *p < 0.05 versus VEH-VEH or VEH-VEH-VEH, respectively.

3.2. Induction of state-dependent memory with anisomycin

During object recognition memory retrieval, the groups VEH-VEH (n = 8; $t = 4.225$; $p = 0.003$; Mean = 0.625; SD = 0.083; $d = 1.494$; *t*-test), VEH-ANI (n = 8; $t = 3.278$; $p = 0.013$; Mean = 0.641; SD = 0.122; $d = 1.159$; *t*-test), and ANI-ANI (n = 8; $t = 4.040$; $p = 0.004$; Mean = 0.684; SD = 0.129; $d = 1.485$; *t*-test) explored the novel object above the chance; whereas the group ANI-VEH (n = 8; $t = 0.655$; $p = 0.5337$; Mean = 0.480; SD = 0.086; $d = -0.231$; *t*-test) did not (Fig. 1, (B) Memory test session). One-way ANOVA analysis showed significant differences in novel object recognition indexes among groups ($F_{(3,28)} = 5.481$, $p = 0.004$, overall effect size $d = 0.718$). Dunnett's multiple comparison test revealed differences in the ANI-VEH group ($p = 0.030$; $d = 0.479$) compared with the VEH-VEH group. The groups VEH-ANI ($p = 0.988$; $d = 0.053$ ANI-ANI ($p = 0.556$; $d = 0.196$ and VEH-VEH exhibited similar novel recognition indexes. ANOVA analysis showed that all groups spent a similar percentage of vehicle exploration time during test session ($F_{(3,28)} = 1.725$, $p = 0.199$) (Table 1). These data indicate that VEH-VEH, VEH-ANI and ANI-ANI groups recognized the novel object, whereas ANI-VEH group did not. These results show that anisomycin did not affect ORM retrieval, and ORM was consolidated in a state-dependent manner. Anisomycin induced recognition memory deficits and could be reversed by the re-administration of anisomycin before retrieval, exhibiting an anisomycin state-dependent memory.

3.3. Anisomycin impairs memory consolidation at 120 min after acquisition

Concerning anisomycin experiments outside early consolidation window (120 min), only the VEH-VEH (n = 7; $t = 4.392$; $p = 0.004$; Mean = 0.665; SD = 0.099; $d = 1.660$; *t*-test) explored the novel object above the chance; regardless of ANI-VEH (n = 7; $t = 0.272$; $p = 0.794$; Mean = 0.503; SD = 0.033; $d = 0.103$; *t*-test) and ANI-ANI (n = 7; $t = 0.020$; $p = 0.984$; Mean = 0.501; SD = 0.098; $d = 0.008$; *t*-test) groups (Fig. 1, (D) Memory recognition test session). Statistical analysis revealed significant differences in novel object recognition indexes among groups ($F_{(2,18)} = 9.002$, $p = 0.002$, ANOVA; overall effect size $d = 0.928$); Dunnett's multiple comparison test showed that VEH-VEH group was different in comparison to ANI-VEH ($p = 0.003$; $d = 0.797$) and ANI-ANI ($p = 0.003$; $d = 0.809$) groups. During memory recognition test session, all groups spent a similar percentage of vehicle exploration time ($F_{(2,18)} = 0.615$, $p = 0.552$, ANOVA; Table 1). These results show that during memory recognition test, VEH-VEH recognized the novel object, whereas ANI-VEH and ANI-ANI groups did not. Therefore, exposure to anisomycin 120 min after sample phase disrupted consolidation of recognition memory. However, memory deficits could not be reversed by the re-administration of anisomycin before memory retrieval. These results suggest that infusion of anisomycin into the insular cortex outside the early consolidation induced amnesia, but the amnesia was not state-dependent. Data obtained in this study evidence that anisomycin induces a state-dependent recognition memory only when administrated immediately after acquisition, and interrupts

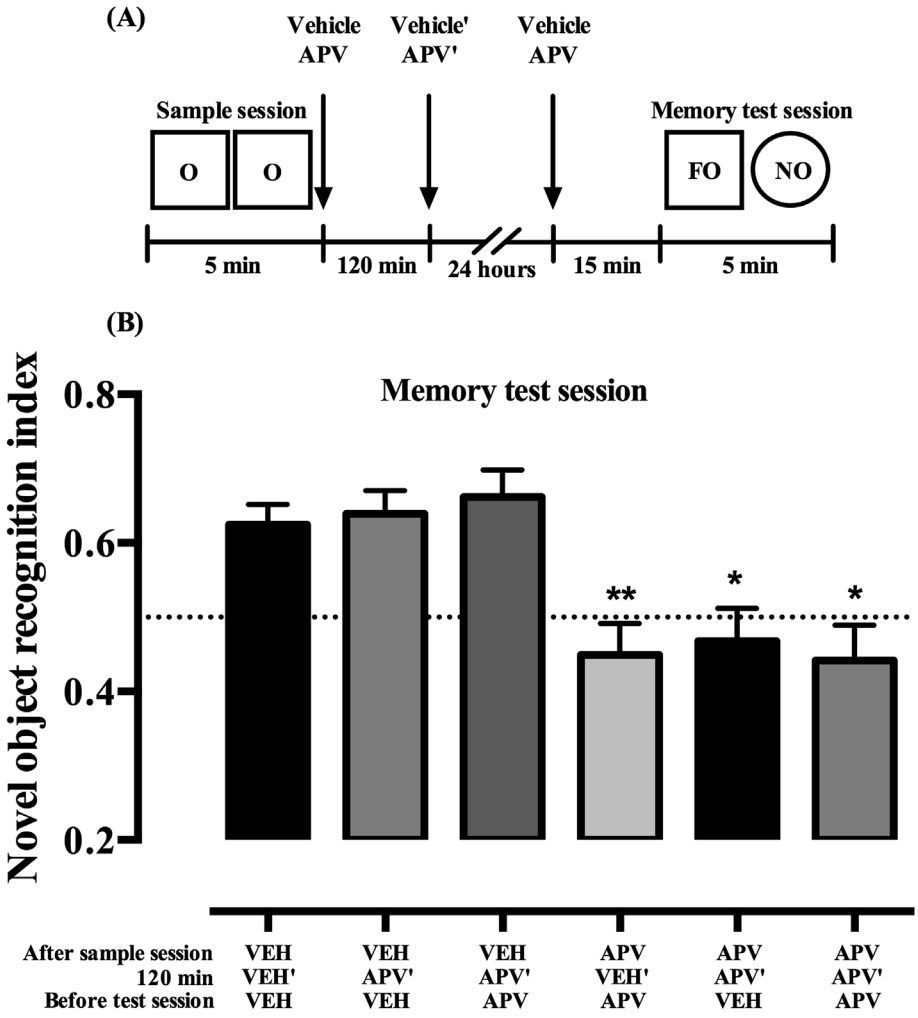

Fig. 4. Prolonged exposure to APV outside early consolidation window does not induce state-dependent recognition memory. (A) Schematic representation of the behavioral and intra-cortical infusion protocol used. (B) Novel object recognition index during memory recognition test session, VEH-VEH′-VEH, VEH-APV′-VEH and VEH-APV′-APV groups showed preference for the novel object; whereas APV-VEH′-APV, APV-APV′-VEH and APV-APV′-APV groups did not show preference. Object (O), Familiar Object (FO) and Novel object (NO). Arrows represent micro-infusions into the insular cortex. Graphics are expressed as means of recognition index ± SEM. Dotted line represents exploration chance (0.5); **p < 0.01 and * p < 0.05 versus VEH-VEH′-VEH, respectively.

recognition memory consolidation when infused at a later stage of consolidation.

3.4. Induction of state-dependent memory with DRB

Amongst DRB experiments, the groups VEH-VEH (n = 7; $t = 3.586$; $p = 0.031$; Mean = 0.641; SD = 0.104; $d = 1.355$; *t*-test) and DRB-DRB (n = 6; $t = 3.048$; $p = 0.028$; Mean = 0.629; SD = 0.104; $d = 1.245$; *t*-test) explored the novel object above the chance, whereas VEH-DRB (n = 7; $t = 0.647$; $p = 0.541$; Mean = 0.470; SD = 0.121; $d = -0.244$; *t*-test) and DRB-VEH (n = 7; $t = 0.865$; $p = 0.42$; Mean = 0.474; SD = 0.078; $d = -0.327$; *t*-test) groups did not. One-way ANOVA analysis showed that novel object recognition indexes were different among groups ($F_{(3,23)} = 4.378$, $p = 0.004$; overall size effect $d = 0.792$) (Fig. 2, (B) Memory test session); Dunnett's test revealed differences in VEH-DRB ($p = 0.013$; $d = 0.595$) and DRB-VEH ($p = 0.016$; $d = 0.580$) groups compared to VEH-VEH group. Animals in the VEH-VEH and DRB-DRB groups exhibited similar novel recognition indexes ($p = 0.995$; $d = 0.036$). During test session, percentage of vehicle exploration times were similar in all groups ($F_{(3,23)} = 0.388$, $p = 0.762$, ANOVA) (Table 2). These results indicate that VEH-VEH and DRB-DRB groups recognized the novel object during memory evaluation, whereas VEH-DRB and DRB-VEH groups did not differentiate the novel object from the familiar one. Our results show that DRB administration established a state-dependent recognition memory. ORM could be retrieved only when the same condition induced by DRB is present during consolidation and retrieval.

3.5. DRB does not induce state-dependent memory when infused 120 min after acquisition

Data obtained from intracortical administration of DRB outside early consolidation window (120 min) shows that VEH-VEH (n = 8; $t = 2.722$; $p = 0.029$; Mean = 0.627; SD = 0.133; $d = 0.962$; *t*-test) and DRB-VEH (n = 8; $t = 3.535$; $p = 0.009$; Mean = 0.646; SD = 0.117; $d = 1.249$; *t*-test) groups explored the novel object above the chance; DRB-DRB group did not show preference for the novel object (n = 7; $t = 1.494$; $p = 0.185$; Mean = 0.475; SD = 0.442; $d = -0.565$; *t*-test) (Fig. 2, (D) Memory recognition test session). Statistical analysis revealed significant differences in novel object recognition indexes among groups ($F_{(2,21)} = 3.972$, $p = 0.034$, ANOVA; overall size effect $d = 0.715$); Dunnett's test showed that VEH-VEH group was different in comparison to DRB-DRB ($p = 0.023$; $d = 0.587$), whereas VEH-VEH and DRB-VEH explored the novel object similarly ($p = 0.917$; $d = 0.074$). During memory recognition test session, all groups spent a similar percentage of vehicle exploration time ($F_{(2,21)} = 0.661$, $p = 0.526$, ANOVA; Table 2). In summary, VEH-VEH and DRB-VEH recognized the novel object, whereas DRB-DRB group did not. These results indicate that DRB infusion 120 min after sample phase did not impair consolidation of recognition memory and did not induce state-dependent recognition memory. Memory deficits observed in the DRB-DRB group are the consequence of DRB impairment on memory retrieval as described previously in Fig. 2 (B, VEH-DRB group). We observed that DRB infusion induces a state-dependent recognition memory only when administered immediately after memory acquisition.

INFORME DE LABORES 2019

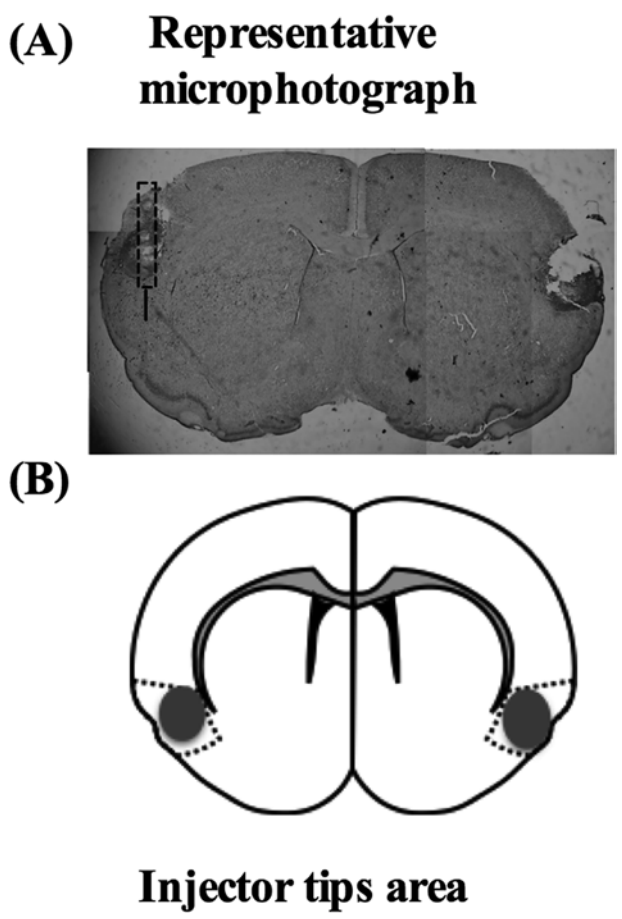

Fig. 5. Representation of the injector tips within the insular cortex. (A) Representative microphotographs of the insular cortex with injector tip. (B) Representation of injector tips location areas.

Taken together, administration of protein synthesis and RNA elongation inhibitors in the insular cortex induces a state-dependent-recognition memory only when infused immediately after acquisition, whereas pharmacological manipulation outside the early consolidation period does not induce state-dependent recognition memory.

3.6. APV impairs memory consolidation, but the amnesia is not state-dependent

Regarding APV experiments, statistical analysis showed that VEH-VEH (n = 7; $t = 3.154$; $p = 0.019$; Mean = 0.664; SD = 0.0818; $d = 2.002$; *t*-test) and VEH-APV groups (n = 6; $t = 2.936$; $p = 0.032$; Mean = 0.581; SD = 0.067; $d = 1.199$; *t*-test) explored the novel object above the chance; whereas APV-VEH (n = 7; $t = 0.722$; $p = 0.497$; Mean = 0.5117; SD = 0.043; $d = 0.274$; *t*-test) and APV-APV (n = 6; $t = 0.726$; $p = 0.500$; Mean = 0.459; SD = 0.135; $d = -0.296$; *t*-test) did not recognize the novel object above the chance (Fig. 3, (B) Memory recognition test session). One-way ANOVA analysis showed that there were significant differences in novel object recognition indexes among groups ($F_{(3,22)} = 4.132$, $p = 0.018$; overall size effect $d = 0.853$); Dunnett's post hoc analysis unveil differences in the APV-VEH ($p = 0.013$; $d = 0.619$) and APV-APV ($p = 0.011$; $d = 0.799$) groups compared to the VEH-VEH group; whereas VEH-VEH and VEH-APV ($p = 0.257$; $d = 0.326$) exhibited similar novel recognition indexes. All groups spent a similar percentage of vehicle exploration time during memory evaluation ($F_{(3,22)} = 0.427$, $p = 0.735$, ANOVA; Table 3). These results indicate that during memory recognition test, VEH-VEH and VEH-APV groups recognized the novel object, whereas APV-VEH and APV-APV groups did not. These results enlighten that APV did not hinder ORM retrieval but impaired recognition memory establishment. Memory deficits could not be rescued by the re-administration of APV before retrieval. Therefore, APV induced amnesia in a non-state dependent manner.

3.7. The increase of APV duration effects establishes a state-dependent memory

Statistical analysis show that VEH-VEH-VEH (n = 6; $t = 3.631$; $p = 0.015$; Mean = 0.626; SD = 0.085; $d = 1.482$; *t*-test) and APV-APV-APV (n = 7; $t = 4.473$; $p = 0.004$; Mean = 0.646; SD = 0.086; $d = 1.00$; *t*-test) groups explored the novel object above the chance, whereas VEH-APV-VEH (n = 7; $t = 0.382$; $p = 0.715$; Mean = 0.475; SD = 0.172; $d = -0.144$; *t*-test), VEH-APV-APV (n = 7; $t = 0.655$; $p = 0.536$; Mean = 0.454; SD = 0.184; $d = -0.248$; *t*-test) and APV-APV-VEH (n = 7; $t = 1.779$; $p = 0.135$; Mean = 0.478; SD = 0.747; $d = -0.290$; *t*-test) groups did not. One-way ANOVA analysis showed that exploration indexes for the novel object were different among groups ($F_{(5,37)} = 3.351$, $p = 0.026$; overall size effect $d = 0.768$) (Fig. 3, (D) Memory test session); Dunnett's multiple comparison analysis revealed novel object recognition index differences in the VEH-APV-VEH ($p = 0.042$; $d = 0.435$), VEH-APV-APV ($p = 0.025$; $d = 0.495$) and APV-APV-VEH ($p = 0.046$; $d = 0.425$) groups compared with VEH-VEH-VEH group; whereas VEH-VEH-VEH and APV-APV-APV groups exhibited similar novel recognition indexes ($p = 0.936$; $d = 0.059$). ANOVA analysis showed no differences in the percentage of vehicle exploration time among groups ($F_{(4,29)} = 0.825$, $p = 0.5219$) (Table 4). These results indicate that VEH-VEH-VEH and APV-APV-APV groups recognized the novel object during the memory test, while VEH-APV-VEH, VEH-APV-APV, and APV-APV-VEH did not. These data provide evidence that a single administration of APV at 60 min after acquisition impaired recognition memory, which was not state-dependent. However, an extended duration of APV effects by a double administration of APV, immediately and 60 min after acquisition, induced a state-dependent recognition memory. Our results suggest that the duration of drug effects is a boundary condition in state-dependency formation.

3.8. Prolonged APV duration effects can induce state-dependent memory only when administered during the early consolidation window

Statistical analysis in APV experiments outside early consolidation window (120 min) showed that VEH-VEH′-VEH (n = 7; $t = 4.526$; $p = 0.004$; Mean = 0.624; SD = 0.073; $d = 1.710$; *t*-test), VEH-APV′-VEH (n = 7; $t = 4.420$; $p = 0.004$; Mean = 0.639; SD = 0.083; $d = 1.671$; *t*-test), VEH-APV′-APV groups (n = 8; $t = 4.396$; $p = 0.003$; Mean = 0.662; SD = 0.104; $d = 1.554$; *t*-test) explored the novel object above the chance; in spite of APV-VEH′-APV (n = 7; $t = 1.194$; $p = 0.277$; Mean = 0.449; SD = 0.112; $d = -0.451$; *t*-test), APV-APV′-VEH (n = 7; $t = 0.046$; $p = 0.964$; Mean = 0.467; SD = 0.108; $d = -0.300$; *t*-test) and APV-APV′-APV (n = 7; $t = 0.329$; $p = 0.752$; Mean = 0.442; SD = 0.117; $d = -0.500$; *t*-test) groups (Fig. 4, (B) Memory recognition test session). Statistical analysis revealed significant differences in novel object recognition indexes among groups ($F_{(5,37)} = 5.056$, $p = 0.001$, ANOVA; overall size effect $d = 0.950$); Dunnett's test revealed that APV-VEH′-APV ($p = 0.010$; $d = 0.508$) APV-APV′-VEH ($p = 0.032$; $d = 0.437$) and APV-APV′-APV ($p = 0.011$; $d = 0.509$) groups were different in comparison to VEH-VEH′-VEH group. In addition, VEH-APV′-APV ($p = 0.923$; $d = 0.112$) and VEH-APV′-VEH ($p = 0.9985$; $d = 0.043$) exhibited similar novel object recognition indexes compared to VEH-VEH′-VEH. During memory recognition test session all groups spent a similar amount of percentage of vehicle exploration time ($F_{(5,37)} = 0.897$, $p = 0.491$, ANOVA; Table 5). Our results show that VEH-VEH′-VEH, VEH-APV′-VEH and VEH-APV′-APV groups recognized the novel object, whereas APV-VEH′-APV, APV-APV′-VEH and APV-APV′-APV groups did not. These findings indicate

that administration of APV 120 min after sample phase did not impair recognition memory and confirm that recognition memory was impaired by the infusion of APV immediately after acquisition and could not be rescued by the re-administration of APV before retrieval. Infusion of APV into the insular cortex at both times, 120 min after ORM acquisition and 15 min before retrieval, spared recognition memory. This effect seems to be as a result of lack of APV effect in memory recognition on late consolidation window and memory retrieval. However, memory impairment observed in APV-APV′-APV group was the result of the immediate infusion of APV after ORM acquisition, since a long temporal separation between administrations restrained drug-induced state integration in recognition memory.

Altogether, our results indicate that there are boundary conditions in order to establish a state-dependent recognition memory: a short half-life of the drug seems to be insufficient to be integrated to the memory trace; and the timing of pharmacological manipulation, since drug administration during the early but not late consolidation window induces state-dependent recognition memory.

4. Discussion

Previous studies have provided experimental evidence of state-dependent memories; memories may be more readily retrieved when a drug-induced brain state during recall is similar to the drug-induced brain state when learning occurred (Overton, 1991; Jovasevic et al., 2015). There is also some evidence suggesting that drugs that are administered shortly after learning may induce state-dependent learning. Such findings propose that, while new memories are active and being consolidated, they may integrate the drug effects into the memory and thus require a similar drug state for subsequent expression of memory (Thompson and Neely, 1970; Thompson and Grossman, 1972; Hinderliter et al., 1975; Mactutus and Riccio, 1978; Mactutus et al., 1980; Bradley and Galal, 1988; Millin and Newman, 2008; Briggs and Olson, 2013; Gisquet-Verrier and Riccio, 2012; Gisquet-Verrier et al., 2015).

In this study, we found that immediate post-training infusions of anisomycin into the insular cortex induces state-dependent recognition memory. This finding is similar to the effect previously observed with cycloheximide (Briggs and Olson, 2013; Gisquet-Verrier et al., 2015). We also found that administration of DRB, an RNA elongation inhibitor, also induced a state-dependent recognition memory. It is important to note that administration of anisomycin or DRB 120 min after ORM acquisition did not induce state-dependent recognition memory. Thus, our findings provide additional support for the idea that as suggested by the integration hypothesis, newly formed memories are susceptible to integrate drug-induced effects that can induce state-dependent memory.

Unlike the state-dependency generated by anisomycin or DRB, cortical administration of APV immediately after training induced amnesia that was not recovered by the infusion of APV before retrieval. Interestingly, the absence of state dependent memory with APV has been reported previously when infused into the amygdala (Maren et al., 1996). However, this lack of effect on state-dependent memory formation might be due to the short half-life of APV (Ji et al., 2005) compared to anisomycin (Wanisch and Wotjak, 2008) and DRB (Nguyen et al., 1994). In support of this possibility, we investigated whether state-dependent memory could be induced when we extended the duration of the APV effect by a double administration, immediately and 60 min after memory acquisition. Our results indicate that the effects of a prolonged duration of APV could be integrated into the processes mediating the newly-formed recognition memory. Importantly, a brief exposure to APV immediately or 60 min after ORM acquisition, impaired memory recognition and could not be reversed when APV was administered before memory retrieval. As the half-life of APV is short, amnesia is observed as a result of an incomplete incorporation of the brain state induced by APV. Our results suggest that induction of state-dependent memory with APV depends on the extended effect that comprises the early consolidation window between 0 and 120 min, since administration of APV during later consolidation window failed to induce state-dependent recognition memory.

Previous findings suggest that progressive stabilization of newly learned information occurs at least during two sensitive windows in which protein-synthesis inhibitors induce amnesia, one early phase immediately after training and a second phase between 2 and 4 h later (Bourtchouladze et al., 1998; Quevedo et al., 1999; Igaz et al., 2002). Here, we observed that infusion of anisomycin into the insular cortex immediately or 120 min after ORM training impaired recognition memory. Additionally, DRB administration into the insular cortex immediately after training impaired recognition memory, but not when administered 120 min after training. Memory deficits induced by anisomycin or DRB administration have been also found in many memory studies using different learning tasks (Balderas et al., 2008; Sherry et al., 2010; Prado-Alcalá et al., 2017; Ozawa et al., 2017; Steinmetz et al., 2017). Thus, memory consolidation may be sensitive to two-time periods (Igaz et al., 2002) in which differential effects of anisomycin or DRB are due to differences in time of infusion and concentration used (Agranoff, 1967; Igaz et al., 2002). In addition, infusion of APV into the insular cortex immediately or 60 min after the acquisition impairs recognition memory; APV administration 120 min after training is ineffective. Previously, we have reported that memory consolidation is affected by the administration of APV into the insular cortex up to 45 min after training (Guzmán-Ramos et al., 2010). However, administration of APV 120 min after training does not alter consolidation processes (Roullet et al., 2001; Tronel and Sara, 2003).

In general, our findings support the idea that induction of state-dependent memory and memory deficits could be differentially generated during two sensitive windows, an early consolidation stage affected by anisomycin, DRB and APV up to 60 min, and a late consolidation phase blocked only by anisomycin. A possible explanation for the differential effects observed between times of drug-administration, is that during early consolidation window, NMDA receptor activation constitutes the principal cellular mechanism for initiating memory processes. NMDA receptor activity has been associated with the regulation of protein synthesis; calcium entry through NMDA receptors modulates several signaling pathways including, among others, CREB and elongation factors (Hoeffer and Klann, 2006; Tran et al., 2007). Thus, increased phosphorylation of CREB factor promotes RNA synthesis, new RNA and pre-existing RNA are translated in proteins required for setting up permanent synaptic changes (Igaz et al., 2002; Tran et al., 2007; Stewart and Schuman, 2001). Modification in any of these molecular events during early consolidation window, disrupts memory establishment. Nevertheless, protein synthesis is critical in both early and late consolidation windows; during the early phase, the pre-existing RNA of the immediate genes is translated into proteins necessary for the synaptic modifications, while the window of late consolidation undergoes structural changes that require new proteins involved in the long-term synaptic remodeling (Igaz et al., 2002; Stewart and Schuman, 2001).

As mentioned, the IC belongs to a dynamic network for salience detection; the salience network has been principally associated with the IC and the nucleus accumbens, but also includes limbic areas such as the amygdala, ventral striatum, dorsomedial thalamus, hypothalamus, substantia nigra and the ventral tegmental area (Menon, 2015). Therefore, the possible key role of the IC of the salience network is recognizing familiar/novel stimuli. In this regard, it has been observed that the IC activity is increased with the strength on familiarity (Morin et al., 2011; Kafkas and Montaldi, 2014). Therefore, the IC can be seen as a dynamic center for detection and selection of salient stimuli (novel vs familiar) (Menon, 2015) and the IC-limbic pathway is critical for processing novel-familiar information (Schmahmann et al., 2007). In addition, there is evidence from animal and human studies suggesting that a network of temporal cortical regions, including the perirhinal,

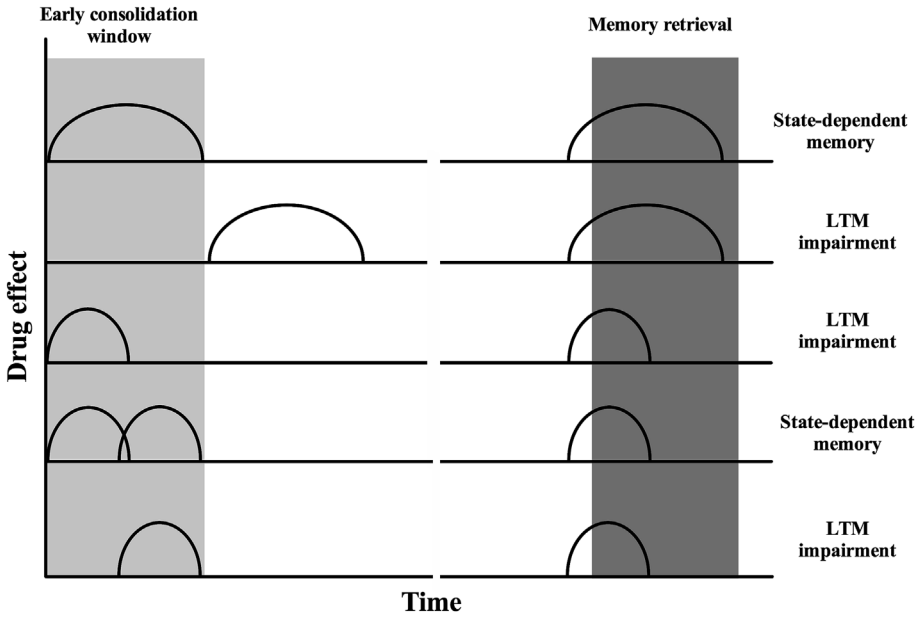

Fig. 6. Schema of the induction of state-dependent memory by amnesic drugs. There are boundary conditions in order to establish a state-dependent memory: a short half-life of the drug seems to be insufficient to be integrated to the memory trace; and the timing of pharmacological manipulation. It is only during early consolidation phase that newly acquired memories integrate information of the induced brain state generated by a long duration of drug effects.

parahippocampal, entorhinal and insular cortices and the hippocampus participates in recognition memory (Tang et al., 1997; Aggleton and Brown, 1999; Malkova and Mishkin, 2003; Reed et al., 2004; Bermúdez-Rattoni et al., 2005; Balderas et al., 2008; Bermúdez-Rattoni, 2014). Thus, a suggested key role of the IC is the detection of behaviorally relevant stimuli during recognition tasks (Menon, 2015). The induction of state-dependent recognition memory through pharmacological manipulations within the IC could be explained as a result of the incorporation of the drug-induced state into the familiar trace of the memory of the object necessary for the novel-familiar recognition.

Interestingly, our results provide evidence that induction of memory dependent on the state could be supported by several brain regions, since intracortical administration of a protein synthesis inhibitor generates state-dependent memories similar to those injected in the hippocampus or intracerebroventricular (Gisquet-Verrier et al., 2015 Jafari-Sabet et al., 2016). However, it remains to study the cellular and molecular mechanisms involved in the formation of state-dependent memory (Radulovic et al., 2017).

Despite the extensive evidence that amnesia induced by anisomycin, DRB or APV is explained by well-known molecular mechanisms, our data indicate that, under some special conditions, memory consolidation is not impaired by such treatments, but rather, is consolidated in a state-dependent manner. Induction of state dependent memory occurs during early consolidation window when memory establishment takes place; it is possible that infusion of drugs with long-lasting effects alters the molecular events of the insular cortex that are capable of inducing a brain state that becomes part of the novel-familiar memory trace in a state-dependent manner. However, amnesia is induced as a result of an incomplete incorporation of the brain state induced by drugs with short-lasting effect during early consolidation window, or by hindering memory long-term structural changes during late consolidation phase.

Differences in the time required for the consolidation and retrieval processes may explain why the integration of a prolonged exposure to drugs during consolidation is necessary, whereas a single injection is sufficient to induce a state that serves as a reference for retrieval. Memory consolidation events are required to make persistent modifications in functional connectivity that are accomplished within the first minutes to hours after memory acquisition (Dudai, 2004). However, memory retrieval processes are consummated very quickly, even in less than a second (Thorpe et al., 1996). Therefore, it is possible that the integration of the brain state induced by a drug requires a longer exposure to drugs compared to a short exposure that serves as a cue-signal during memory retrieval.

In agreement with previous studies (Rodríguez-Ortiz et al., 2012; Igaz et al., 2002; Ozawa et al., 2017; García-Delatorre et al., 2014, Osorio-Gómez et al., 2016; Liang et al., 1996; Izquierdo et al., 2002; Roullet et al., 2001; Winters and Bussey, 2005), we observed that anisomycin and APV do not disrupt memory retrieval. However, we found that administrations of DRB impaired ORM retrieval as reported previously (Igaz et al., 2002; Ozawa et al., 2017). Although memory retrieval impairments reported in literature are explained in terms of retrieval-related mechanisms, an alternative explanation is that memory expression is impaired because the brain-state during retrieval is different from the induced-state during memory formation. Nevertheless, our findings indicate that only DRB, but not anisomycin or APV, disrupted memory retrieval. However, all drugs used in this study serve as a state-dependent cue for recognition memory retrieval.

5. Conclusion

Summarizing, our data indicate that incorporation of the brain state induced by anisomycin and DRB in a state-dependent memory manner is due to their prolonged half-life. State-dependency could also be induced with APV when the duration of action was extended by double administration. The time of administration is crucial to state-dependent memory formation. Integration of drug-induced effects into memory occurs strictly at early consolidation window, whereas later consolidation window is vulnerable to consolidation disruption in a non-state dependent nature. Taken together, these results indicate that drugs' half-life and time of administration are boundary conditions creating state-dependent memory (see Fig. 6).

A B S T R A C T

The relationship between the mechanisms that underlie longevity and aging and the metabolic alterations due to feeding conditions has not been completely defined. In the present work, through the deletion of the gene encoding catalase, hydrogen peroxide (H_2O_2) was uncovered as a relevant regulator of longevity and of liver metabolism. Mice lacking catalase ($Cat^{-/-}$) fed ad libitum with a regular diet showed a shorter lifespan than wild type mice, which correlated with reduced body weight, blood glucose levels and liver fat accumulation, but not with increased oxidative damage or consistent premature aging. High fat diet (HFD) and fasting increased oxidative damage in the liver of wild type animals but, unexpectedly, this was not the case for that of $Cat^{-/-}$ mice. Interestingly, although HFD feeding similarly increased the body weight of $Cat^{-/-}$ and wild-type mice, hyperglycemia and liver steatosis did not develop in the former. Fat accumulation due to fasting, on the other hand, was diminished in mice lacking catalase, which correlated with increased risk of death and low ketone body blood levels. Alteration in expression of some metabolic genes in livers of catalase deficient mice was consistent with reduced lipogenesis. Specifically, *Pparγ2* expression up-regulation in response to a HFD and down-regulation upon fasting was lower and higher, respectively, in livers of $Cat^{-/-}$ than of wild type mice, and a marked decay was observed during $Cat^{-/-}$ mice aging. We propose that catalase regulates lipid metabolism in the liver by an evolutionary conserved mechanism that is determinant of lifespan without affecting general oxidative damage.

1. Introduction

Aging is the process of organism deterioration that progressively reduces the capacity to keep the general organism homeostasis, increasing the likelihood of death. In contrast, longevity is the length of life from birth to death. Aging is a complex process involving multiple factors going from genetic to environmental and acting at different stages of organism life, including gestation [1]. Since all factors causing aging also reduce lifespan, delaying aging may not extend longevity, but it would extend the healthy life (i.e., health-span; [1,2]).

The good correlation between cellular oxidative damage and aging has been on the basis of the prevalent but still controversial oxidative theory of aging [3]. A premise of this theory is that molecular oxidation causes the cellular damage that accompanies aging. Therefore, lifespan would be determined by the amount of reactive oxygen species (ROS) produced and the capacity to protect against oxidation (e.g., by antioxidants) or the toxic effect of oxidized macromolecules (e.g., by repair or removal; [4]). However, attempts to change the maximal lifespan by increasing or reducing oxidative stress in mice have not resulted in consistent correlations predicted by the oxidative theory, but it does influence the development of a pathology [5]. These observations suggest that under chronic stress, proper function of antioxidant mechanisms could contribute to health-span. Therefore, the role of oxidative stress on aging and health-span is worth of further investigation.

The fact that ROS are unavoidable molecules produced during the process of oxidative phosphorylation as well as of other metabolic reactions such as the β-oxidation of fatty acids implies that metabolic activity would be an intrinsic component of the aging process. Metabolic activity might be a limiting determinant of lifespan as suggested by the key role of the insulin/IGF1 signaling pathway in *Caenorhabditis elegans* (*C. elegans*) and the extension of lifespan promoted by caloric restriction in several species. However, the level at which the control of lifespan due to changes in metabolic activity relies on oxidative damage or ROS-mediated signaling is yet to be determined.

Several antioxidant systems contribute to keep the redox state

INFORME DE LABORES 2019

required for normal cell functioning and the prevention of cell damage. For example, controlled balance of cofactors such as NAD^+/NADH and $NADP^+$/NADPH is necessary for a broad diversity of reactions, including the ones involved in metabolism and aging [6]. Antioxidant enzymes are expected to contribute to this regulation and, generally, to the control of ROS levels; however, their intracellular localization indicates more specific cellular functions, some directly related with metabolic activity [7]. For example, the mitochondrial localization of superoxide dismutase 2 controls the superoxide produced by the oxidative phosphorylation [8]. On the other hand, the membrane localization of glutathione peroxidase 4 suggests that it protects lipids from peroxidation [9]. In the cytosol, many antioxidant enzymes are present, but the glutathione peroxidase 1 (GPX1) appears to be relevant for proper insulin signaling [10]. Catalase is preferentially located in the peroxisome where likely regulates the levels of H_2O_2 produced as a by-product of, among other oxidation reactions, the very long chain fatty acid β-oxidation [11–13]. These functions appear to be irrelevant during mammalian embryogenesis, but the abnormal phenotypes observed in the absence of some of them suggest a function during adult life [14–17].

The liver can be considered a metabolic center where signals from the nervous system and peripheral organs (e.g., pancreas, adipose tissue) converge to maintain the homeostasis of many metabolites required for the well-functioning of cells and organs. In particular, lipid metabolism in hepatocytes is fundamental for the maintenance of systemic energy homeostasis, such that under fed condition insulin promotes lipogenesis and lipoprotein secretion, whereas under fasting, fatty acid oxidation increases eventually producing ketone bodies, an essential energetic resource when glucose is depleted. These processes are critically altered in obesity resulting in accumulation of fat in the liver, a condition that often correlates with the hyperglycemia and insulin resistance that typically characterize type 2 diabetes [18]. Hepatocytes are rich in peroxisomes where catalase is the main protein component, though has also been detected in the cytosol and mitochondria [11,19]. Therefore, it is expected that catalase perform a key antioxidant role in hepatocytes, especially during active fatty acid oxidation.

The catalase of mammals is a homotetrameric enzyme that contains a heme moiety in the active site of each subunit [11]. Mammals have a single gene encoding catalase or homologous enzymes. The catalytic reaction of catalase uses two H_2O_2 molecules, the only natural substrate known, to oxidize iron in the heme and release water and oxygen. Catalase activity is among the highest known to be able of degrading H_2O_2 in a wide range of concentrations [11]. In the present work, we found that mice lacking catalase have a shorter lifespan than wild type mice and reduced fat accumulation, without an evident increase in oxidative damage. Therefore, we explored the role of catalase in liver under conditions that promote degradation of fatty acids in the liver, a high fat diet and fasting. Our data support a relevant role of peroxisomal H_2O_2 in the regulation of lipid metabolism in the liver, a process that could significantly influence lifespan by an evolutionary conserved mechanism.

2. Material and methods

2.1. Cat null allele generation

The null mutation in the gene encoding catalase (*Cat*) was generated in embryonic stem (ES) cells (AB2.2 line) by standard gene targeting procedures. The 5'- (3.5 kb) and the 3'- (3.3 kb) arms specific for the *Cat* genomic region were inserted in the pPGKNeoloxPA vector containing the Neo^r gene under the control of the PGK promoter flanked by loxP sequences (Fig. S1A). Because of homologous recombination, a 6.2 kb region, containing exons 4–6 and a fragment of 7, was deleted (Figs. S1A and B). The chimeric mice, resulting after blastocyst ES cell injection, were backcrossed with mice of the C57BL/6NJ strain obtained from Jackson Laboratories for more than 10 generations giving rise to the heterozygous $Cat^{+/-}$ line used in the present work. Heterozygous $Cat^{+/-}$ mice were intercrossed to produce mice with $Cat^{+/+}$, $Cat^{+/-}$ and $Cat^{-/-}$ genotype and, in some cases, $Cat^{-/-}$ mice were also produced by incrosses. Mice were genotyped by PCR with specific primers for the wild-type (forward TTGTTACCGCTTTCCTAAACTCC; reverse: TGACTTCCTTGGTCAGATCAAATG) and mutant alleles (forward TGTC ATTCTATTCTGGGGGG; reverse: GGACGACACTTATGAAGCAATC).

2.2. Animal protocols

The mice were maintained in plastic cages within a pathogen-free animal facility with humidity-monitored rooms and a 12-h light/dark cycle. Male mice were used for all experiments and were euthanized by cervical dislocation and collected tissues and blood samples stored at −70 °C. Survival along aging was determined in cohorts consisting of 28, 30 and 31 male mice with the $Cat^{+/+}$, $Cat^{+/-}$ and $Cat^{-/-}$ genotypes, respectively, which were maintained in cages with 2–3 individuals, fed with regular chow ad libitum, had free access to water and received standard animal care. The exact birth and death date were recorded, and mice that developed acute skin ulcers, typical of C57BL/6NJ strain, were euthanized and not considered for the survival analysis; relevant to mention is that emergence of skin ulcers did not correlate with the *Cat* genotype (14/28 $Cat^{+/+}$, 11/30 $Cat^{+/-}$ and 14/31 $Cat^{-/-}$) but it did correlate with age (2/89 of 2–9 months, 19/79 of 10–17 months and 18/51 of 18–25 months). Ambulatory and fine activity of individual 12- or 24-month-old (mo) mice $Cat^{+/+}$ or $Cat^{-/-}$ was determined with the Photobeam Activity System (San Diego Instruments Inc, San Diego, CA, USA) and the data analyzed with the PAS Home Cage software (San Diego Instruments Inc, San Diego, CA, USA). Briefly, the activity chamber (11.75" (W) x 18.75" (L)) records the number of times the mouse crosses a photobeam grid oriented on an x and y axis; consecutive photobeam breaks occurring in adjacent photobeams were scored as an ambulatory movement while breaks occurring at same photobeam were scored as fine activity. Cumulative ambulatory and fine activity counts were recorded every 5 min for 24 h (7:00–7:00 daytime); the total activity was the sum of ambulatory and fine activity. Groups of at least 3 mice with the $Cat^{+/+}$ and $Cat^{-/-}$ genotype were collected for each diet or feeding condition. High fat diet (HFD; 60% calories from fat; D12492, Diets Research, New Brunswick, NJ, USA) feeding was initiated, either immediately after winning (i.e., at 21 days of age) and continued for 6 months, or at 3 months of age and continued for 2 or 12 weeks. HFD-control low fat diet for these experiments was the one recommended by the provider (10% calories from fat; D1245B, Diets Research, New Brunswick, NJ, USA). For starvation protocols, 3-mo male mice with a defined *Cat* genotype were collected, fed with a standard diet (1218SX, Envigo, Indianapolis, IN, USA) and food removed at 7:00 daytime and animals sacrificed 24 or 48 h later; in some cases, refeeding was allowed for 12 h starting at 7:00 daytime. Newborn mice with the genotype required for starvation experiments were produced by timed matings of homozygous mice with the desired genotype ($Cat^{+/+}$ *or* $Cat^{-/-}$); at 19 days post coitum a cesarean was performed on pregnant mice. Newly delivered mice were kept in a humidified chamber at 37 °C and continuously monitored to determine survival. Another group of pregnant mice gave birth naturally, and 12 h later pups were transferred to the humidified chamber to follow survival. For the capture of X-Ray images, mice were anesthetized with intranasal 1% isoflurane (Sofloran Vet, PiSA Agropecuaria, Guadalajada, JAL, México) and images captured in a 15 cm^2 view field, aperture f/stop of 2.8 and an acquisition time of 5 s with a 0.4 mm filter using the Multimodal Animal Rotation System (MARS) in the In-vivo Xtreme instrument (Bruker, Germany). The AKT activation by insulin was performed in 2-mo mice fed with the standard diet; mice were fasted for 12 h before ip injection of insulin (3 U/kg) or of a saline solution and euthanized 30 min later. All animal procedures described were approved by the Bioethical Committee of our Institute and

rigorously meet international standards.

2.3. Blood and serum analysis

Blood was collected from the tail or by cardiac puncture after sacrifice. To obtain serum, blood was incubated for 2 h at room temperature and centrifuged at 2000 g for 10 min; the supernatant recovered was stored at −70 °C until used. Levels of glucose and ketone bodies were determined with the Ascencia Countour glucometer (Bayer, Japan) or the FreeStyle ketone/glucometer (Abbot, Maidenhead, UK), respectively. Insulin was measured with the Ultra-Sensitive Mouse Insulin ELISA kit (Crystal Chem, Downers Grove, IL, USA). Triglycerides and cholesterol in serum were determined using the Triglycerides reagent (BioSystem, Costa Brava, Barcelona, Spain) or the Cholesterol reagent (BioSystem, Costa Brava, Barcelona, Spain) following the manufacturer's instruction. For the glucose tolerance test, glucose (2 mg/kg) was intraperitoneally (ip) injected after a 12 h starvation period and blood glucose concentration immediately measured (time "0") and then at 15, 30, 60 and 120 min after injection. For the insulin tolerance test, 4 h-starved mice were ip injected with a recombinant human insulin (Gibco, Invitrogene, CarlsBad, CA, USA) and blood glucose concentration immediately measured (time "0") and then at 15, 30, 60 and 120 min after injection.

2.4. Quantification of total hepatic cholesterol, triglycerides and glycogen

Lipids of liver were extracted by homogenization of 50 mg of tissue in 1 mL of PBS, followed by the addition of 4 ml of Folch reactive (chloroform/methanol 2:1). After vortexing, the suspension was centrifuged at 3000 g for 10 min, and the organic phase transferred to a glass vial for evaporation to dryness at 37 °C overnight. The precipitate was resuspended in 500 µl of 1% sodium deoxycholate solution, and triglycerides and cholesterol concentration determined using the Triglycerides reagent (BioSystem, Costa Brava, Barcelona, Spain) or the Cholesterol reagent (BioSystem, Costa Brava, Barcelona, Spain) following the manufacturer's instruction. For hepatic glycogen content, 40–100-mg of tissue were homogenized in 100 µl of 30% KOH at 100 °C for 30 min. The homogenates were cooled to room temperature and then 100 µl of 20% Na_2SO_4 followed by 1 ml ethanol were added. The mixture was left at −20 °C for 6 h and then centrifugated at 3000 g for 10 min; after removal of the supernatant, the pellet was resuspended in 500 µl of 0.2 M sodium acetate buffer pH 4.8 and incubated with 5 units of amyloglucosidase (Sigma-Adrich, Saint Louis, MO, USA) for 8 h at 55 °C. Finally, glucose concentration was measured using the Glucose reagent (BioSystem, Costa Brava, Barcelona, Spain); the data were expressed as nmol equivalents of glucose/g liver.

2.5. Determination of conjugated dienes and catalase activity

Livers were homogenized in PBS and total amount of protein recovered determined with the Bradford reagent (Bio-Rad, Hercules, CA, USA) for each resulting sample. Conjugated dienes were determined in lipids extracted as referred above and using previously described procedures [20]. The catalase activity was determined in whole liver homogenates by two methods: (a) in-gel activity, detected by the absence of the Prussian blue precipitate in non-denaturing gels embedded first with H_2O_2 and then with a potassium ferrocyanide/ferric chloride solution, or (b) by spectrophotometrically determining the decline in concentration of H_2O_2 substrate with time. Both methods were performed following the protocol described by Weydert and Cullen [21].

2.6. Histological analysis

Liver tissue samples were fixed with 4% paraformaldehyde overnight and embedded in paraffin wax or in Tissue-Tek (Sakura Finetek, Torrance, CA, USA) for microtome (RM2145, Leica, Nussloch, Germany) or freezing Cryostate sections (CM1850, Leica, Nussloch, Germany), respectively. Paraffin-embedded liver slices were stained with a hematoxylin-eosin cocktail (Sigma-Adrich, Saint Louis, MO, USA) following the manufacturer's instructions. Slices from frozen tissues were stained with red-oil and counterstained with hematoxylin (Sigma-Adrich, Saint Louis, MO, USA), or stained for β-galactosidase activity at pH 6 using the Beta-Galactosidase Tissue Stain Base Solution (Merk-Millipore, Darmstadt, Germany) and counterstained with eosin (Sigma-Adrich, Saint Louis, MO, USA) following the manufacturer's instructions. Similar procedure was followed for hematoxylin-eosin staining of adipose tissue slices but Bouin's fixing solution (Sigma-Adrich, Saint Louis, MO, USA) was used. Bright-field images were acquired using the Olympus BX51 microscope and a C-5050 camera (Olympus, Tokyo, Japan). β-gal-eosin images were quantified using the Image J software (version 2.0.0). Briefly, H&E color deconvolution was applied to each image and the layer corresponding to 'hematoxylin" was selected and converted to a 8-bit format before establishing a threshold. After that, the analysis of particles was performed to obtain the count of blue spots, the mean average of spot size and the total stained area; three images per liver were analyzed.

2.7. Immunoblotting

Liver tissue lysates (35 µg protein) prepared in RIPA lysis buffer (50 mM Tris pH7.5, 150 mM NaCl, 1% Triton X-100, 0.5% sodium deoxycholate, 0.1% SDS with protease and phosphatase inhibitors) were separated by electrophoresis on 10% SDS-PAGE gels and transferred to Immobilon-FL membranes (Merk-Millipore, Darmstadt, Germany). The blots were blocked with the Odyssey blocking buffer (LI-COR Biosciences, Lincoln, NE, USA) at room temperature for 1 h and then incubated overnight with the primary antibodies obtained from Cell Signaling (Cell Signaling Technology, Danvers, MA, USA): anti-AMPK (#2532, 1:2000 dilution), anti-pAMPK (#2535, 1:1000 dilution), anti-tubulin (#3873, 1:7000 dilution), anti-AKT (#9272, 1:1000 dilution), anti-pAKT (#2965, 1:1000 dilution), anti-SQSTM1/p62 (#23214, 1:1000 dilution) anti-LC3A/B (#4599, 1:100 dilution). After washing 3 times for 5 min each in a Tris-buffered saline-Tween 20 (0.1%, vol:vol) solution, the membranes were incubated with a goat anti-rabbit IgG or anti-mouse IgG secondary antibodies coupled to infrared fluorophores (emission at 689 or 778 nm; LI-COR Biosciences, Lincoin, NE, USA) at room temperature for 1 h. After washing, the protein bands were visualized in the Odyssey Classic Imaging System (LI-COR Biosciences, Lincoin, NE, USA). Twenty percent SDS-PAGE was used only for the detection of LC3 using liver lysates prepared with RIPA containing 1% SDS. Protein carbonylation was determined using the OxyBlot Oxidation Detection Kit (Merk-Millipore, Darmstadt, Germany). Briefly, carbonyls in proteins were derivatized into 2,4-dinitrophenyhydrazone (DNP-hydrazone) and then processed for western-blot; oxidized proteins were detected with an anti-DNP antibody and visualized in the Odyssey Classic Imaging System (LI-COR Biosciences, Lincoin, NE, USA). Protein bands were quantified by densitometry using the ImageJ software (version 2.0.0).

2.8. Gene expression analysis

Total liver RNA was obtained using the RiboEx total RNA isolation solution (GeneAll Biotecnology, Seoul, Korea) following the manufacturer's instructions. This RNA was used as template to synthesize cDNA with the HyperScrip reverse transcriptase (GeneAll Biotecnology, Seoul, Korea) using random hexamers as primers (Invitrogen, US). The quantitative PCR (qPCR) reaction was performed with the SYBR Green mix (KAPA Biosystems, Cape Town, South Africa) in the Rotor-Gene Q thermocycler (Qiagene, Germantown, MD, USA). The sequence of specific oligonucleotides were taken from either reports of others or designed by us using the PrimerBlast3 (see Table S1 for details). In some cases, equal amounts of cDNA from at least 3 individuals were

mixed before qPCR. The relative gene expression level was estimated by the ΔΔCT method, using *Rplp0* expression as an internal control and the indicated mouse group as experimental control.

2.9. Statistical analysis

All statistical analyses were done with the Prism software version 5.0b (La Jolla, CA, US) using the Long-Rank test for survival and the two-way variance analysis followed by the Bonferroni test for the other rest of experiments; minimal significance considered was 0.05 (*0.05, **0.01, ***0.001) with a "n" minimal value of 3. All graphs shown are the media ± standard deviation.

3. Results

3.1. Catalase gene (Cat) inactivation causes premature death without signs of increased oxidative damage or general advanced aging

The *Cat* gene is abundantly expressed in early mouse embryos (Figs. S1C and D) and in several adult organs and tissues like liver, kidney and spleen (Fig. S1E). To determine the function of catalase during embryogenesis and in adult life, we generated a null *Cat* allele by deleting a region (exons 4–6) encoding an essential catalase domain in embryonic stem cells (Figs. S1A and B). Mice homozygous for this null allele ($Cat^{-/-}$) did not show catalase activity (Fig. S1E) supporting that, at least in the tissues tested, there is no other homologous gene that encodes an enzyme with a similar activity. $Cat^{-/-}$ mice were viable, born with the expected mendelian ratio but, interestingly, showed a decreased lifespan in comparison with $Cat^{+/+}$ and $Cat^{+/-}$ mice (Fig. 1A). Twelve-months old (mo) or 24-mo mice lacking catalase did not show evident signs of more advanced aging than wild type such as higher density of gray hairs, alopecia or reduced motor activity (Fig. 1B and C). Accordingly, the increasing lipid peroxidation observed along the first 10 months of life in several organs was similar between wild type and mice lacking catalase (Fig. 1D) or even lower in livers of 24-mo $Cat^{-/-}$ mice (see below). However, X-ray images revealed kyphosis (hunchback) in $Cat^{-/-}$ mice since 12-months of age, a phenotype that was more pronounced in 24-mo mice (Fig. 1E). Despite this latter evident phenotype associated with advanced aging, no other data indicated premature aging as the cause of death. Relevant to mention is that, although initial increase in weight with age was similar, mutant 24-mo mice were slimmer than wild type mice (Fig. 1E and F), despite the fact that there were no signs of any sickness (e.g., piloerection, presence of tumors) and that, in general, animals were active near death (Fig. 1C). In addition, the characteristic hyperglycemia of old mice did not develop in mice lacking catalase (Fig. 1G), though insulin levels increased with age as in wild-type mice (Fig. 1H). Circulating levels of triglycerides, cholesterol and ketone bodies were as in wild-type mice (Fig. 1I–K).

Since a distinctive characteristic of liver is the presence of high catalase activity, this organ of $Cat^{-/-}$ mice would be expected to show detectable cellular and molecular alterations. Increased lipid oxidative damage occurred in the liver of wild type mice with aging but, unexpectedly, this was not found in the liver of $Cat^{-/-}$ mice, which showed even reduced lipid oxidative damage at the age of 24 months (Fig. 2A) and there was no difference in liver protein oxidation between $Cat^{-/-}$ and wild type mice at 12- and 24-months of age (Fig. 2B). No compensatory activity of peroxidases (Fig. S1E) or an antioxidant response were detected in the liver of mice lacking catalase (Fig. S1F). In contrast, staining for β-galactosidase at pH6, a commonly used indicator of cellular senescence within a tissue, emerged in livers of $Cat^{-/-}$ at earlier age and spots were in higher number and covered a larger area than in those of $Cat^{+/+}$ mice (Fig. 2C). However, the association of this difference with cellular senescence could not be established because, as expected, livers of wild type and of $Cat^{-/-}$ mice showed similarly increasing levels with age in *p16*, *p21* and *p53* expression (Fig. 2D). Interestingly, liver fat accumulation with aging, as revealed by red oil staining, in *Cat* deficient mice was lower than in wild type mice (Fig. 2E), and particularly coincided with triglycerides and cholesterol levels detected in livers of 24-mo mice (Fig. 2F and G). No difference in liver glycogen content was found between wild-type and $Cat^{-/-}$ mice at any age tested (Fig. 2H). Therefore, the liver of $Cat^{-/-}$ mice do not show consistent characteristic of premature aging.

3.2. The lack of catalase prevents from oxidative damage and fat accumulation in the liver in response to feeding with a HFD

Oxidative damage or premature aging was not obviously related with the reduction in lifespan of catalase deficient mice. Instead, the slim appearance of old mutant mice together with their relatively low levels of blood glucose and of accumulated liver fat suggested that metabolic alterations are behind premature death. In agreement with the participation of catalase in fat metabolism in the liver (Fig. 3A), wild type mice fed with a HFD markedly decreased catalase activity (Fig. 3B) with a corresponding increment in lipid peroxidation (Fig. 3C). Paradoxically, the liver of $Cat^{-/-}$ mice did not show the increment in lipid peroxidation in response to HFD, though increased levels were detected when these mice were fed with the HFD-control diet (Fig. 3C). The contrasting difference between this latter observation and the one shown above (Fig. 2A) could be due to the diet composition; particularly, the HFD-control has 2/3 of the amount of polyunsaturated fat in standard chow, and the caloric supply of fat and carbohydrates in HFD-control is lower and higher, respectively, than those in standard chow (see more details in Table S2). These data together indicate that the absence of catalase prevents from the rise in ROS levels in association with a HFD.

An evident sign of the effect on fat metabolism due to a long-term HFD feeding is the accumulation of fat in liver, pathology known as hepatic steatosis. In agreement with the absence of evident abnormalities due to the lack of catalase, $Cat^{-/-}$ and $Cat^{+/+}$ mice fed with a HFD-control diet did not show body weight or feeding behavior differences during adult life (Fig. 3D, Fig. S2A). In addition, the pattern of increase in body weight and feeding behavior under a HFD was also similar for mice with either genotype (Fig. 3D, Fig. S2A). However, mice lacking catalase showed attenuated hepatic steatosis (Fig. 3E) and decreased triglycerides and cholesterol content in liver in comparison with wild type mice after 3 months feeding with a HFD (Fig. 3F and G), though an alteration in liver weight associated with the lack of catalase was not evident (Fig. S2B). The absence of catalase did not seem to affect adipocyte size or level of macrophage infiltration in the white tissue of epididymus (Fig. S2C), common in obese mice. Brown subcutaneous interscapular or white epidydimal fat tissue weight did not change in association with the levels of catalase (Figs. S2D and E) and evident accumulation of white adipose tissue was noted in all mice fed with a HFD (Fig. S2F). Therefore, HFD, instead of increasing oxidative damage in livers of $Cat^{-/-}$ mice, causes changes in the lipid metabolic pathways that generate steatosis (see below).

3.3. Mice lacking catalase fed with HFD do not develop hyperglycemia and glucose intolerance

It is widely known that mice fed for a long term with a HFD causes obesity and, consequently, hyperglycemia, glucose intolerance and insulin resistance. Recent data have also shown that these alterations in glycemia are strongly associated with liver steatosis [22]. The glycemia determined at 12-weeks after feeding with a HFD showed that $Cat^{-/-}$ mice did not develop the typical hyperglycemia observed in wild type mice, and glucose levels remained in a similar range as mice fed with the HFD-control diet (Fig. 3H). In agreement with this observation, the increase in insulin, typical in response to HFD feeding, was not observed in $Cat^{-/-}$ mice (Fig. 3I) and levels were similar to those observed in mice fed with the standard diet (Fig. 1H). Accordingly, and in

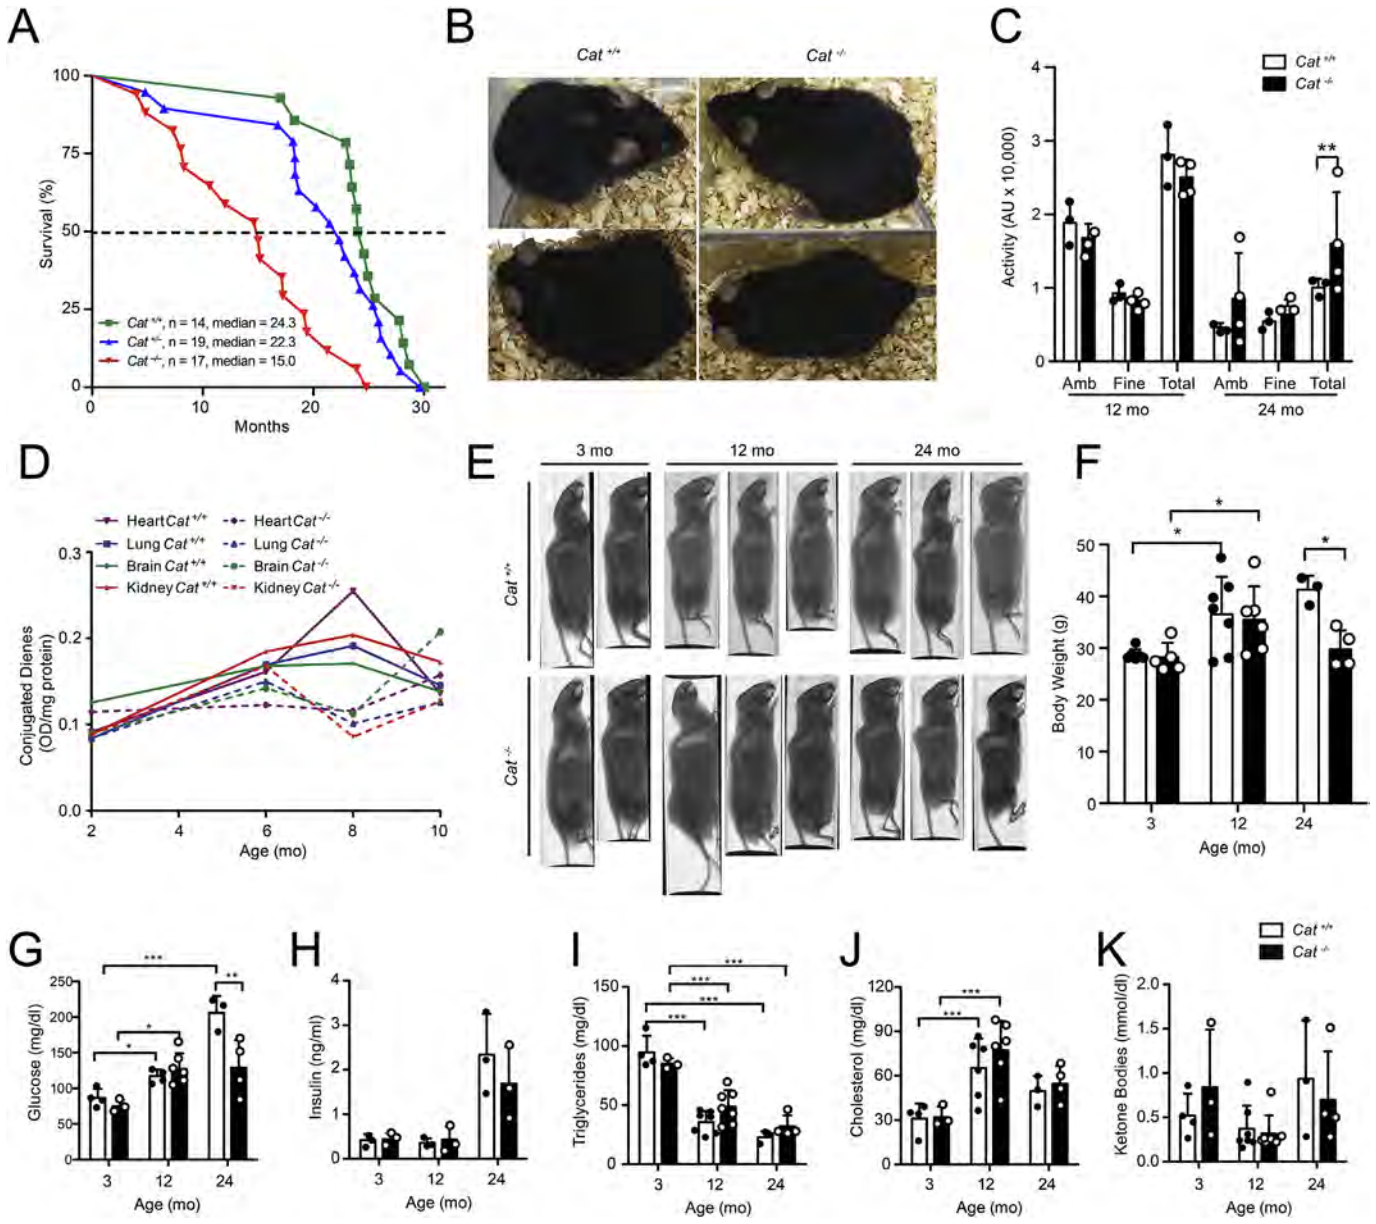

Fig. 1. Lifespan and aging parameters of mice with ($Cat^{+/+}$) or without ($Cat^{-/-}$) catalase. (A) Lifespan of $Cat^{+/+}$, $Cat^{+/-}$ and $Cat^{-/-}$ mice. Survival difference between $Cat^{+/+}$ and $Cat^{-/-}$ mice is statistically significant ($p < 0.0001$, Long-Rank test) and also between $Cat^{+/-}$ and $Cat^{-/-}$ mice ($p < 0.0012$) but not between $Cat^{+/+}$ and $Cat^{\pm}$ mice ($p < 0.1773$). (B) Representative photographs of 18-mo $Cat^{+/+}$ and $Cat^{-/-}$ mice. (C) Motor ambulatory (Amb), Fine (F) and Total (T), activity of 12- and 24-mo $Cat^{+/+}$ and $Cat^{-/-}$ mice. (D) Lipid oxidation, as estimated by the amount conjugated dienes, in whole extracts of heart, lung, brain and kidney of 2–10-mo mice. (E, F) X-ray images (E) and body weight (F) of 3-, 12- and 24-mo mice. (G–K) Glucose (G), insulin (H), triglycerides (I), cholesterol (J) and ketone bodies (K) levels in serum of 3-, 12- and 24-mo mice. Note that the lack of catalase in mice did not correlate with increased oxidative damage in several organs or consistent premature aging, but lower blood glucose levels and body weight were observed in mice lacking catalase. All values shown are the mean ± SD; n = 3–9. $*p < 0.05$, $**p < 0.01$ and $***p < 0.001$ (two-way variance analyses).

contrast with wild type animals, the $Cat^{-/-}$ mice fed with a HFD responded to an elevation in blood glucose concentration in a similar manner as wild type or mutant mice fed with the HFD-control diet (Fig. 3J). Interestingly, the response to high insulin dose of $Cat^{-/-}$ mice fed with a HFD-control diet was as of wild type mice, whereas when feeding was with a HFD, the initial response was similar among mice with any *Cat* genotype but recovery towards normal glucose levels was notoriously more rapid in animals lacking catalase (Fig. 3K). This phenomenon does not seem to be related to alterations in insulin signaling, since basal and insulin-stimulated levels of AKT phosphorylation were not modified by the absence of catalase (Fig. 3L,M; see also data below); nonetheless, increased gluconeogenesis could be responsible of the rapid recovery in glucose levels after the decline induced by insulin. These data are in agreement with the reduced accumulation of fat in the liver of $Cat^{-/-}$ mice that, consequently, prevents from losing the homeostatic control of glucose under a HFD.

3.4. The lack of catalase decreases the viability of mice under fasting conditions

Another condition that causes significant changes in lipid metabolism is fasting. Shortly after food deprivation, free fatty acids are brought from the adipose tissue to the liver causing the accumulation of fat in the form of lipid droplets [23]. The immediate source of glucose under food deprivation is glycogen but later fatty acids are directed to produce ketone bodies which are used as a major energetic source when

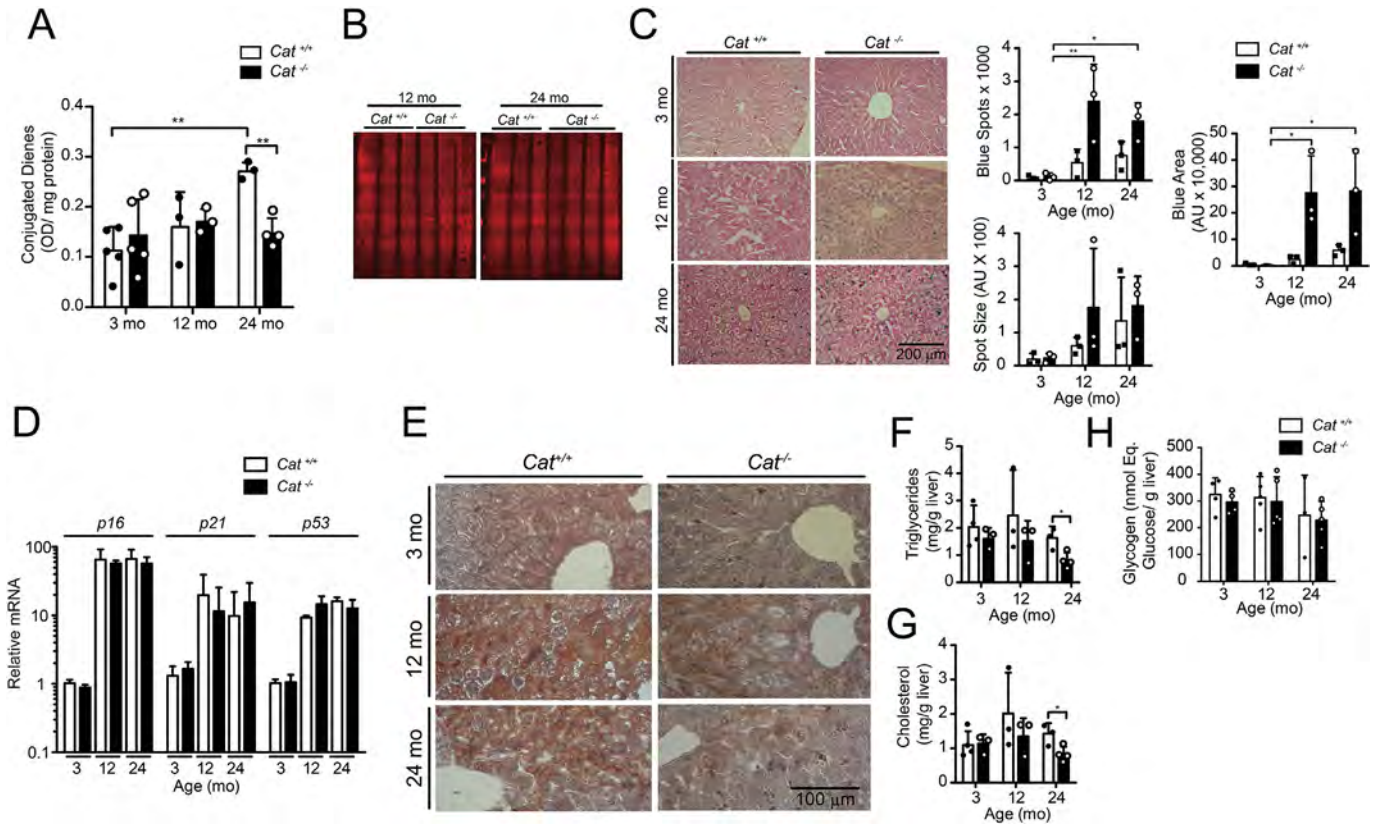

Fig. 2. Oxidative damage, cellular senescence and fat accumulation in livers of aging mice with ($Cat^{+/+}$) and without ($Cat^{-/-}$) catalase. Determinations were done in 3-, 12- and 24-mo mice. (A) Lipid oxidation in liver as determined by the amount of conjugated dienes. (B) Protein oxidation (immunoreactivity against DNP) in livers of 12- and 24-mo mice; no signal was detected before carbonyl derivatization into DNP-hydrazone. (C) Representative images of β-galactosidase stained liver sections. Level of staining was determined by counting the number of blue dots and estimating the area covered by them in representative sections of livers. (D) Expression of the senescence-related genes indicated determined by qRT-PCR. (E) Representative images of red-oil stained liver sections. (F, G, H) Triglycerides (E), cholesterol (F) and glycogen (H) content in liver. Note that the levels of oxidative damage correlated better with fat accumulation than with markers of cellular senescence. All values shown are the mean ± SD; n = 3–5. $*p < 0.05$, $**p < 0.01$ and $***p < 0.001$ (two-way variance analyses).

glucose supply is short [24].

In wild type mice, catalase activity and expression of its gene decreased during fasting, and their recovery was still incomplete 12 h after refeeding (Fig. 4A, Fig. S3A). In agreement with the decrease in catalase activity, the lipoperoxidation increased (Fig. 4B), suggesting that catalase normally participates in the metabolic changes associated with this condition. Weight loss throughout 48 h fasting and the corresponding weight gain after refeeding was not markedly altered in $Cat^{-/-}$ mice in comparison with wild type mice (Fig. 4C). Also, the lack of catalase did not cause significant differences in the early elevation and abrupt decline of blood glucose (Fig. S3B), and the expected increase in ketone bodies (Fig. 4D). Blood levels of cholesterol and triglycerides, and the liver glycogen content after 24 h and 48 h fasting in $Cat^{-/-}$ was as in wild type mice (Fig. S3 C-E). In contrast, the characteristic fat accumulation (Fig. 4E–G) and increased lipoperoxidation at 48 h (Fig. 4B) in the liver of wild type mice was reduced in $Cat^{-/-}$ mice. In agreement with a rise in protein recycling due to fasting, expression of autophagy/lysosome genes (*Atg5*, *Atg7*, *LC3B*, *p62*, *Lamp2*) and a gene associated with activation of ubiquitin-proteosome (*Atrogin-1*) increased in livers of $Cat^{-/-}$ and $Cat^{+/+}$ mice after 24 h of fasting (Fig. S3F). However, although the levels of p62 decreased similarly in livers of mice of both genotypes, the levels of LC3II, the autophagosome-associated form of LC3I that reflects autophagy activity [25], were moderately higher in livers of mice lacking catalase (Fig. S3G). Therefore, as in the HFD feeding condition, reduced fat accumulation accompanied by a lower oxidative damage was the major consequence of fasting in livers of mice lacking catalase.

The metabolic alterations described above were apparently no life-threatening for $Cat^{-/-}$ mice. However, it was common to find that some catalase deficient mice at 48 h of starvation, just before sacrifice, got still, a characteristic that correlated with an evident necrotic small bowel and was considered a sign of imminent death (Fig. 4H). Interestingly, these dying $Cat^{-/-}$ mice also showed an abrupt exhaust of ketone bodies (Fig. 4D, red dots). No wild type mice showed any of these characteristics at this time of fasting. Since it is well-known that the viability of starved newborn mice strongly depends on their capacity to use the energetic resources available (e.g., glycogen and ketone bodies; [26,27]), we tested the viability of newborn $Cat^{-/-}$ mice. Interestingly, the survival of $Cat^{-/-}$ newborn mice was reduced in comparison with wild type newborn mice under acute (Fig. 4I) or moderate starvation (Fig. 4J). Serum ketone bodies sharply decreased in $Cat^{-/-}$ mice after 6-h fasting, whereas reduction in $Cat^{+/+}$ mice was noted until 12-h fasting (Fig. 4K). Likewise, glucose levels decreased earlier in $Cat^{-/-}$ than in wild type (2-h vs. 6-h fasting; Fig. 4L), though this effect did not correlate with glycogen content (Fig. S3H). No major differences were detected in cholesterol and triglycerides liver content (Figs. S3I and J). Therefore, the depletion of substrates needed for production of ketone bodies might be behind the reduced viability, although the reduction in other energetic resources relevant under these conditions (e.g., amino acids; [28]) should also be considered.

3.5. Catalase deficiency reduces lipogenesis and maintains relatively high AMPK activity in the liver

The previous results suggest that the absence of catalase promote metabolic alterations that are detected when mice are subjected to

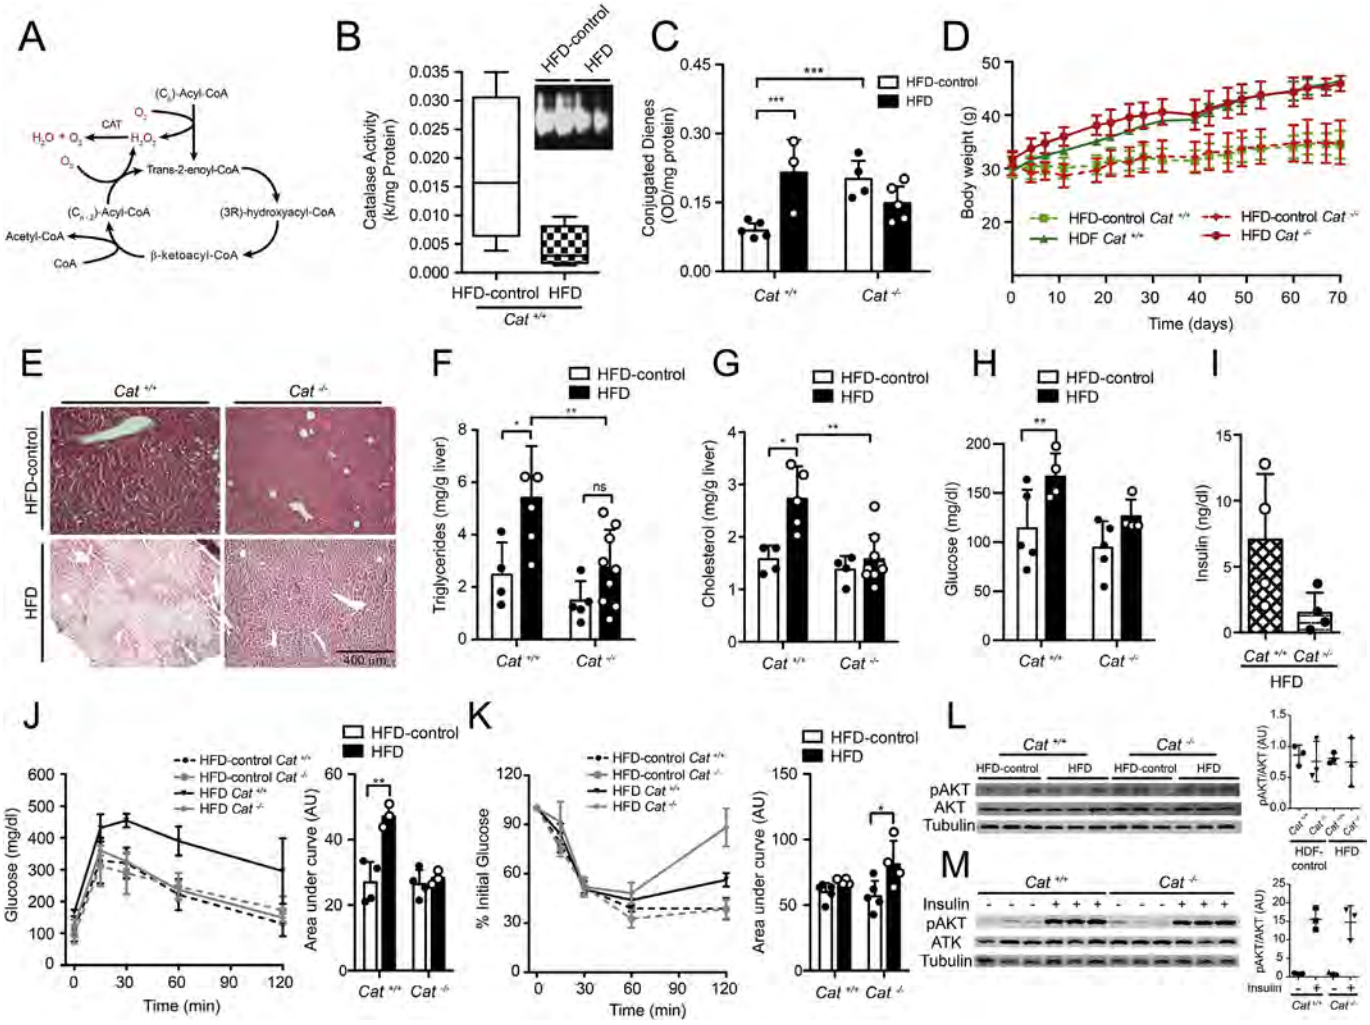

Fig. 3. Liver oxidative damage and metabolic parameters in mice with ($Cat^{+/+}$) and without ($Cat^{-/-}$) catalase under a high fat diet. Determinations were done in samples from mice fed with HFD-control diet or high fat diet (HFD) for 6 months. (A) Schematic representation of H_2O_2 production throughout every cycle of peroxisomal fatty acid β-oxidation. (B) Liver catalase activity. Inset shows catalase activity determined by a gel-based assay. (C) Liver oxidative damage, as estimated by the amount of conjugated dienes. (D) Body weight gain. (E) Representative images of hematoxilin-eosin stained liver sections. (F, G) Triglycerides (F) and cholesterol (G) content in liver. (H, I) Glucose (H) and insulin (I) serum levels. (J, K) Glucose levels during the glucose (J) and insulin (K) tolerance tests performed on mice after fed with the diets indicated. Areas under the curve are shown for statistical comparative analyses. (L, M) Liver pAKT and AKT, determined by western-blot, in mice fed with HFD-control and HFD (L) and after insulin infusion to mice fed with standard chow (M). Note that the liver oxidative damage and fat accumulation in response to HFD did not occur in mice lacking catalase, observations that correlated with the apparent increased insulin sensitivity. All values shown are the mean ± SD; n = 3–9. *$p < 0.05$, **$p < 0.01$ and ***$p < 0.001$ (two-way analysis variance).

feeding regimes that affect lipid metabolism. In order to get insights into the metabolic pathways altered in the liver by the lack of catalase, we estimated the expression levels of metabolic genes. In basal conditions (i.e., ad libitum ingestion of standard chow), gene expression showed downregulation of several selected genes (e.g., *Gck, Pparγ2, Spot14, Fasn*) in the liver of $Cat^{-/-}$ mice (Fig. S4A). When this comparison was done with liver samples from animals fed with food pellets of different composition (i.e., HFD-control diet; Tables S2–S4), some of the genes tested showed a contrasting expression pattern (*Gck*, *Pck1*, *G6pc*, *Fgf21*, *Cpt1a*) and downregulation of some lipogenic genes was not as evident in livers of mutant mice (e.g., *Spot14, Fasn*; Fig. S4B). This differential gene expression detected is possibly due to the nutrient composition of food pellets provided (Tables S2–S4) that, as described above, also affected the levels of lipid peroxidation.

Under feeding with a HFD for 3 months, mRNA levels of lipogenic genes (*Acc, Fasn*, *Elov6, Scd1* and *mGpat*), included the positive regulators *Pparγ2* and *Spot14*, were lower in livers of $Cat^{-/-}$ than of wild type mice (Fig. S4C). The expected expression up-regulation of *Fasn*, *Spot14* and *Pparγ2* was detected since 15 days after HFD feeding in the liver of wild type mice, whereas no or a mild effect was observed in the liver of mice lacking catalase (Fig. 5A); of note was the significant response of the *Pparγ2* gene in livers of wild type mice that, although upregulated in livers of $Cat^{-/-}$ mice, the increase in mRNA levels was much lower. Significant difference in the liver expression levels of gluconeogenic genes was not detected when comparing wild type mice with mice lacking catalase fed with a HFD (Fig. 5A). The downregulation of lipogenic gene expression in the liver of $Cat^{-/-}$ mice under a HFD is in agreement with the key role of lipogenesis in the generation of hepatic steatosis [22,29].

On the other hand, the mRNA levels of genes associated with catabolism such as *Gck* (encoding the first enzyme in the degradation of glucose), *Acox1* (encoding the first enzyme of the peroxisomal fatty acid β-oxidation pathway) and *Fgf21* (encoding a growth factor released in association with lipolysis) were higher in $Cat^{-/-}$ mice after 3 months of HFD feeding (Fig. S4C). Among these genes, only the expression of *Gck* responded to two-weeks HFD feeding (Fig. 5A), showing upregulation in livers of wild type mice as previously reported [30], but this effect was reduced in those of $Cat^{-/-}$ mice. These data together suggest

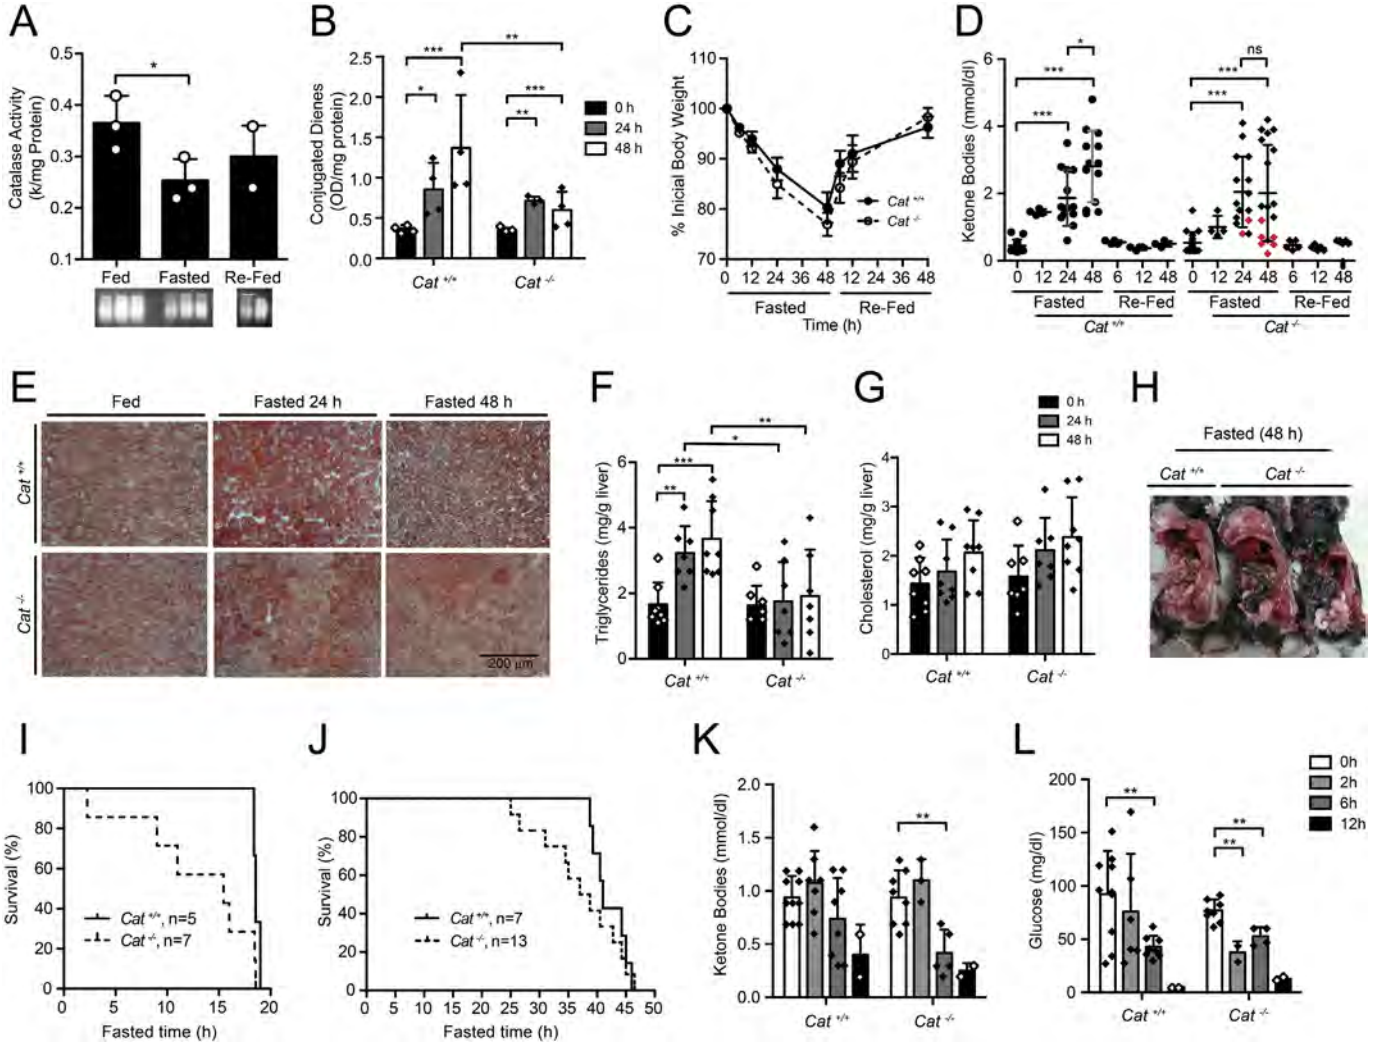

Fig. 4. Oxidative damage and fat accumulation in livers of mice with ($Cat^{+/+}$) and without ($Cat^{-/-}$) catalase after fasting. Adult mice were fasted for up to 48 h and measurements were done at the same daytime (9 AM). (A) Liver catalase activity after 24 h fasting and after refeeding for 12 h. The picture below shows catalase activity determined by a gel-based assay. (B) Liver oxidative damage, as estimated by the amount of conjugated dienes. (C) Percent of body weight loss across 48 h fasting/48 h refeeding. (D) Serum ketone body levels across 48 h fasting/48 h refeeding. Red dots are serum ketone body levels of mice that are about to die (i.e., still and did not respond to touch) at the time of fasting indicated. (E) Representative images of red-oil stained sections from livers of mice, fed or fasted, with the genotype indicated. (F, G) Triglycerides (F) and cholesterol (G) content in livers. (H) Aspect of bowel of mice after 48 h fasting. Note the necrotic aspect of the bowel of fasted mice lacking catalase. (I, J) Survival of fasted (I) or 6 h-fed (J) newborn mice. (K, L) Serum ketone body (K) and glucose (L) levels of newborn mice across fasting. Note that, apparently, reduced fat accumulation and ketone body production is the cause of reduced survival of mice lacking catalase. All values shown are the mean ± SD; n = 3–10. $*p < 0.05$, $**p < 0.01$ and $***p < 0.001$ (two-way analysis variance). (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

that the lack of catalase causes a reduction in lipogenesis leading the metabolic balance to favor catabolic activity.

Fasting is a short-term metabolic shift that could reveal the direct metabolic consequence of lacking catalase. The expression of *Pparγ2, Spot14*, *Fasn*, *Scd1* and *Gck* was similarly reduced upon fasting for 24 h, though the recovery to the level before fasting did not occur in all these genes at 12 h after refeeding. In contrast with the downregulation observed in the expression of lipogenic genes and *Gck*, the expression of gluconeogenic (*Pck1*) and catabolism-associated (*Ppara*, *Fgf21*, *Cpt1a*) genes was upregulated upon fasting and downregulated after refeeding (Fig. 5B and C). Despite the expression level of some genes in livers of $Cat^{-/-}$ were lower than those of wild type mice, generally the regulatory patterns described above were similar, although it was particularly interesting to note that *Pparγ2* downregulation upon fasting was more pronounced in samples of $Cat^{-/-}$ mice (7- vs. 16-fold reduction; Fig. 5B). In newborns, *Gck* in livers of $Cat^{-/-}$ mice was expressed at higher levels than in livers of $Cat^{+/+}$ mice, and a pronounced downregulation was detected in the former but not in the latter after fasting; the liver expression of other genes tested similarly changed in newborn mice of either genotype in response to fasting (Fig. 5D). The downregulation and upregulation response upon fasting of lipogenic and gluconeogenic genes, respectively, in livers of adult $Cat^{-/-}$ mice indicate that the main insulin/glucagon regulatory pathways that control metabolic gene expression are not markedly affected due to the lack of catalase and, thus, reduced lipogenesis and fat accumulation in mice lacking catalase is rather due to an affected central modulator of liver metabolism.

Activation of AMPK by phosphorylation reduces lipogenesis and increases general catabolism [31]. Under HFD-control diet for at least 2 weeks, the liver of mutant mice showed higher levels of activated AMPK than the liver of wild type mice (Fig. 6A), and no change in pAMPK levels could be detected when HFD was provided for as long as 3 months to either $Cat^{-/-}$ or $Cat^{+/+}$ mice (Fig. 6B). Feeding with the standard chow did not result in consistent higher levels of pAMPK in

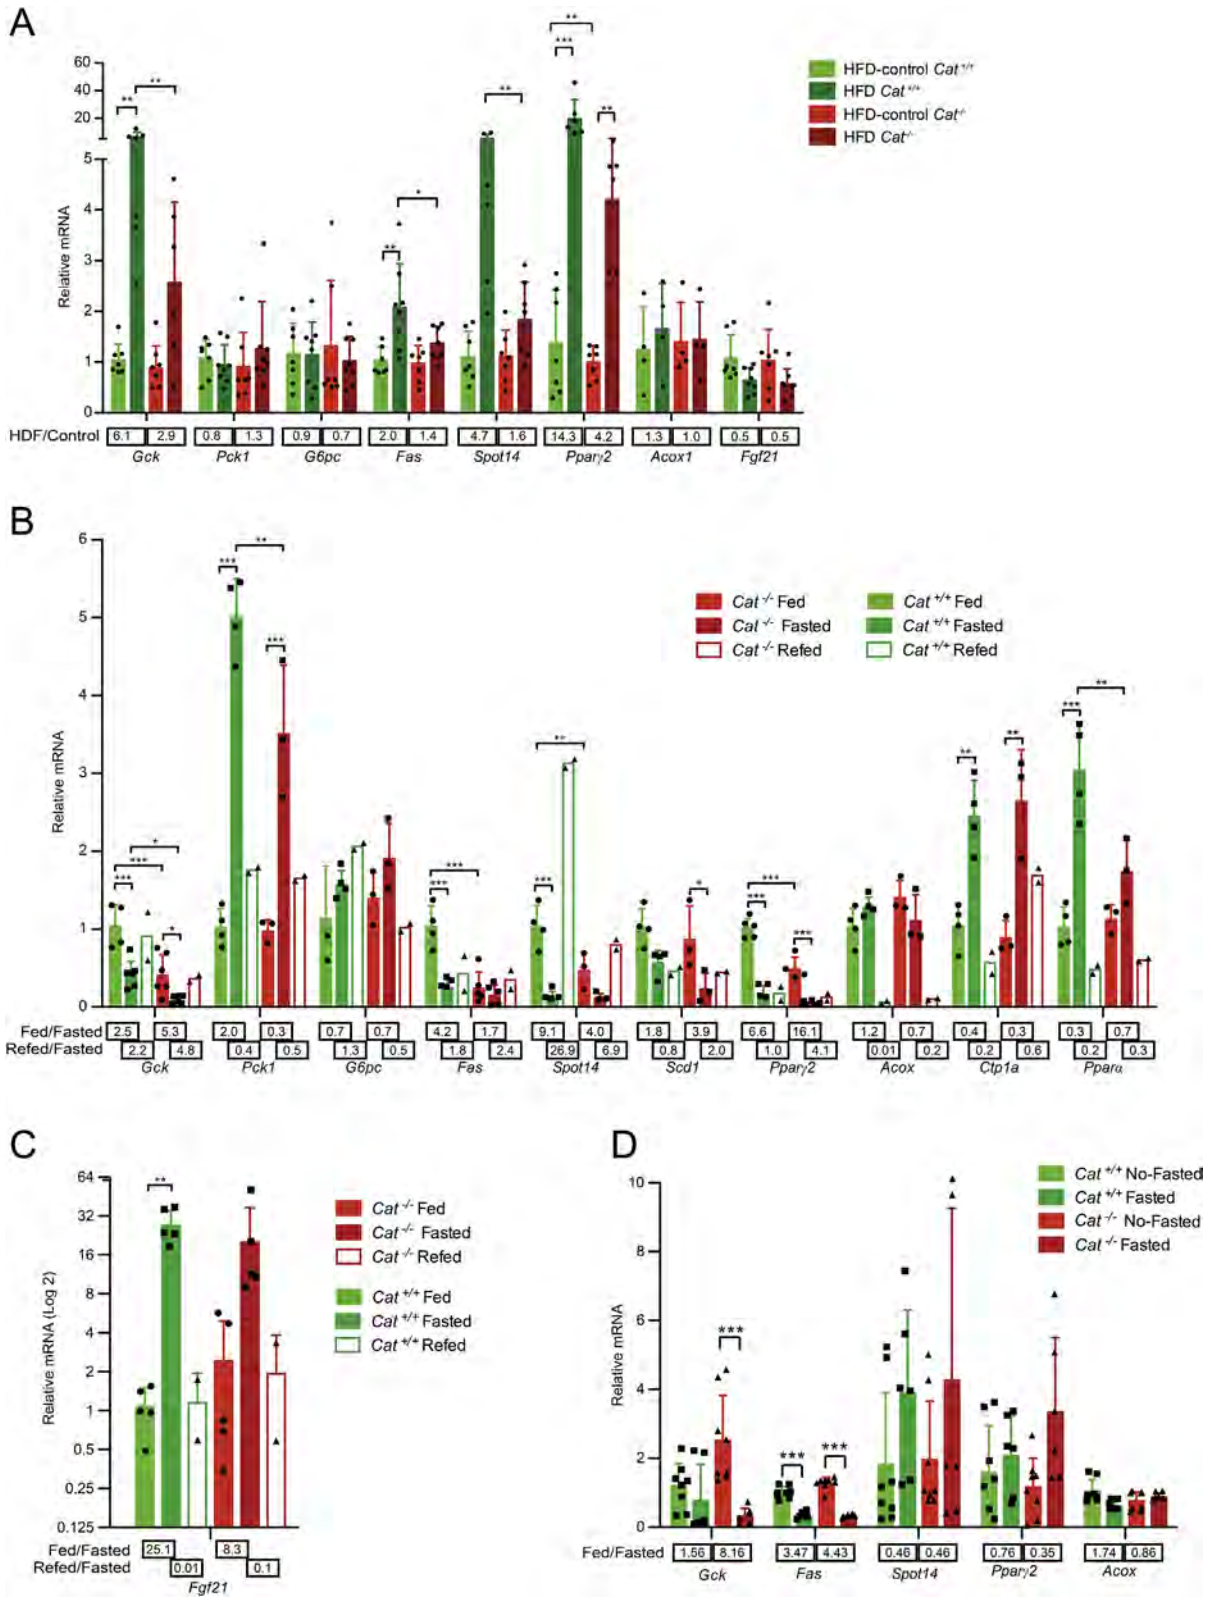

Fig. 5. Expression of metabolic genes in livers of mice with (*Cat*$^{+/+}$) and without (*Cat*$^{-/-}$) catalase fed with high fat diet or fasted. Expression levels in the liver of individual mouse either fed with a high fat diet (HFD) for 2 weeks or fasted for 24 h were determined for the genes indicated. (A) Gene expression in livers of mice fed with HFD-control diet or HFD. (B–C) Gene expression in livers of fed, fasted or refed mice. (D) Gene expression in livers of 12 h fasted newborn mice. Numbers within squares are the fold difference between bars above (estimated from the ratio of corresponding averages). Note the reduced up-regulation (upon HFD) or expression levels (before and after fasting) of *Gck* and lipogenic genes. All values shown are the mean ± SD; n = 3–5. *$p < 0.05$, **$p < 0.01$ and ***$p < 0.001$ (two-way analysis variance).

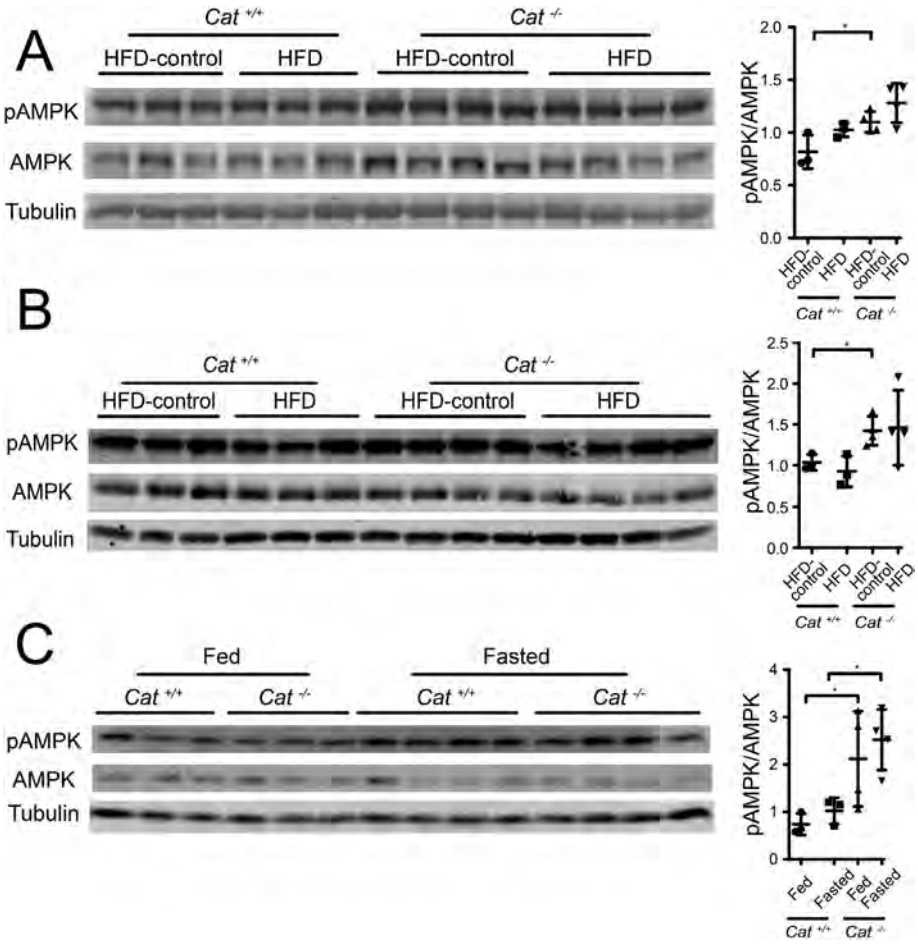

Fig. 6. Levels of activated AMPK in livers of mice with (*Cat*$^{+/+}$) and without (*Cat*$^{-/-}$) catalase fed with high fat diet or fasted. AMPK activation in liver was inferred from levels of phosphorylated AMPK (pAMPK) determined by western-blot. Quantification of the pAMPK/AMPK ratio is shown in graphs. (A, B) Activated AMPK in liver of mice fed with HFD-control diet and HFD for 2 weeks (A) or for 3 months (B). (C) Activated AMPK in liver of mice fed or fasted for 24 h. Note a higher level of activated AMPK in livers of mice lacking catalase. All values shown are the mean ± SD; n = 3–4. *$p < 0.05$ (two-way analysis variance).

livers of *Cat*$^{-/-}$ mice in comparison with those of *Cat*$^{+/+}$ mice but, as expected, the proportion of pAMPK increased in response to fasting (Fig. 6C). Therefore, at least in the presence of HFD, higher levels of activated AMPK in livers lacking catalase could contribute to lipogenesis downregulation.

3.6. Downregulation of the lipogenic master gene Pparγ2 and the lipolytic gene Fgf21 could contribute to the reduction in lifespan of mice lacking catalase

Short longevity of *Cat*$^{-/-}$ mice could be related to the metabolic alterations described above. Aged mice (12-mo or 24-mo) showed elevated expression levels of gluconeogenic genes in livers of both *Cat*$^{+/+}$ and *Cat*$^{-/-}$ mice in comparison with their corresponding young animals (3 mo; Fig. 7A), which might be expected due to the development of insulin resistance with aging [32]. *Fasn* expression increased with age (3-mo, 12-mo and 24-mo) in both wild type and mice lacking catalase and, although the difference in level of expression remained, was not significant in old animals. Higher levels of pAMPK were particularly notorious in 24-mo mutant mice (Fig. 7B). In previous experiments the pattern of *Fasn* expression positively correlated with that of *Spot14*, however, during aging, *Spot14* expression levels did not change in mice of either *Cat* genotype. Remarkably, while *Pparγ2* expression in liver did not markedly change along wild type mice aging, it was reduced with age in *Cat*$^{-/-}$ mice. Also, the liver of 24-mo mice lacking catalase showed significant lower levels of *Fgf21* expression than the liver of 24-mo wild type mice; low expression levels of *Fgf21* correlated with reduced expression of other catabolic genes such as *Cpt1* and *Acox* (Fig. 7A). In kidney, *Pparγ2* has shown to be a positive transcriptional regulator of *α-Klotho* [33], a gene involved in the control of longevity [34]. In the liver, *β-Klotho* is much more abundant than *α-Klotho* [35] and is the specific co-receptor of Fgf21 [36], therefore, we investigated whether its expression correlated with the one determined for *Pparγ2*. Despite the great difference in *α-* and *β-Klotho* expression level in liver (estimated of more than 100-fold), the expression levels of both *Klotho* genes increased in aged mice (i.e., 12- and 24-mo) regardless of the presence or absence of catalase (Fig. 7C). Autophagy was not notably affected by the absence of catalase along aging (Fig. 7D, Fig. S4D), though a consistent LC3 isoform of slightly higher molecular weight than LC3-II was exclusively present in livers of 12-mo and 24-mo *Cat*$^{-/-}$ mice (Fig. 7D). In summary, low fat accumulation, involving the participation of PPARγ2 activity, and diminished catabolic activity, involving the participation of FGF21 signaling, in the liver could be the cause of the limited lifespan of aged *Cat*$^{-/-}$ mice.

4. Discussion

Traditionally, ROS have been considered damaging molecules for the cell but, presently, a variety of studies indicate that ROS play a regulatory role in many cell processes [37,38]. The fact that the activity of many proteins depends on their oxidation state is in agreement with this regulatory role of ROS. Here we propose that H_2O_2, rather than

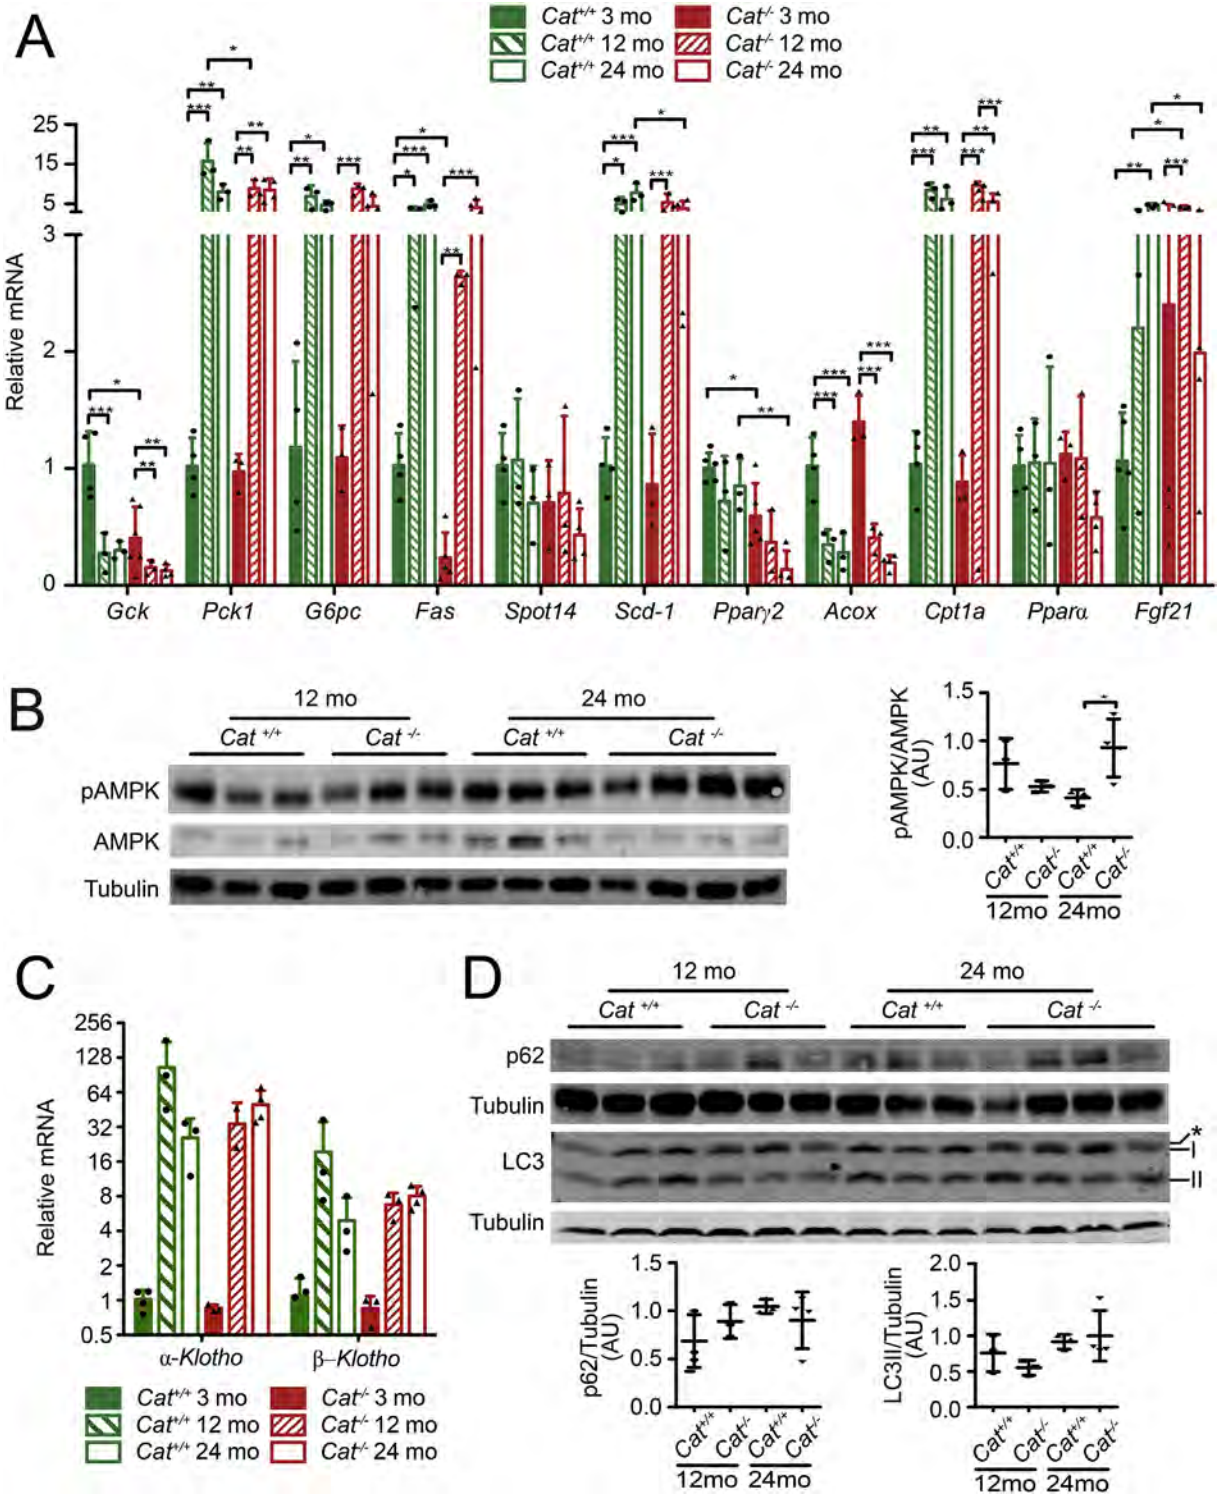

Fig. 7. Metabolic gene expression and levels of activated AMPK in livers of aging mice with (*Cat*$^{+/+}$) and without (*Cat*$^{-/-}$) catalase. Determinations were done in livers of 3-, 12- and 24-mo mice. (A) Expression of selected metabolic genes. (B) Levels of activated AMPK (pAMPK). Quantification of the pAMPK/AMPK ratio is shown in graphs. Note the marked up-regulation of gluconeogenic genes in 12- and 24-mo mice of either genotype and the contrasting pattern of *Pparγ2* expression across aging. Also, pAMPK was very abundant in livers of 24-mo mice lacking catalase. (C) Expression of *α-Klotho* and *β-Klotho* genes. (D) Levels of autophagy markers p62 and LC3; asterik in blot photograph points the extra band above LC3-I detected only in livers of mice lacking catalase. All values shown are the mean ± SD; n = 3–4. $p < 0.05$, $^{**}p < 0.01$ and $^{***}p < 0.001$ (two-way analysis variance).

causing a general macromolecular damage, alters metabolism with consequences in the mechanisms that determine longevity. Apparently, the metabolic pathways affected by the lack of catalase are influenced by feeding conditions and additional genetic factors [39,40].

4.1. Peroxisome and lipid metabolism

Due to the many oxidase reactions occurring in the peroxisome, this organelle produces a high amount of H_2O_2 [12,13]. Accordingly, peroxisomes are also rich in many antioxidants, among which catalase is

the most abundant. H_2O_2 could diffuse throughout the peroxisomal membrane passively and the derived ROS (i.e., hydroxyl radical) generally damage cellular macromolecules. However, it is apparent that intraperoxisomal-produced ROS restricts their influence to the redox state of peroxisomes and mitochondria, whereas, peroxisomes are rather resistant to oxidation by ROS produced from different cell compartment including mitochondria [41]. Therefore, the absence of general increased lipid oxidation due to the expected rise in H_2O_2 in mice lacking catalase could be due to the restricted oxidation of macromolecules in peroxisomes and mitochondria, whereas the diminished liver oxidative damage caused by a HFD or fasting could be a consequence of the metabolic alterations downstream resulting from specific protein oxidation or changes in the redox balance within these organelles (see below). Hormesis, possibly generated from the moderate increase in ROS in mice lacking catalase, could also contribute to explain the better handling of the rise in ROS under a HFD or fasting, however, up to date we have not detected evidence of a compensatory antioxidant response (Figs. S1E and F), in agreement with other reports [39,42].

The function of peroxisomes in fatty acid metabolism is presently well established [12]. Without disregarding other fundamental functions such as synthesis of ether-phospholipids, biliary acids and essential precursors of cholesterol, one major function of peroxisomes, as mitochondrial β-oxidation efficiency reduces, is a significant contribution to oxidation of long-chain fatty acids and the exclusive oxidation of very long-chain fatty acids [12,13]. Our results indicate that catalase has a relevant function in the regulation of fatty acid metabolism in the liver such that lack of catalase resulted in reduced lipid storage. Under a HFD, liver lipid storage is increased, at least in part, by increased lipogenesis [43]. Lipogenesis upregulation in this condition could derive from AMPK downregulation followed by the rise in SREBP-1c activity due to reduced AMPK-mediated phosphorylation and, consequently, upregulation of lipogenic genes [43]. Contribution of PPARγ2 is particularly relevant in this regard, functioning as a positive regulator of lipogenesis and also of fat storage, causing steatosis when upregulated [44]. In addition, the increase in *Gck* expression observed under a HFD, might provide the essential amount of NADPH to fuel lipogenesis [45]. The relatively higher levels than wild type of pAMPK and reduced upregulation of *Pparγ2* and *Gck* in livers of $Cat^{-/-}$ mice, which correlated with lower amount of *Fasn* and *Acc* mRNA are in accordance with reduced lipogenesis as the cause of limited steatosis after a HFD. Although there is not a clear mechanism by which alterations in the peroxisome could affect lipogenesis, products of peroxisomal lipolysis could represent either a significant amount of substrates for lipogenesis or PPARγ2 ligands [46]. Since liver steatosis upon feeding with a HFD can occur in the absence of peroxisomes and with decreased lipogenesis [47], indirect effects of lack of catalase on fatty acid transport and storage should also be considered (see below).

Fasting is another condition that promotes liver fat accumulation which, paradoxically, is associated with increased lipolysis and reduced lipogenesis [23]. A simple explanation to this phenomenon is the inability of liver to process all fatty acids released from the adipose tissue and imported into the liver under this condition; however, the actual mechanism is still a puzzle. Based on the regulation of gene expression, the reduced fat accumulation in the liver of mice lacking catalase upon fasting could hardly be due to the reduced expression levels of lipogenic genes before food deprivation, though it should not be discarded the possibility that a precondition (i.e., hormesis) is set in association to the reduced basal lipogenic activity under fed conditions. Increased lipolysis seems unlikely too, since not only minor differences were detected in levels of lipolytic gene expression, but also ketone bodies reached similar levels than wild type up to 48 h of fasting. Interestingly, NRF2, a transcription factor that controls an antioxidant response, prevents of excess fat accumulation in the liver upon fasting, apparently, by a mechanism that does not involve major alterations in lipogenesis or lipolysis [48,49]. It is tempting to speculate that increased β-oxidation due to fasting together with the lack of catalase elevates H_2O_2 to a level that does not cause significant oxidative damage and maintains NRF2 during fasting and, as a consequence, causes reduced fat accumulation. This mechanism could also contribute to reduced fat accumulation during a HFD, since lack of NRF2 promote hepatic steatosis. The regulation of *Pparγ* by NRF2 supports a role of this latter transcription factor in the liver metabolic phenotype of mice lacking catalase [50,51].

4.2. Lipid metabolism and aging

The effects of lack of catalase on liver fat accumulation point to lipid metabolism as the cause of shorter than wild type lifespan of $Cat^{-/-}$ mice. Accordingly, body weight and liver fat accumulation was reduced in aged $Cat^{-/-}$ mice. Although the cause of death of old animals has not been identified, this could be related to the mechanism that causes death of fasted mice. Survival of fasted mice is critically dependent on the existing energetic reserves at the time of food deprivation. In particular, after glycogen exhaustion in fasting conditions, fatty acid β-oxidation in the liver becomes essential for the production of ketone bodies, the systemic energetic source when glucose is scarce. Thus, survival of fasted newborn mice is compromised by the absence of ketolysis [26]. Newborn mice lacking catalase died upon fasting with a similar pattern as mice unable to use ketone bodies and, although the rapid use of ketone bodies limited the detection of their complete depletion before death, the decline in ketone bodies at 6 h of fasting were significant only in mice lacking catalase. In agreement with this view, adult $Cat^{-/-}$ mice that died under fasting correlated with an abrupt reduction in ketone bodies. Although we cannot discard that other reserves distinct from lipids also limit the survival of $Cat^{-/-}$ mice under fasting, our data suggest lipid shortage as a determinant of survival in conditions of food restriction or during aging. In agreement with this conclusion, the gene encoding PPARγ2, which promote lipid storage and its absence causes premature aging [52], was downregulated before fasting and in aged $Cat^{-/-}$ mice.

The participation of lipid metabolism in survival under food restriction and longevity has been previously determined. In *C. elegans*, DAF-16, a classical promotor of longevity in association with reduced insulin/IGF signaling, induces lipid synthesis [53]. However, the role of lipid metabolism in longevity is remarked by the increased lifespan of *C. elegans* lacking germ cells in which fat accumulation is an evident characteristic [54]. Interestingly, *SKN1*, a functionally-related *Nrf* homologous gene, is required for extended longevity in this condition, and although it protects against oxidative stress, also limits excess accumulation of fat [55]. Suggesting the participation of peroxisomal catalase in this phenomenon, *C. elegans* deficient in *ctl-3*, the gene encoding the peroxisomal catalase in this organism, exhibit, as in mice, shortened lifespan and reduced oxidative damage [56]. In addition, lack of peroxisomal catalase or H_2O_2 derived from fatty acid β-oxidation rescue *C. elegans* lacking AMPK from death under the hibernation-like dauer state by increasing, with minimal oxidative damage, accumulation of fat, an energetic reserve required for survival in this condition [57]. Therefore, the function of peroxisomal catalase in the regulation of lipid metabolism, maintenance of fat reserves, and longevity is conserved among distant organisms, though the mechanism may vary depending on environmental or genetic conditions.

4.3. Concluding remarks

The present work reveals a relevant role of catalase in the modulation of lipid metabolism. Physical interaction between lipid droplets and peroxisomes [12] suggests that peroxisomal activity and, thus, peroxisomal H_2O_2, are part of the regulatory mechanism. Since long fatty acids can be degraded in peroxisomes, this metabolic activity might explain why the penetrance of *Cat* deficiency in lipid metabolism was mainly revealed when mice ingested HFD or under extended

INFORME DE LABORES 2019

fasting. Genetic factors also appear to have a profound effect on the consequences associated with reduced catalase activity. For instance, an opposite phenotype to the one reported here (i.e., increased body weight and fat accumulation) has been observed in a mouse strain with in a slightly different genetic background (i.e., C57BL/6J vs. C57BL/6 N of the present study) [39,40]; the possible genetic modifier in this case is *Nnt*, a nuclear gene encoding the mitochondrial nicotinamide nucleotide transhydrogenase that is expected to affect the balance NAD^+/NADH and $NADP^+$/NADPH in mitochondria and has been related to body weight gain and obesity [58,59].

Catalase deficiency uncovers a mechanism by which ROS regulate lipid metabolism without oxidative damage, with implications in the mechanism that control longevity. Although alterations determined in the liver due to the lack of catalase are sufficient to provoke systemic metabolic alterations that can put at risk animal survival, direct cell autonomous damages in other tissue cannot be discarded. The ability of peroxisomal catalase to diminish cellular replicative senescence of human fibroblast [60] indicate that this enzyme can perform cell autonomous functions. However, the origin of the phenotype of animals lacking catalase cannot be conclusively attributed at this time to a cell autonomous function in hepatocytes, and non-cell autonomous functions involving, among others, adipose tissue should be considered.

The production and efficient use of reserves should be especially important for animals in the wild, since food is not equally available during the whole year. Thus animals, should have evolved mechanisms to survive under shortage of food, including those to store energetic resources and to efficiently use them [61]. Catalase can be an essential enzyme in these mechanisms that, through the control of peroxisomal H_2O_2, supports an optimal metabolic balance by regulating, at least, lipid metabolism. In this context, it is tempting to speculate that lifespan determination during evolution was critically influenced by the capacity of animals to survive under food restriction. The peroxisomal catalase could, then, be an evolutionary conserved component required for optimal use of metabolic reserves, before than protecting from the oxidative damage that characterizes aging.

Acknowledgements

We appreciate the support by members of our group throughout fruitful discussions. We thank to all service units in our institution, in particular, the animal facility (supervised by Graciela Cabeza, Sergio Trujillo and Elizabeth Mata) and the DNA synthesis unit, without their assistance this work would not be possible. We also appreciate the technical contribution of Olivia Vázquez-Martínez, Deisy Gasca-Martínez and Mayra L. López-Cervantes of the INB-UNAM, and of Concepción Valencia of the IBT-UNAM. We also thank all the support provided by Landsteiner Scientific, SA de CV. This work was supported by grants IN209813 and IN213416 from PAPIIT-UNAM. JRPE was recipients of a CONACYT fellowship for graduate studies.

ABSTRACT The flagellar lipoprotein FlgP has been identified in several species of bacteria, and its absence provokes different phenotypes. In this study, we show that in the alphaproteobacterium *Rhodobacter sphaeroides*, a Δ*flgP* mutant is unable to assemble the hook and the filament. In contrast, the membrane/supramembrane (MS) ring and the flagellar rod appear to be assembled. In the absence of FlgP a severe defect in the transition from rod to hook polymerization occurs. In agreement with this idea, we noticed a reduction in the amount of intracellular flagellin and the chemotactic protein CheY4, both encoded by genes dependent on σ^{28}. This suggests that in the absence of *flgP* the switch to export the anti-sigma factor, FlgM, does not occur. The presence of FlgP was detected by Western blot in samples of isolated wild-type filament basal bodies, indicating that FlgP is an integral part of the flagellar structure. In this regard, we show that FlgP interacts with FlgH and FlgT, indicating that FlgP should be localized closely to the L and H rings. We propose that FlgP could affect the architecture of the L ring, which has been recently identified to be responsible for the rod-hook transition.

IMPORTANCE Flagellar based motility confers a selective advantage on bacteria by allowing migration to favorable environments or in pathogenic species to reach the optimal niche for colonization. The flagellar structure has been well established in *Salmonella*. However, other accessory components have been identified in other species. Many of these have been implied in adapting the flagellar function to enable faster rotation, or higher torque. FlgP has been proposed to be the main component of the basal disk located underlying the outer membrane in *Campylobacter jejuni* and *Vibrio fischeri*. Its role is still unclear, and its absence impacts motility differently in different species. The study of these new components will bring a better understanding of the evolution of this complex organelle.

KEYWORDS bacterial flagellum, FlgH, FlgJ, FlgP, L ring, *Rhodobacter sphaeroides*, flagellar basal disk, outer membrane, rod-hook transition

The bacterial flagellum is a rotary nanomachine embedded in the cell envelope. The motor is powered by the electrochemical ion gradient formed across the cytoplasmic membrane. The rotating part has three well-defined structures: the basal body, which expands from the cytoplasm to the outer membrane; the hook that is the first extracellular structure; and the helical filament that thrusts the cell forward through rotation of the flagellar motor (1, 2). The rotor is surrounded by a stator formed by multiple transmembrane subunits of MotA/MotB, or PomA/PomB in bacteria with H^+- or Na^+-driven motors, respectively (3–7). These proteins form a channel that conveys ions across the membrane and couples ion flow to rotation (8–10). In *Escherichia coli* and *Salmonella enterica* serovar Typhimurium (from here on *Salmonella*), the basal body is formed by four rings and a rod that expands from the cytoplasm to the outer

membrane (OM), while the membrane/supramembrane (MS) ring is formed by 26 subunits of FliF that is located at the inner membrane (IM) (11, 12). At the cytoplasmic side the MS ring connects with the C-ring that is formed by FliG, FliM, and FliN; these proteins have been implicated in torque generation and morphogenesis (13–15). The periplasmic side of the MS ring couples with the flagellar rod through the adaptor protein FliE (16, 17). The rod formed by FlgB, FlgC, FlgF, and FlgG spans the cell wall and the OM crossing the P and L rings, which act as bushings for the rotating rod (18–21). FlgI and FlgH form the P and L rings, respectively (22). It has been recently proposed that L-ring formation contributes to dislodging the scaffolding protein FlgJ from the tip of the growing rod; this enables the transition from rod to the polymerization of the hook (23). The hook is the first extracellular structure, and it is formed by approximately 120 subunits of FlgE. The flagellar filament is formed by thousands of flagellin subunits and connects to the hook by means of the hook-associated proteins FlgK and FlgL (12, 24, 25).

Recently, electron cryotomography (ECT) of cells from different bacterial species allowed *in situ* visualization of the intact flagellum. These studies have revealed that the basal body has a central core structure that is conserved; however, around it a great diversity of additional components were observed (5, 7, 26, 27). The protein composition of these additional elements is still mostly unknown. In this regard, it has also been recognized that the presence of certain flagellar proteins is restricted to specific bacterial groups, and their characterization is incipient. This is the case for FlgT and FlgP, which are both absent in *E. coli* and *Salmonella*. FlgT is present in several species of *Vibrio* and *Aeromonas*, whereas FlgP has been reported to be present in species of *Vibrio* and in *Campylobacter jejuni* (28–32).

FlgT forms the H ring that covers the L and P rings and which is instrumental in supporting the high swimming velocities reported for several species of *Vibrio* (28). FlgP is a lipoprotein that was first identified and characterized in *Vibrio cholerae* and *C. jejuni* (29, 30, 32). In *V. cholerae* the absence of FlgP provokes a reduction in the number of flagellated cells, and morphologically the filaments were shorter than those observed in wild-type cells (29, 32). In contrast, a *flgP* mutant strain of *C. jejuni* was able to assemble a normal flagellum that showed a paralyzed phenotype (Mot$^-$) (30). Recently, flagella of a *flgP* mutant of *V. fischeri* and *C. jejuni* were observed by ECT, and the reconstructed images were compared to those of the wild-type cells. It was suggested that FlgP is a component of a structure named basal disk, which seems to be in contact with the OM (7). The basal disk is required to form other flagellar structures such as the medial and proximal rings in *C. jejuni* or to recruit the stator complexes in *V. fischeri* (7). These authors also observed that in the *flgP* mutant of *C. jejuni* the flagellum is formed, which agrees with previous reports; however, in contrast to what had been reported for *V. cholerae*, the *flgP* mutant of *V. fischeri* seldom forms a flagellum (7).

Rhodobacter sphaeroides is an alphaproteobacterium with two different flagellar systems (33). Transcription of the *fla1* set produces a single subpolar flagellum that is expressed constitutively under the growth conditions commonly used in the laboratory (33, 34). The products encoded by the *fla2* set produce several polar flagella (33, 35). However, the expression of the *fla2* genes is achieved only under very particular conditions. Fla2 flagella were detected in a mutant strain lacking the master activator of the *fla1* genes that acquired a gain of function mutation in the histidine kinase CckA (36). Phylogenetic analysis of these flagellar gene systems suggested that the *fla1* set was acquired by *R. sphaeroides* from an ancestral gammaproteobacterium, whereas the *fla2* set is vertically inherited (33).

The *fla1* system of *R. sphaeroides* includes the *flgT* and *flgP* genes. FlgT forms the periplasmic H-ring that covers the P and L rings, similar to the observed situation in *Vibrio* species; however, the phenotype of the *flgT* mutant strain differs from that of these bacteria, given that in *V. cholerae* and *V. alginolyticus* the absence of FlgT results in a reduction of the number of flagellated cells, but in *R. sphaeroides* the absence of FlgT yields a Mot$^-$ phenotype, where the flagellum is paralyzed (37–40).

INFORME DE LABORES 2019

In this study, we characterized FlgP from *R. sphaeroides*. This protein is absolutely required for the assembly of the Fla1 flagellum, and its absence results in the lack of hook and filament. FlgP was detected in isolated wild-type filament basal body structures, and evidence is presented suggesting that FlgP interacts with FlgH and FlgT.

(This study was conducted by C. Pérez-González in partial fulfillment of the requirements for a Doctorado en Ciencias Biomédicas degree from the Universidad Nacional Autónoma de Mexico, Mexico City, Mexico.)

RESULTS

FlgP is required for swimming and filament assembly. In *R. sphaeroides* the gene *flgP* encodes a 177-amino-acid polypeptide. The N terminus shows a short sequence similar to the consensus sequence recognized by the signal peptidase II (SPaseII) that has a predicted cleavage site between Ala20 and Cys21, with Ala at position +2. The identity of the residue at the +2 position after the cleavage site indicates if the polypeptide will be retained at the IM or directed to the OM (41, 42). Therefore, the presence of Ala at this position, suggests that FlgP is localized in the OM (Fig. 1A). This protein shows a 25/27% identity with homologs in *V. cholerae* and *C. jejuni*. In *R. sphaeroides flgP* is the first gene of a putative operon formed by *flgP*, *flgT*, *flgA*, *flgM*, and RSWS8N_05380 *orf* (Fig. 1A). The first three genes show overlapping of the translation stop and start codons. *flgT* encodes the protein that forms the H ring, which is present is some bacterial species (28), FlgA is a chaperone that assists in the assembly of the L ring and, FlgM is the anti-σ^{28} factor required to transcribe the late flagellar genes. RSWS8N_05380 encodes a 123-amino-acid protein that has not been reported to be involved in either flagellar biogenesis or swimming.

To characterize the role of FlgP in the flagellar biogenesis of *R. sphaeroides*, a mutant strain in *flgP* (Δ*flgP*::*aadA*) was constructed. This mutant was unable to swim and introduction of the plasmid that expresses *flgP* (pRK_flgP) did not restore swimming; however, when the plasmid pRK_flgPT (that drives the expression of *flgP* and *flgT*) was introduced, swimming was recovered (Fig. 1B). These results suggest that the allele Δ*flgP*::*aadA* generates a polar effect on the expression of *flgT*. Nevertheless, the role of FlgP on swimming was clearly appreciated in the Δ*flgP*/pRK_flgT strain, since the expression of *flgT* did not restore swimming, suggesting the absence of *flgP* by itself is responsible of this defect. The presence in these strains of FlgP and FlgT was verified by Western blotting (Fig. 1C) and, as expected, FlgT is absent in the strain carrying the Δ*flgP*::*aadA* allele but is present in the nonmotile Δ*flgP*/pRK_flgT strain. Furthermore, FlgP was detected in the wild-type strain and also in the Δ*flgP* strain harboring pRK_flgP and pRK_flgPT (Fig. 1C). Given that in this bacterium the flagellar hierarchy is controlled by the master activator FleQ (43), the absence of FlgP in the Δ*fleQ* mutant strain indicates that *flgP* is expressed as a part of the flagellar regulon (Fig. 1C).

Overlapping of the translation stop and start codons *of flgP*, *flgT*, and *flgA* suggests that these genes form an operon. We noticed that the Δ*flgP*::*aadA* allele affects the expression of *flgT* but not the expression of *flgA*, since the Δ*flgP*::*aadA*/pRK_flgPT strain was fully motile (and the lack of FlgA would have produced a Fla$^-$ phenotype). From these observations, it could be hypothesized that the absence of FlgT in the Δ*flgP*::*aadA* mutant could be caused by translational coupling. This possibility would also explain why the insertion of the nonpolar gene *aadA* (44) could affect the expression of the downstream gene; alternatively, in the absence of FlgP, FlgT could be unstable. Unfortunately, several attempts to isolate a *flgP* mutant without a resistance marker were unsuccessful; therefore, we carried out experiments to characterize the Δ*flgP* (Δ*flgP*::*aadA*) mutant always in the presence of the plasmid pRK_flgT. In this strain the amount of FlgT detected by Western blotting is similar to the amount detected in WS8N (Fig. 1C), suggesting that FlgT should not be limiting for flagellum formation and functioning.

Filaments were easily detected in the microscope in the wild-type strain, but this structure was not observed in Δ*flgP* and Δ*flgP*/pRK_flgT strains, indicating that these

(C) Immunodetection of FlgT and FlgP in total cell extracts of the Δ*flgP*::*aadA* mutant and strains expressing FlgP, FlgT, and FlgPT from the promoter of pRK415. WT, wild-type strain WS8N.

two mutant strains are Fla$^-$ (Fig. 2). In contrast, the filament was visible in Δ*flgP*/pRK_flgP cells. Given that a strain lacking of *flgT* shows a Mot$^-$ phenotype (37), the presence of the flagellar filament in the Δ*flgT* mutant was expected (Fig. 2). From these results, we conclude that the absence of FlgP causes the loss of the flagellar filament.

INFORME DE LABORES 2019

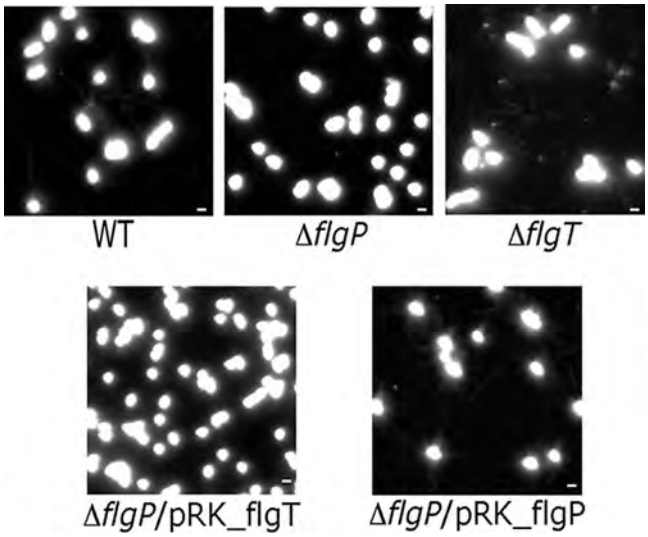

FIG 2 Flagellar filament detection. Cells were stained with DAPI and observed by fluorescence microscopy as indicated in Materials and Methods. WT, wild-type strain WS8N. Scale bars, 1 μm.

This phenotype is different from that reported for *C. jejuni* and *V. cholerae* (29, 30) but is similar to what was observed in *V. fischeri* (7).

Role of FlgP in the formation of other flagellar structures. Given that the flagellar filament is absent in the Δ*flgP*/pRK_flgT mutant cells, we proceeded to investigate whether the flagellar hook would be assembled in the absence of FlgP. For this, Δ*flgP*/pRK_flgT cells were labeled with an anti-FlgE antibody previously conjugated with Alexa Fluor 488 and then observed by fluorescence microscopy. The hook was readily observed as small fluorescent foci that are placed laterally on wild-type strain cells (Fig. 3A). In contrast, the Δ*flgP*/pRK_flgT mutant strain did not show fluorescent foci, indicating that the hook is not formed in the absence of FlgP (Fig. 3A).

A simple explanation for the lack of hook and filament in the Δ*flgP*/pRK_flgT strain could be that FlgE and FliC were not being synthesized. This possibility was tested by probing total cell extracts by Western blotting using anti-FliC and anti-FlgE antibodies (Fig. 3B). The intensity of the signal for FlgE was similar in the wild-type cells and Δ*flgP*/pRK_flgT mutant, indicating that the absence of the hook is not due to a lack of protein. However, the amount of FliC was severely reduced in the mutant strain (Δ*flgP*/pRK_flgT). This is the logical outcome of a lack of hook, since the anti-sigma factor FlgM cannot be exported from the cells, and transcription by σ^{28} of the late flagellar genes does not take place (43, 45–47). The expression of CheY4 was used to corroborate this notion, given that it is also σ^{28} dependent (48). As expected, a severe reduction in the amount of CheY4 was observed in the Δ*flgP*/pRK_flgT strain (Fig. 3B).

In Δ*flgP*/pRK_flgT cells, the hook was not detected but FlgE was observed in total cell extracts, raising the possibility that FlgE could be exported from the cell but not assembled. To test this idea, the supernatants of WS8N and Δ*flgP*/pRK_flgT cultures were probed by Western blotting for the presence of FlgE. No protein was detected in these samples, indicating that FlgE is not exported (data not shown). As a control, the cells of these cultures were vigorously vortexed to promote the mechanical shearing of the flagella. After centrifugation, the supernatants were tested by Western blotting. In these samples, FlgE was detected in the culture supernatant of WS8N but not in the Δ*flgP*/pRK_flgT strain (see Fig. S1 in the supplemental material), confirming the notion that, in the absence of FlgP, FlgE is not exported or assembled.

To determine whether the MS ring is formed in the absence of FlgP, we evaluated the localization of the GFP-FliF fusion protein as an indirect evidence of the presence of this structure. As shown in Fig. 4A, GFP-FliF was detected as a single focus in wild-type and Δ*flgP* cells, suggesting that the formation of the MS ring is not affected by the absence of FlgP.

(B) Western blots of total cell extracts of the indicated strains, using anti-FlgE, anti-FliC, and anti-CheY4 antibodies. WT, wild-type strain WS8N.

It has been shown that in *Salmonella* FlgE is degraded in strains where the rod genes have been deleted. This was caused by the high sensitivity of FlgE to periplasmic proteases (49). We tested by Western blot analysis whether FlgE could be detected in rod mutants, type III export apparatus mutants, and the Δ*flgP*/pRK_flgT mutant. Total cell extracts of these strains revealed the presence of FlgE in the wild-type strain, in the export apparatus mutants (*fliE*, *fliR*, and *fliO*), and also in the Δ*flgP* mutant (Δ*flgP*/pRK_flgT) and its absence in the rod mutants (Δ*flgB* and Δ*flgC*) (Fig. 4B). A reduction of

INFORME DE LABORES 2019

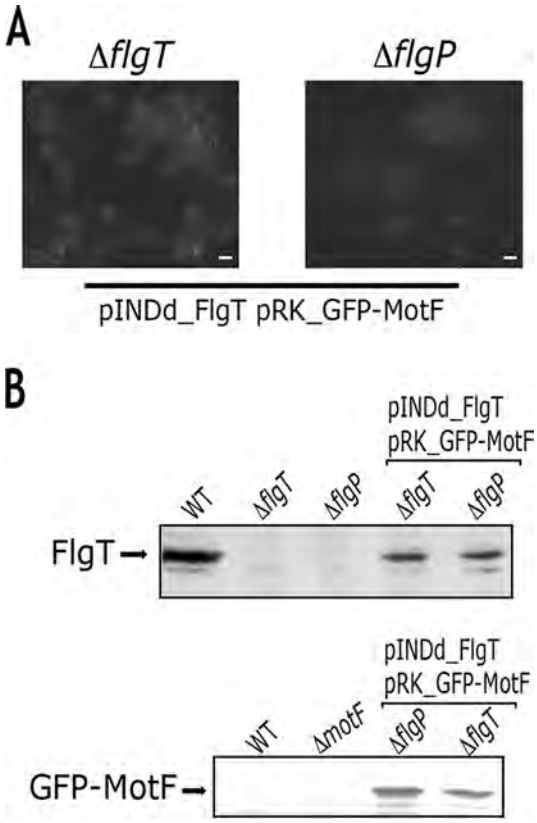

FIG 5 GFP-MotF detection by fluorescence microscopy. (A) Cells expressing FlgT from pINDd and GFP-MotF from pRK415. Scale bars, 1 μm. (B) Immunoblotting detection of FlgT and GFP-MotF in total cell extracts of the indicated strains. WT, wild-type strain WS8.

FlgE in the Δ*flgI* mutant was noted; this is in accordance with the results previously reported for *Salmonella* (49). The mutants lacking the flagellar master regulator, *fleQ*, and the hook gene *flgE* were included as negative controls. The presence of FlgE in Δ*flgP*/pRK_flgT cells (Fig. 4B) suggests that in the absence of FlgP the rod is completed since FlgE is not degraded by the periplasmic proteases, as has been previously reported (49).

FlgT is another flagellar protein localized in the periplasm, it is required to form the H ring that covers the P and L rings. In *R. sphaeroides* the absence of FlgT did not affect flagellar biogenesis (37). To determine whether FlgT is present in the flagellum in the absence of FlgP, we took advantage of the fact that the flagellar protein MotF (present exclusively in *R. sphaeroides*) requires the presence of FlgT to be localized (50). Therefore, we determined if green fluorescent protein (GFP)-MotF is localized in the absence of FlgP. We used strain SF3 (Δ*flgT*) carrying the plasmids pINDd_flgT and pRK_GFP-MotF as a positive control for this experiment. We observed the presence of fluorescent foci in these cells, suggesting that GFP-MotF is localized in the flagellar structure (Fig. 5A). However, no fluorescent foci were detected in Δ*flgP* cells carrying pINDd_flgT and pRK_GFP-MotF, suggesting that in the absence of FlgP the H ring could be destabilized or severely affected. The presence of FlgT and GFP-MotF in total cell extracts of these strains was detected by immunoblotting (Fig. 5B).

FlgP is an integral protein of the basal body and is stable in different genetic backgrounds. We isolated filament basal body structures of WS8N cells and used this preparation for electron microscopy (EM) and for immunodetection of FlgP. An example of the EM images obtained from intact flagellar structures, shows the H ring covering the L and P rings, as previously reported (37) (Fig. 6A). In this same sample, we were able to detect FlgP by immunoblotting, indicating that this protein is a part of this structure (Fig. 6B).

Downloaded from http://jb.asm.org/ on October 20, 2020 at UNAM INST DE INVEST BIOMEDICAS

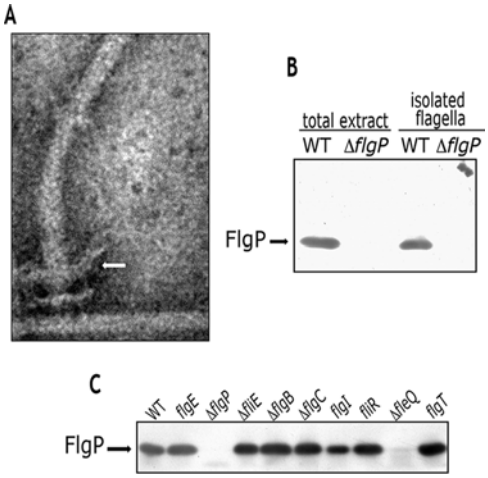

FIG 6 Presence of FlgP in isolated filament basal body preparations and stability of FlgP in the absence of other flagellar components. (A) Sample of an isolated flagellum from the wild-type strain. The arrow denotes the H ring. (B) Immunoblotting of total cell extracts using anti-FlgP antibodies (left lanes) and isolated flagella (right lanes). (C) Stability of FlgP in different genetic backgrounds. Western blots of total cell extracts were probed with anti-FlgP antibodies. WT, wild-type strain WS8N.

In *C. jejuni* FlgP was generally absent or present at low levels in whole-cell lysates of proximal rod (*flgB* and *flgC*) and type III export apparatus (*flip* and *flhA*) mutants (7), indicating that FlgP stability was dependent on other flagellar components. In contrast, we detected FlgP in rod (*flgB* and *flgC*) and type III export apparatus (*fliE* and *fliR*) mutants (Fig. 6C), demonstrating that in *R. sphaeroides* this protein is not particularly unstable.

FlgP interacts with FlgT and FlgH. Given that FlgP is part of the flagellar basal body structure, we evaluated possible interactions of FlgP with other periplasmic flagellar proteins, such as FlgH, FlgT, and MotF. The interactions of the periplasmic region of FlgP with the periplasmic regions of FlgH, FlgT, and MotF were tested using a yeast two hybrid assay. In this assay, we observed that FlgP interacts with FlgH and FlgT (Fig. 7). The possible interaction between FlgP with MotF could not be evaluated given the autoactivation of these proteins (Fig. 7). It should be noted that Gal4BD-FlgP by itself allows growth in the absence of histidine; therefore, only strong interactions that alleviate adenine auxotrophy were considered positives (Fig. 7). In this assay, the interaction of FlgP with FlgP does not occur, since a yeast strain expressing AD-FlgP and BD-FlgP recovered the prototrophy only for histidine (data not shown). Interestingly, FlgH showed a positive interaction with FlgT (Fig. 7).

The interaction of FlgP with FlgP was evaluated by blue native polyacrylamide gel electrophoresis (PAGE). Two different species of FlgP were detected: one with an apparent molecular mass around 36 kDa that may represent the monomeric form and another that was around 56 kDa (Fig. 8A), suggesting that under these conditions FlgP could form a dimer. In these experiments, we also detected the monomeric and dimeric forms of FlgT (54 and 113 kDa, respectively). When FlgP and FlgT were mixed together, a weak but conspicuous band of around 90 kDa appeared, which was interpreted to represent the oligomeric complex formed by the association of FlgP with FlgT. Since high-molecular-weight markers were used in this native electrophoresis, the apparent molecular masses of the complexes may be overestimated. Denaturing two-dimensional SDS-PAGE (lanes 2 to 4) show that the bands observed in the native gels belong exclusively to FlgP, to FlgT, or to the FlgP/FlgT mixture (Fig. 8B).

The interaction of FlgP with FlgT was also detected by pulldown using glutathione *S*-transferase (GST)–FlgP as a bait (Fig. 9A). In contrast, the interaction between FlgP and FlgH could not be detected using this assay, given that FlgH showed nonspecific interactions with GST (data not shown). Nonetheless, we were able to corroborate the

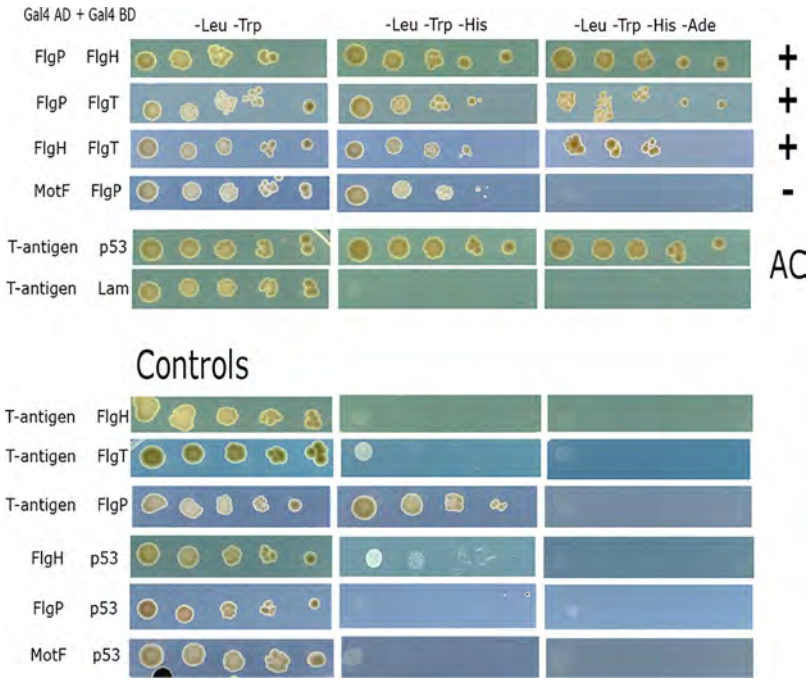

FIG 7 Double hybrid assay. Yeast were transformed with the plasmids indicated at the left. The pairs Gal4AD T-antigen with Gal4 p53, and Gal4AD T-antigen with Gal4 BD Lam served as positive and negative controls, respectively (labeled "AC" [assay controls]). Transformant cells were seeded on the medium indicated at the top. To rule out spurious activation of the reporter genes, yeast cells transformed with a control plasmid, either Gal4 AD T-antigen or Gal4 BD p53, and a flagellar gene in the BD or AD plasmid. The growth of these cells was tested and corresponds to the six combinations in the lower part of the figure (Controls).

interaction between FlgP and FlgH by far-Western analysis (Fig. 9B). For this experiment, GST-FlgP was incubated with the blotted proteins $His_{6\times}$-FlgH and $His_{6\times}$-GFP. The presence of complexes was tested using anti-FlgP antibodies (Fig. 9B). The blotted proteins were also incubated with GST, and the absence of unspecific complexes was confirmed using anti-GST (Sigma) antibodies (Fig. S2).

DISCUSSION

Several new ancillary proteins different from the well-characterized flagellar components of *E. coli* and *Salmonella* have been identified in various bacterial species. These new elements in some cases improve flagellar rotation by recruiting a larger number of stator complexes (7); in others, they contribute to remodel other bacterial structures such as the outer membrane (OM) (51). FlgP is absent in *E. coli* and *Salmonella* but is present in several species of *Vibrio* and many *Epsilonproteobacteria* (29, 30, 52). ECT images suggest that FlgP could form a basal disk located underneath the OM. It has also been suggested that the basal disk (FlgP) attaches to the motor via the P ring (FlgI) in *C. jejuni* and in *V. fischeri* through the H ring (FlgT) (7).

In *R. sphaeroides*, the absence of FlgP causes a Fla$^-$ phenotype that contrasts with the phenotypes observed in other species so far studied. In *C. jejuni*, a Δ*flgP* mutant forms flagella (30), whereas a reduction in the number of flagellated cells was observed for the Δ*flgP* mutant in *V. cholerae* (29). This suggests that in *R. sphaeroides* the role of this protein is not redundant; perhaps the absence of flagellar rings, such as the T ring (present in *Vibrio*) or the proximal and medial disks (found in *C. jejuni*), makes flagellar assembly impossible in the absence of FlgP.

A closer inspection of the Δ*flgP* strain of *R. sphaeroides* revealed that the flagellar hook is not assembled even though the presence of the hook protein FlgE was detected by Western blotting. In addition, the fact that flagellin (FliC) and the chemotactic protein CheY4 were not detected in total cell extracts of the Δ*flgP* mutant

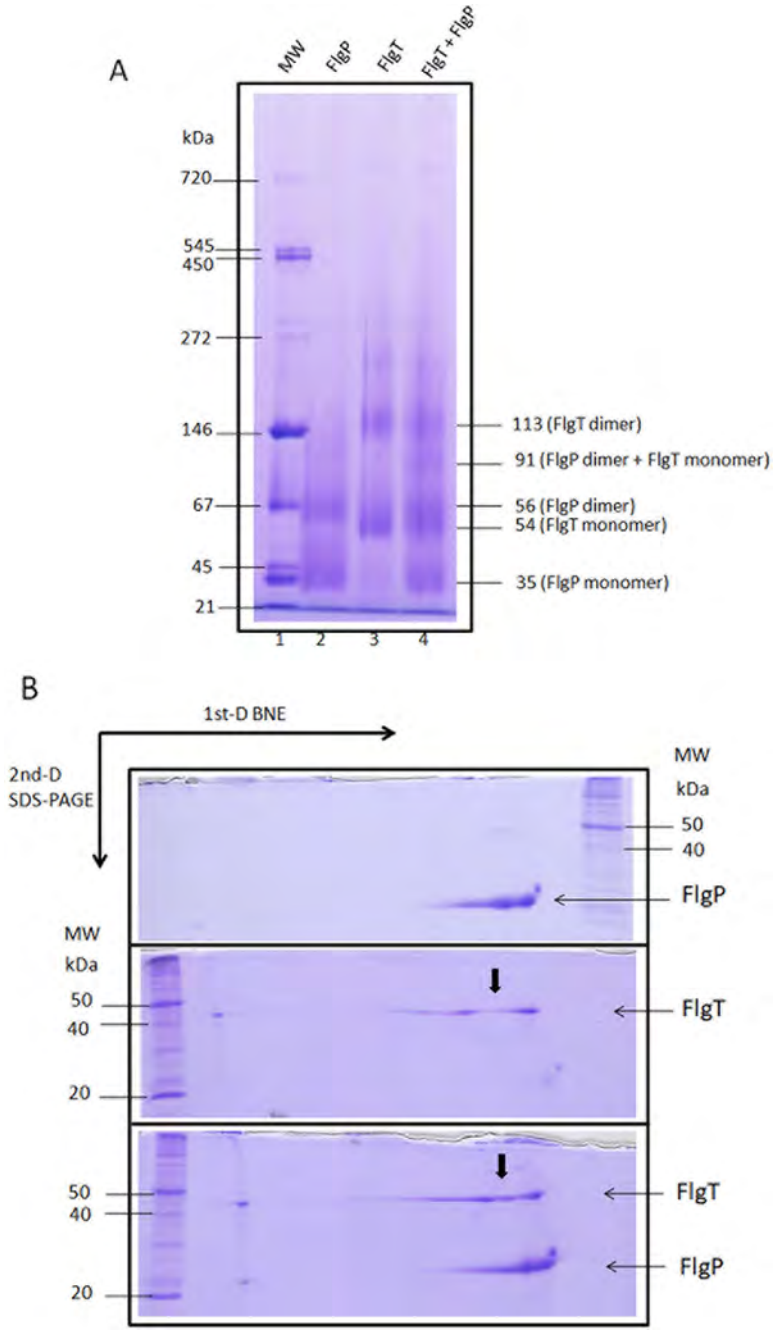

FIG 8 Blue native gel electrophoresis. (A) Portions (100 μg) of $His_{6\times}$-FlgPp (lane 2), FlgTp-$His_{6\times}$ (lane 3), or a mixture of both proteins (lane 4) were dialyzed overnight in PBS (pH 7.4), mixed with sample buffer, and loaded into a native 4 to 12% acrylamide gradient gel. Lane 1 was loaded with molecular weight protein markers. Gel casting and electrophoresis were performed as described previously (44). (B) Parallel lanes of each sample of interest from panel A were cut and subjected to denaturing two-dimensional SDS-PAGE (14%). The presence of FlgT in the complex formed with FlgP is indicated by an arrow.

indicates that the anti-sigma factor FlgM is not exported. This is consistent with the well-established idea that a structural defect in the hook basal body (HBB) impairs secretion of FlgM (45–47). Nevertheless, in the absence of FlgP, the flagellar rod is assembled, and FlgE was not detected in the culture supernatant. Therefore, the absence of FlgP could be altering the rod to filament transition. This idea is in accordance with the images observed by ECT for the *flgP* mutant of *V. fischeri*, where the rod and the P, L, H, and T rings are formed, but the presence of the hook is not evident (7).

INFORME DE LABORES 2019

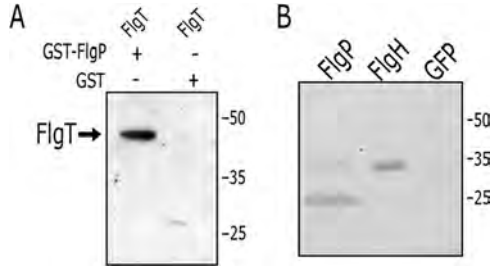

FIG 9 FlgP interaction with FlgT and FlgH. (A) Pulldown assay using glutathione-agarose beads containing either GST-FlgP or GST, followed by incubation with FlgT. After a washing step, the presence of FlgT retained by the tested proteins was revealed by Western blotting. (B) Interaction between FlgP and FlgH tested by far-Western analysis. Purified $His_{6\times}$-FlgP, $His_{6\times}$-FlgH, and $His_{6\times}$-GFP were subject to 12% SDS-PAGE and blotted on nitrocellulose. The membrane was incubated with GST-FlgP for 2 h. After a washing step, the presence of FlgP was detected using anti-FlgP antibodies.

As a result of the absence of FlgT (H ring) in *R. sphaeroides*, MotF is not localized in the flagellar motor (37). Furthermore, we have observed in the present study that in the absence of FlgP, MotF is not recruited to the flagellum, suggesting that the H ring is not formed or that the architecture of the H ring is modified. In agreement with the possible remodeling of these rings as they are being assembled, it was observed in *V. fischeri* that in the absence of FlgP, all the rings were formed (i.e., P, L, T, and H rings), but the stator complexes were not recruited, suggesting that FlgP could modify the architecture of the H and T rings (7).

It is conceivable that the flagellar structure of *R. sphaeroides* has a basal ring similar to that observed in *C. jejuni* and *V. fischeri*. In this regard, our results indicate that FlgP can interact with itself, suggesting that it could be a part of an oligomeric structure, such as the basal disk. Besides this interaction, FlgP also interacts with FlgT, indicating that the OM is in close contact with the H ring through FlgP. In spite of the strong interaction between FlgP and FlgT, recruitment of FlgP to the growing structure should not be dependent only on FlgT, given that the flagellum is formed in its absence (37) but not in the absence of FlgP. This indicates that even in the absence of FlgT, FlgP must be recruited to the growing flagellum. This recruitment could be achieved by a FlgP-FlgH interaction. This is in contrast to the observed situation in *V. fischeri*, where it was proposed that the H ring provides a platform for assembly of FlgP (7).

We observed that FlgP is stable in the different flagellar mutants tested. In contrast, in *C. jejuni*, FlgP was not detected in total cell extracts of proximal rod and type III export apparatus mutants (7). This difference could be explained by a different intrinsic stability of these proteins or by the presence of ancillary flagellar proteins, such as FlgQ and FlgO (52), that are absent in *R. sphaeroides*. FlgQ is required for FlgP stability in *C. jejuni* (30), whereas FlgO of *Vibrio* seems to be a part of the H ring and is located at the OM similar to FlgP (29).

To explain the Fla^- phenotype of the Δ*flgP* strain, we propose that the L ring could be remodeled by the basal disk. This event could be part of the check point that involves the removal of the rod scaffolding protein FlgJ to enable hook assembly. It is possible that in other species in which the flagellar hook can be assembled in the absence of FlgP, other proteins collaborate to form an L ring suitable for the removal of FlgJ or that FlgH could accomplish this task by itself, as occurs in *E. coli* and *Salmonella*. A model summarizing the findings reported in this is presented in Fig. 10.

MATERIALS AND METHODS

Strains, plasmids, growth conditions, and oligonucleotides. All strains and plasmids used in this study are listed in Table 1. *R. sphaeroides* was grown in Sistrom's minimal medium at 30°C (53). Cultures were grown heterotrophically in Erlenmeyer flasks with orbital shaking (200 rpm). *E. coli* was grown in Luria broth at 37°C (54). When needed, the following antibiotics were used at the indicated concentrations: 25 μg/ml kanamycin, 50 μg/ml spectinomycin, and 1 μg/ml tetracycline. For *E. coli*, the antibiotics used were 100 μg/ml ampicillin, 50 μg/ml kanamycin, 50 μg/ml spectinomycin, 30 μg/ml gentamicin, 25 μg/ml chloramphenicol, and 10 μg/ml tetracycline. The oligonucleotides used are also listed in Table 1.

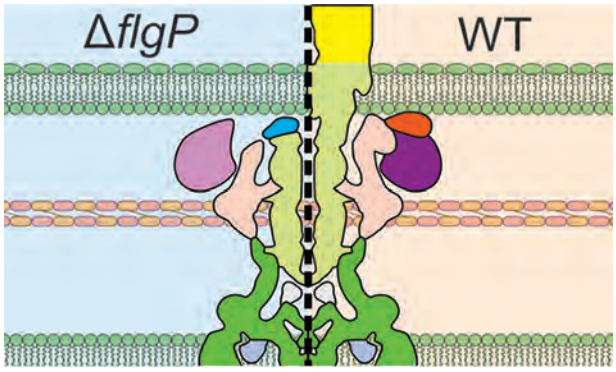

FIG 10 Model showing the possible role of FlgP during flagellar biogenesis in *R. sphaeroides*. The right side depicts the wild-type flagellum where FlgP (orange) interacts with FlgH (pink) and FlgT (violet). The hook (yellow) is formed. The left side shows that, in the absence of FlgP, the hook is not assembled. A possible perturbation in the formation of the L ring (formed by FlgH) prevents the progression of the flagellar biogenesis beyond the outer membrane. In the absence of FlgP, the possible presence of FlgJ (blue) at the tip of the growing flagellum is shown. In addition, FlgT is shown in light violet, indicating that it may also be absent.

Molecular biology techniques. Standard methods were used to isolate and analyze chromosomal or plasmid DNA (54). Restriction and other DNA-modifying enzymes were purchased either from New England BioLabs (NEB, Ipswich, MA), Roche (Basel, Switzerland), or Invitrogen (Carlsbad, CA). Plasmids used for sequencing were purified using an Illustra plasmidPrep minispin kit (GE Healthcare Life Sciences, Buckinghamshire, UK). DNA was amplified with the appropriate oligonucleotides using PrimeSTAR HS DNA polymerase (TaKaRa Bio, Inc., Mountain View, CA) according to the manufacturer's recommendations.

Isolation of mutant strains. The CP1 strain (Δ*flgP*::*aadA*) was obtained by cloning together two PCR products that amplified the upstream and downstream regions of *flgP* in pTZ19R. The 756-bp product from the upstream region of *flgP* was obtained using the oligonucleotides orf_11 and RvRSP0035B, whereas the downstream product of 1,293 bp was obtained with the oligonucleotides FwRSP0035B and orf_12. These PCR products were joined through a BglII site designed in the oligonucleotides and cloned in pTZ19R. A 1.4-kb PCR fragment carrying the *aadA* gene, which encodes the streptomycin/spectinomycin adenylyltransferase (Spc^r) (44), was cloned into pTZ_ΔflgPup-down previously digested with BglII. The resultant plasmid, pTZ_ΔflgP::aadA, was digested with XbaI, and the fragment carrying the allele Δ*flgP*::*aadA* was subcloned in plasmid pQJ200mp18. To obtain the CP2 strain (Δ*flgH*::*aadA*), a similar strategy to that used to obtain CP1 was followed; in this case, the 700-bp product from the upstream region of *flgH* was obtained using the oligonucleotides Fw_flgH and Rvi_flgH, whereas a downstream product of 1,008 bp was obtained with Fwi_flgH and Rv_flgH. These products were joined through a BamHI site designed in the oligonucleotides and cloned in pTZ19R_BamHI−. The fragment carrying the *aadA* gene was cloned in pTZ_flgHup-down previously digested with BamHI. The fragment carrying Δ*flgH*::*aadA* was subcloned in pJQ200mp18.

Plasmid constructions. pRK415_flgP plasmid carries a 1,086-bp fragment that includes the coding region of *flgP* (534 bp), 501 bp upstream and 51 bp downstream. pRK_flgPT carries a 2,300-bp fragment that includes the coding regions of *flgP* and *flgT* (1,083 bp), 501 bp upstream of *flgP* and 186 bp downstream of the stop codon of *flgT*. pINDd_flgT was obtained by cloning the 1,083-bp PCR product encoding the complete polypeptide of FlgT in pINDd.

Protein purification. The coding region of *flgP* lacking the segment corresponding to the signal peptide was amplified by PCR using the oligonucleotides 0035fwBAD and 0035RvBAD and cloned in pBAD-HisB. The resultant plasmid was introduced to the strain LMG194 strain. A culture of this strain was grown until midexponential phase and induced with 0.2% arabinose for 6 h at 28°C. The culture was harvested and resuspended in buffer containing 50 mM Tris, 5% glycerol, 50 mM NaCl, and 1 mg/ml lysozyme (pH 8). The cell suspension was sonicated on ice with three bursts of 10 s. Cell debris were removed by centrifugation. The supernatant was mixed with nickel-nitrilotriacetic acid (Ni-NTA)–agarose beads (1/250 of the original culture volume) and incubated by 1 h on ice, with occasional mixing. The beads were washed with 3 volumes of phosphate-buffered saline (PBS; pH 7.4). The protein was eluted in PBS containing 20% glycerol and 200 mM imidazole. The purity of the $His_{6\times}$-FlgPp (periplasmic region of FlgP) was evaluated by SDS-PAGE and Coomassie blue staining. The sample was dialyzed overnight using PBS (pH 7.4). To purify FlgH, the fragment encoding from Ala58 to the stop codon of *flgH* (FlgHp) was amplified by PCR using the oligonucleotides flgH-pGABfw and flgH-pBADB and cloned in pET28a. The purification protocol was similar to the procedure used to purify $His_{6\times}$-FlgPp, except that induction of the cell culture was carried out with 0.25 mM IPTG for 4 h at 28°C. FlgTp-His_{6X} and $His_{6\times}$-MotFp were purified using the procedures previously described (37, 50). The plasmid expressing glutathione *S*-transferase fused to the mature polypeptide of FlgP (GST-FlgPp) was constructed by cloning in pGEX-4T-2, the PCR product obtained with the oligonucleotides 0035FwpGEX and 0035RvpGEX that encompasses the coding region of *flgP*, excluding the segment that encodes the signal peptide

[a]Cm[r], chloramphenicol resistance.

sequence. The resultant plasmid was used to transform the *E. coli* strain Rosetta. The resultant cells were grown in Luria broth medium (30 ml) supplemented with chloramphenicol and ampicillin at 37°C to an optical density at 600 nm (OD_{600}) of 0.6. The culture was induced by the addition of IPTG (isopropyl-β-D-thiogalactopyranoside) to a final concentration of 0.25 mM, cultured for 4 h at 30°C, and collected by centrifugation. The cell pellet was resuspended in 1 ml of PBS containing 20% glycerol (pH 7.4) and 1 mg/ml lysozyme. The cell suspension was let stand on ice for 1 h before sonication with three bursts of 9 s. Cell debris was removed by centrifugation. The supernatant was mixed with 100 μl of glutathione-agarose beads and incubated for 1 h on ice, mixing by inversion every 10 min. The beads were washed with 3 volumes of PBS. GST-FlgPp protein was eluted in elution buffer (50 mM Tris HCl, 10 mM reduced glutathione [pH 8]). GST was purified according to a similar protocol.

Immunoblotting and antibody production. Samples were obtained from heterotrophically grown cultures at an OD_{600} of 0.6. At this point, the cells were harvested and lysed by boiling in a solution containing 2% SDS, 1% β-mercaptoethanol, and 50 mM Tris (pH 7.5). Western blotting was performed as previously described (55). Briefly, these samples were separated using 12% SDS-PAGE. After electrophoresis, proteins were transferred to nitrocellulose membranes. Membranes were blocked with 2% fat-free milk in TBST (20 mM Tris, 150 mM NaCl, containing 0.1% Tween 20 [pH 7.4]) for 12 h. After a wash in TBST, the membranes were incubated with the primary antibody in the same buffer, as indicated. Removal of excess primary antibody was carried out by washing the membrane three times in TBST. The secondary antibody (phosphatase alkaline-conjugated, anti-mouse IgG secondary antibody) diluted 1:30,000 was incubated with the membrane in TBST for 1 h. After being washed, the membranes were incubated with CDP-Star (Thermo Fisher Scientific, Waltham, MA) reagent for detection on X-ray films. Polyclonal antibodies were raised in female BALB/c mice against $His_{6\times}$-FlgPp and $His_{6\times}$-FlgHp according to previously reported protocols (55).

Microscopy. Slides were covered with an agarose pad containing Sistrom's culture medium. Images were taken with a Hamamatsu Orca-ER camera and a Nikon E600 microscope. The flagellum was stained DAPI (4′,6′-diamidino-2-phenylindole) according to a previous report (50). Immunofluorescent detection of FlgE was carried out by fixing cells from a heterotrophically grown culture, where cells were swimming (OD_{600}, ~0.6) with paraformaldehyde (3%); after 20 min at room temperature, the paraformaldehyde was removed by centrifugation. The cell pellet was resuspended in 1/10 of the original volume in PBS–1% bovine serum albumin (BSA). Anti-FlgE γ-globulins were stained with Alexa Fluor 488 (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions.

Yeast two-hybrid assays. The assays were performed according to the directions of the manufacturer (Clontech). In summary, yeast cells of the strain AH109 were cotransformed with pGBKT7 and pGADT7 plasmids expressing the mature polypeptide of FlgP, or FlgH, fused to the activation (AD) or DNA binding (BD) domain of Gal4. The DNA fragment encoding the periplasmic regions of FlgP and FlgH was obtained by PCR using the oligonucleotides 0035fw pGA-pGB and 0035rvBAD or the oligonucleotides flgH-pGABfw and flgH-pBADB, respectively. The plasmid expressing pGBD-flgT was previously reported (37). pGBKT7 and pGADT7 plasmids restore prototrophy for leucine (LEU) and tryptophan (TRP), respectively. For interaction assays, the AH109 strain carrying the appropriated plasmids was grown overnight in synthetic defined (SD) minimal medium supplemented with histidine (HIS) and adenine (ADE), washed in SD medium without HIS and ADE, diluted at OD_{600} of 0.5, and serially diluted in the same medium. From these dilutions, 10-μl aliquots were seeded on plates containing SD supplemented with HIS and ADE (–LEU –TRP), ADE (–LEU –TRP –HIS), or HIS (–LEU –TRP –ADE).

Blue native PAGE. A total of 100 μg of $His_{6\times}$-FlgPp, FlgTp-$His_{6\times}$, or a mixture of both proteins was dialyzed overnight in PBS (pH 7.4), mixed with sample buffer, and loaded in a native 4 to 12% acrylamide gradient gel. Gel casting and electrophoresis were performed as described before (56). The lines of each sample were cut and subjected to denaturing two-dimensional SDS-PAGE (14%).

Pulldown interaction assay. Next, 5 μg of GST-FlgPp or GST bound to glutathione-agarose beads in PBS (pH 7.4) was mixed with FlgT-$His_{6\times}$ in a 1:1 molar ratio. The volume was adjusted to 250 μl with PBS containing 10% glycerol and 3% BSA. The mixture was incubated for 2 h at 4°C, with mixing by inversion every 10 min. The beads were collected by centrifugation for 1 min at 3,000 rpm. The supernatant was discarded, and the beads were washed three times with 1 ml of PBS. To elute the protein, the beads were resuspended in 100 μl of buffer containing 100 mM Tris (pH 8) and 10 mM reduced L-glutathione. After 10 min, the sample was centrifuged for 1 min at 5,000 rpm. An aliquot (10 μl) of the supernatant was analyzed by Western blotting with Penta-His antibodies (Qiagen).

Downloaded from http://jb.asm.org/ on October 20, 2020 at UNAM INST DE INVEST BIOMEDICAS

Far-Western assay. Far-Western blotting was performed according to a method reported previously (57). Briefly, 5 μg of $His_{6\times}$-FlgHp and $His_{6\times}$-GFP protein was mixed with an equal volume of 2× Laemmli sample buffer without β-mercaptoethanol, loaded onto 12% acrylamide (wt/vol), and electrophoresed at 100 V. Proteins were transferred electrophoretically to nitrocellulose membranes as described previously (55). Membranes were incubated in blocking buffer (5% nonfat dry milk in PBS [pH 7.4] and 0.05% Tween 20) for 1 h with shaking. Blocked membranes were incubated with 17 μg of purified GST-FlgPp or GST proteins in 10 ml of blocking buffer for 1 h with shaking. Membranes were washed three times for 5 min in PBS (pH 7.4) and 0.05% Tween 20, followed by incubation with anti-FlgP or anti-GFP antibodies diluted 1:5,000, for 1 h, and then washed again three times for 10 min in PBS–0.05% Tween 20, followed by incubation with anti-mouse AP antibody (Sigma, 1:30,000) for 45 min. Antibody binding was detected by incubation with CDP-Star reagent according to the manufacturer´s instructions and visualized by autoradiography.

Population imaging of neural activity in awake behaving mice

Kiryl D. Piatkevich[1,2,11], Seth Bensussen[3,11], Hua-an Tseng[3,11], Sanaya N. Shroff[3], Violeta Gisselle Lopez-Huerta[4], Demian Park[1,2], Erica E. Jung[1,5], Or A. Shemesh[1,2], Christoph Straub[6], Howard J. Gritton[3], Michael F. Romano[3], Emma Costa[1], Bernardo L. Sabatini[6], Zhanyan Fu[4], Edward S. Boyden[1,2,7,8,9,10]* & Xue Han[3]*

A longstanding goal in neuroscience has been to image membrane voltage across a population of individual neurons in an awake, behaving mammal. Here we describe a genetically encoded fluorescent voltage indicator, SomArchon, which exhibits millisecond response times and is compatible with optogenetic control, and which increases the sensitivity, signal-to-noise ratio, and number of neurons observable several-fold over previously published fully genetically encoded reagents[1–8]. Under conventional one-photon microscopy, SomArchon enables the routine population analysis of around 13 neurons at once, in multiple brain regions (cortex, hippocampus, and striatum) of head-fixed, awake, behaving mice. Using SomArchon, we detected both positive and negative responses of striatal neurons during movement, as previously reported by electrophysiology but not easily detected using modern calcium imaging techniques[9–11], highlighting the power of voltage imaging to reveal bidirectional modulation. We also examined how spikes relate to the subthreshold theta oscillations of individual hippocampal neurons, with SomArchon showing that the spikes of individual neurons are more phase-locked to their own subthreshold theta oscillations than to local field potential theta oscillations. Thus, SomArchon reports both spikes and subthreshold voltage dynamics in awake, behaving mice.

Near-infrared genetically encoded voltage indicators (GEVIs) derived from rhodopsins offer high temporal fidelity, and are compatible with optogenetics[1,12,13], whereas green fluorescent GEVIs derived from the voltage-sensing domains of phosphatases or opsins are often slower and brighter[2,3,14–17]. Translating these voltage sensors into the living mammalian brain has been challenging, because of poor membrane localization, low photostability, and low signal-to-noise ratio (SNR). So far, amongst fully genetically encoded reagents, only Ace2N and paQuasAr3-s have been used to optically report voltage dynamics in a living mouse brain, reporting the activities of up to four cells in one field of view (FOV) in awake mice[4,17]. Recently, we developed a robotic directed-evolution approach and created the improved GEVI Archon1[13]. To further improve SNR in the dense, living mammalian brain, we conducted a screen for peptides to localize Archon1 to the soma[18–21], so that neuropil contamination could be reduced (Extended Data Fig. 1; see Supplementary Table 1 for the sequences of the motifs). The molecule Archon1–KGC–EGFP–K_V2.1-motif–ER2, which we call SomArchon (Fig. 1a), exhibited the highest relative change in fluorescence ($\Delta F/F$) during 100-mV voltage steps (Fig. 1g) and was well-localized to the soma (Extended Data Fig. 1h–k).

SomArchon fluorescently reported action potentials in mouse brain slices after in utero electroporation (IUE) into the cortex and hippocampus, and after adeno-associated virus (AAV)-mediated expression in the cortex, striatum, and thalamus (Extended Data Fig. 2). SomArchon was localized primarily to the membrane within 30–45 μm of the cell body in the cortex, striatum, and hippocampus (Fig. 1b, Extended Data Fig. 1h–k). The sensitivity of SomArchon was about twofold greater (Fig. 1c, d) than our previously published values for Archon1[13], and it had comparable kinetics (Fig. 1e) and SNR (defined as the maximum fluorescence change observed during an action potential divided by the standard deviation of the baseline) (Fig. 1f). SomArchon linearly reported voltage (Fig. 1g), and did not alter membrane properties or resting potential in mouse brain slices, induce gliosis, or mediate light-induced phototoxicity (Extended Data Figs. 3, 4). It has previously been demonstrated that Archon1 exhibits essentially no crosstalk under blue light illumination as used commonly for optogenetic neural activation[13]. We used a bicistronic expression system (Fig. 1h) to co-express SomArchon and the high-performance channelrhodopsin CoChR[22] in the same cell, and demonstrated that brief blue light pulses could reliably evoke action potentials that were visible in SomArchon fluorescence (Fig. 1i, j).

We performed a side-by-side comparison of SomArchon with soma-localized versions of several next-generation voltage sensors—specifically QuasAr3-s[4], paQuasAr3-s[4], ASAP3[5], and Voltron$_{525}$[6]—in mouse cortical brain slices under identical expression conditions, focusing on layer 2/3 neurons (Supplementary Table 3). The spectrally similar sensors QuasAr3-s, paQuasAr3-s, and SomArchon were recorded under identical imaging conditions (1.5 W mm^{-2}) during CoChR-mediated action potentials. ASAP3 and Voltron were recorded with the filter sets described[5,6] under similar excitation intensities as used in the initial description of Voltron[6] (25–29 mW mm^{-2}), during action potentials evoked upon application of 4-aminopyridine. Under these conditions, SomArchon exhibited the highest $\Delta F/F$ and SNR per action potential (Extended Data Fig. 5); in addition, SomArchon exhibited values higher than those previously reported for Ace2N-mNeon[7], ASAP1[2], MacQ-mCitrine[3], and QuasAr2[8] (Supplementary Table 3). In addition, SomArchon showed higher photostability than soma-localized versions of ASAP3 and Voltron$_{525}$ under comparable imaging conditions in cultured neurons (Extended Data Fig. 5e).

We virally expressed SomArchon in vivo in the mouse motor cortex, visual cortex, striatum, and hippocampus, and imaged neural activity while mice were awake with their heads fixed under a conventional one-photon microscope (Fig. 2a) using a scientific complementary metal-oxide semiconductor (sCMOS) camera and laser excitation light at 637 nm, at a power of around 1.6 W mm^{-2} (75 mW; 20× objective lens), 4 W mm^{-2} (75 mW; 40× objective lens), or 1.6 W mm^{-2} (95 mW; 16× objective lens). Cells expressing SomArchon could be resolved at depths of about 50–150 μm below the imaging surface (Fig. 2b). We could detect individual spikes in single cells in all four brain regions (Fig. 2c, e, g, i, Supplementary Video 1). The SNR per action potential ranged from about 7 to about 16 across the brain regions examined (Fig. 2d, f, h, j). To our knowledge, no other paper has reported SNR

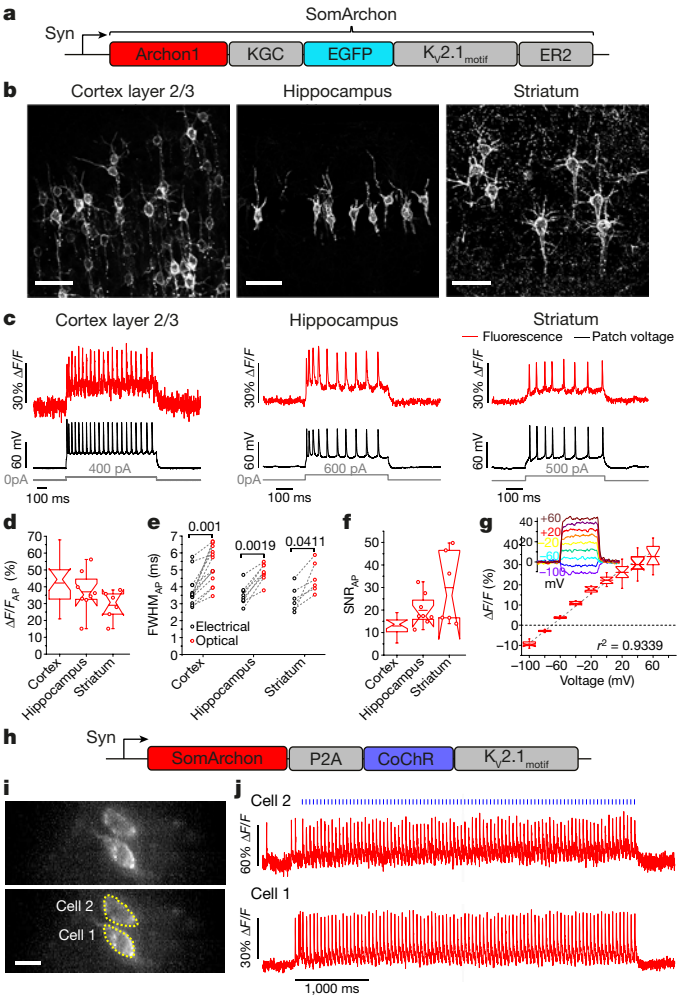

Fig. 1 | SomArchon enables high-fidelity voltage imaging in brain slices. a, Diagram of the SomArchon construct. **b**, Confocal images of SomArchon-expressing neurons in cortex layer 2/3 (left), hippocampus (middle), and striatum (right). Excitation wavelength (λ_{ex}) = 488 nm laser, emission wavelength (λ_{em}) = 525/50 nm (representative images selected from 8, 10 and 6 slices, respectively, from 2 mice each). Scale bars, 50 μm. **c**, Single-trial SomArchon fluorescence (red), and concurrent membrane voltage recorded via whole-cell patch-clamp (black), during action potentials evoked by current injection (grey); λ_{ex} = 637 nm laser at 0.8, 1.5, and 1.5 W mm^{-2} for cortex, hippocampus, and striatum, respectively. **d**, $\Delta F/F$ per action potential across recordings exemplified in **c** (representative traces selected from n = 18, 8, and 6 neurons from 5, 2, and 2 mice, respectively). Box plots: 25th and 75th percentiles with notch, median; whiskers, 1.5× interquartile range from the 25th and 75th percentiles; middle horizontal line, mean; individual data points, open circles when $n < 9$). **e**, Electrical and optical action potential waveform full-width-at-half-maximum ($FWHM_{AP}$; dashed lines connect the same neurons) across recordings exemplified in **c** (P values above brackets are from two-sided Wilcoxon rank-sum test; Supplementary Table 2). **f**, SNR per action potential across recordings exemplified in **c**. **g**, Population fluorescence of SomArchon in response to voltage steps in voltage-clamp mode, normalized to the fluorescence at −70 mV (inset, optical recordings for a representative neuron) recorded in cortex (n = 12 neurons from 2 mice). **h**, Diagram of SomArchon–P2A–CoChR–$K_V2.1_{motif}$. **i**, Fluorescence image of neurons in hippocampal slice expressing SomArchon–P2A–CoChR–$K_V2.1_{motif}$ (top) with two cells identified (bottom); λ_{ex} = 637 nm, exposure time 1.3 ms (selected from n = 3 slices from 2 mice). Scale bar, 25 μm. **j**, Representative single-trial optical voltage traces from cells shown in **i** with blue light stimulation (2 ms pulse at 20 Hz). Acquisition rate, 777 Hz.

values per action potential in living mouse brain, so we cannot directly compare our molecule to others in this regard. We were able to resolve short segments of proximal dendrites next to the soma, and detected voltage fluctuation patterns that sometimes differed from those in the soma (Extended Data Fig. 6c–f). In addition, simultaneous optical control and voltage imaging was feasible using the strategy shown in Fig. 1h, in awake behaving mice (Fig. 2k–m).

Electrophysiological studies have shown that many striatal neurons increase their responses during movement[9,23], while others decrease their responses[9,10]. Although electrophysiological recordings largely discard spatial information regarding the relative locations of the neurons being observed, recent calcium imaging studies have revealed that spatially clustered striatal neurons are activated by similar aspects of movement[11]. These calcium imaging studies focused on the increases in activity during movement; decreases in activity are harder to observe with calcium imaging. We performed voltage imaging while mice ran on a spherical treadmill (Fig. 3a), identified cell bodies and spikes from cells in the striatum (Fig. 3b–d), and aligned spiking activity to movement (Fig. 3d). Some neurons exhibited firing patterns known to occur in striatal fast spiking interneurons[24] or cholinergic interneurons[25] (Extended Data Fig. 7a–d). We found that 4 of the 14 neurons imaged were positively modulated by movement speed, and that 2 were negatively modulated by movement speed (Fig. 3e, f, Extended Data Fig. 7e, f; see Supplementary Table 2 for statistics). Furthermore, adjacent neurons did not respond to movement speed in identical ways. For example, in two recordings of three neurons each, one of the three neurons was positively modulated by movement speed whereas the other two were not (Fig. 3f, Extended Data Fig. 7a, c (cells 1, 2, 3 and cells 6, 7, 8), Supplementary Table 2). Thus, SomArchon can readily detect decreases in striatal neuron spiking during movement, and can help to disambiguate activity changes amongst spatially clustered striatal neurons.

We performed wide-field voltage imaging with SomArchon in hippocampal CA1 neurons in awake, head-fixed mice, while simultaneously recording local field potentials (LFPs). In vivo patch-clamp recordings have shown that the spikes of a CA1 neuron are more strongly phase-locked to its own intracellular theta frequency (4–10 Hz) oscillations than to the theta oscillations of the across-neuron averaged LFP[26,27]. We found that 6 of the 16 neurons had spikes phase-locked to both intracellular and LFP theta oscillations (Fig. 4a), and that 9 were phase-locked only to intracellular theta oscillations and not to LFP theta oscillations (Fig. 4b). As a population, neurons exhibited stronger phase-locking to intracellular theta oscillations than to LFP theta oscillations (Fig. 4c, d). SomArchon thus supports the analysis of subthreshold intracellular oscillations, although interpretation of these measurements must take into account background fluorescence, which—in densely labelled tissue—may result in crosstalk that affects correlations.

We evaluated the photostability of SomArchon in vivo, and found a slight decrease in fluorescence intensity in both the striatum and the hippocampus over time. However, the SNR remained largely stable in both brain regions (Extended Data Fig. 8). In the hippocampus, firing rates remained constant over time, and we were able to continuously image for up to 80 s with minimal changes in SNR (Extended Data Fig. 8i–m, Supplementary Video 1). This lack of toxicity is consistent with our results from cultured neurons (Extended Data Fig. 3).

Owing to the high performance and soma-targeted nature of SomArchon, we were able to routinely image multiple neurons at once in both cortical and subcortical brain regions (Figs. 2k, l, 3b, c, Extended Data Fig. 6a, b). In the hippocampus, using a 20× objective lens, we were able to record from 14 neurons at once, 8 of which were spiking (Fig. 4e, f). In addition, using a 16× objective lens, we routinely recorded from around 13 cells at once (n = 13.1 ± 3.5 (mean ± s.d.) neurons per FOV from 13 recording sessions in 2 awake mice). Of the 170 manually identified neurons, 107 (63%) spiked during the recording periods (duration: 13.5–27 s) (Extended Data Fig. 6g–j, Supplementary Table 4). The ability to record from multiple neurons simultaneously enabled us to examine the correlation and coherence of subthreshold activities between pairs of neurons, although background fluorescence crosstalk between nearby neurons will need to

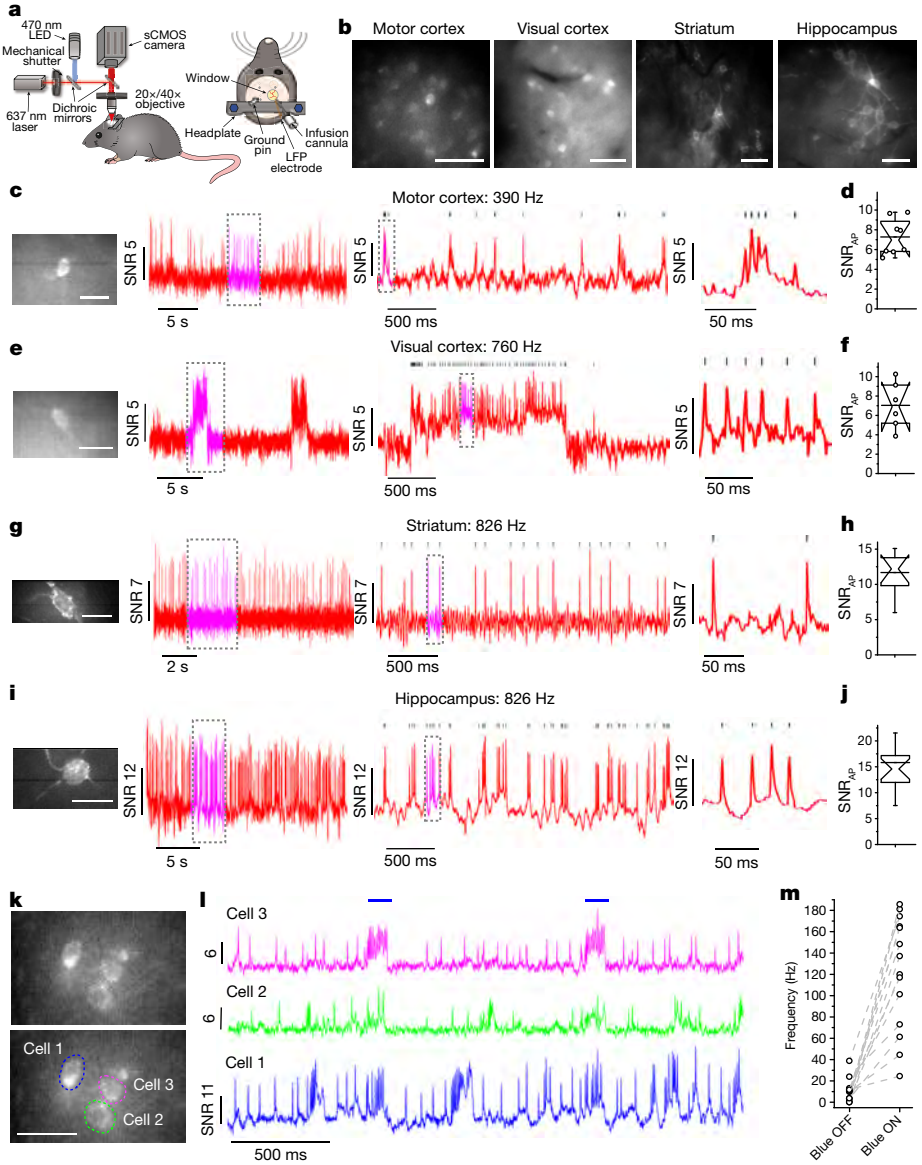

Fig. 2 | SomArchon enables single-cell voltage imaging in multiple brain regions of awake mice, using a simple wide-field imaging setup. **a**, Experimental setup. Left, awake mice had their heads fixed under a wide-field microscope; right, surgical window implant coupled with an infusion cannula and an LFP recording electrode. **b**, Representative SomArchon-expressing neurons visualized via EGFP fluorescence in motor cortex, visual cortex, striatum, and hippocampus (λ_{ex} = 470/25 nm LED, λ_{em} = 525/50 nm). Scale bars, 50 μm. **c**, **e**, **g**, **i**, Voltage imaging in motor cortex (**c**), visual cortex (**e**), striatum (**g**), and hippocampus (**i**). Left, SomArchon fluorescence image of the cell in vivo; right, optical voltage trace acquired from the cell (dashed boxes indicate time intervals shown at successively expanded time scales; vertical bars indicate peaks of action potentials identified by a custom spike-sorting algorithm). λ_{ex} = 637 nm laser at 1.6 W mm^{-2} for visual cortex and motor cortex, 4 W mm^{-2} for striatum and hippocampus, λ_{em} = 664 long-pass. Scale bars, 25 μm. **d**, **f**, **h**, **j**, Quantification of SNR per action potential for motor cortex (**d**), visual cortex (**f**), striatum (**h**), and hippocampus (**j**). Box plots as in Fig. 1. In **b**–**j**, representative images and traces were selected from, and statistics performed on, n = 8, 6, 10, and 17 cells from 3, 2, 3, and 4 mice for the motor cortex, visual cortex, striatum, and hippocampus, respectively. **k**, Fluorescence image of selected FOV showing hippocampal neurons expressing SomArchon–P2A–CoChR–$K_V2.1_{motif}$ (top) with neurons identified (bottom); λ_{ex} = 637 nm, exposure time 1.2 ms. Scale bar, 20 μm. **l**, Representative single-trial optical voltage traces from cells shown in **k** with blue light stimulation (100 ms pulse). Image acquisition rate, 826 Hz. **m**, Firing rate changes during blue light off versus blue light on conditions in individual neurons. In **k**–**m**, representative image selected from, and statistics performed on, n = 14 cells from 2 mice.

be considered when interpreting pairwise correlation and coherence measurements (Extended Data Figs. 9e–h, 10, Supplementary Discussion).

Compared to existing fully genetically encoded voltage indicators, SomArchon achieves a severalfold improvement in the number of cells that can be imaged simultaneously, while using inexpensive one-photon microscopy. The previously published record for fully genetically encoded voltage imaging was four spiking cells recorded simultaneously in an awake behaving mouse, but this required a specialized imaging setup that combined two-photon structural imaging to support patterned single-photon excitation illumination targeting individual cell bodies, as well as the blue-light-gated molecule paQuasAr3, which is incompatible with commonly used pulsed blue light optogenetic modulation[4]. ASAP3 has been used to image three dendrites at once, with 2-photon microscopy, but this approach can be used to record only single cells at the fast rates typical for voltage imaging[5]. The hybrid GEVI sensor Voltron enables imaging of 46 neurons[6], but requires the addition of chemicals delivered to the living brain that complicate in vivo mammalian use, is not compatible with optogenetics, and exhibits a lower dynamic range than SomArchon (Extended Data Fig. 5). Voltron, ASAP3, and Ace2N-mNeon all exhibit crosstalk with rhodopsins, hampering their use with optogenetic actuators. Voltage

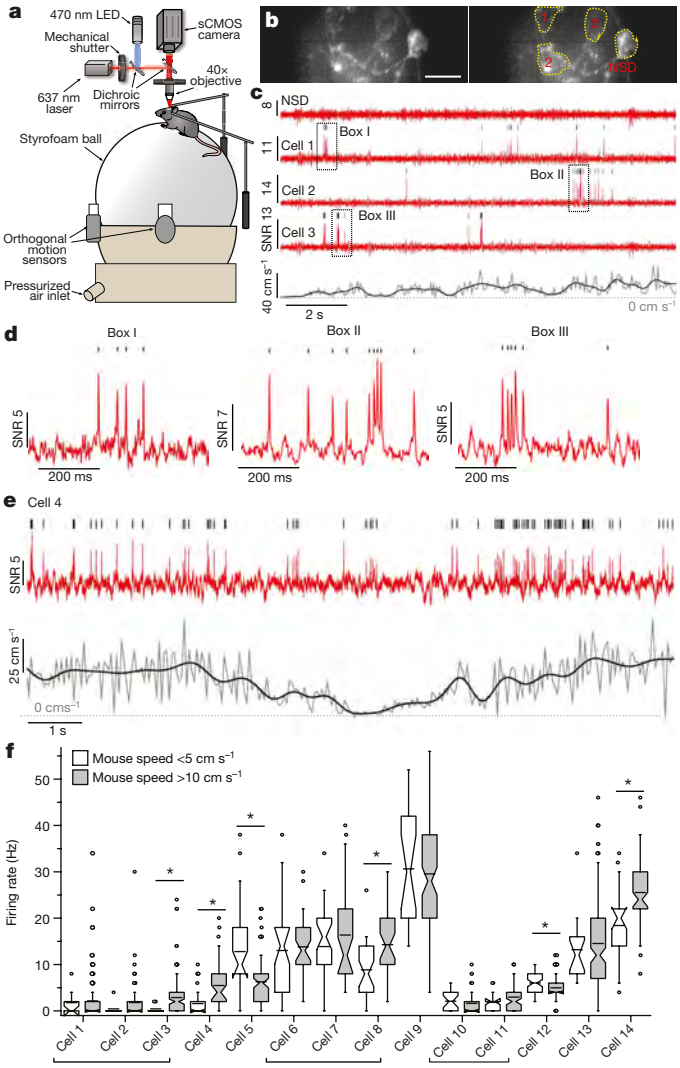

Fig. 3 | Voltage imaging of striatal neurons during locomotion. a, Schematic of the experimental setup, similar to that in Fig. 2a, but with mice positioned on a spherical treadmill. Imaging was performed with a 40× objective lens. **b**, Left, SomArchon fluorescence image of striatal cells; right, identified regions of interest (ROIs) corresponding to somas. $\lambda_{ex} = 637$ nm, exposure time 1.2 ms (representative image selected from $n = 9$ FOV from 2 mice). Scale bar, 20 μm. NSD, no spikes detected. **c**, Optical voltage traces acquired from cells in **b** and corresponding mouse movement speed (black, low-pass-filtered at 1.5 Hz; grey, raw data; representative traces selected from $n = 2$ FOV from one mouse). Image acquisition rate, 826 Hz. **d**, Magnified views of the three periods indicated by black boxes in **c**. **e**, Optical voltage trace (red) for a neuron modulated by movement speed and corresponding movement speed (black and grey; representative trace selected from $n = 14$ neurons from 2 mice). **f**, Firing rates of individual striatal neurons, during periods with low (open box plots) versus high (grey box plots) movement speed ($n = 14$ neurons from 2 mice, brackets indicate neurons from the same FOV). $^*P < 0.05$, two-sided Wilcoxon rank-sum test. Box plots as in Fig. 1.

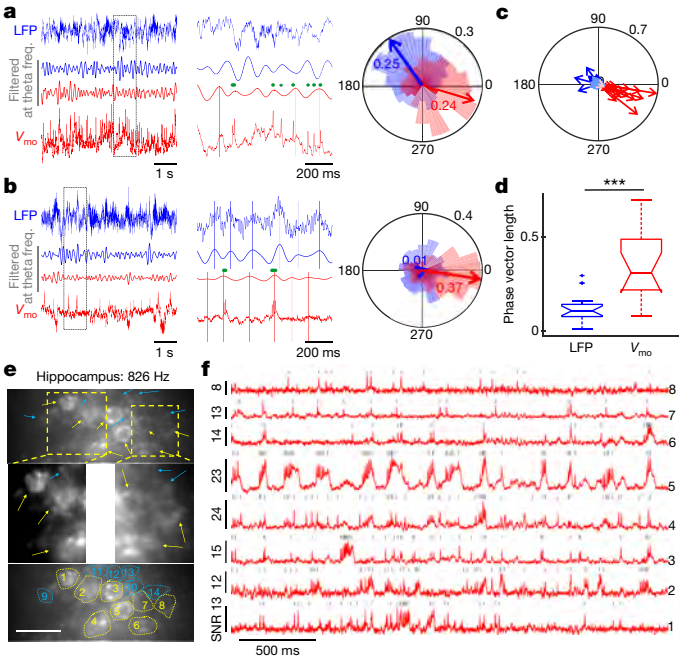

Fig. 4 | Population voltage imaging of spikes and subthreshold voltage activities in CA1 neurons. a, Neuron with spikes phase-locked to theta oscillations of LFPs (blue) and optically recorded membrane voltage (V_{mo}, red). Left, raw LFPs (top) and V_{mo} (bottom), and theta frequency-filtered traces (middle). Middle, magnified view of the boxed period on the left. Theta oscillation peaks are indicated by blue and red vertical lines, and spikes by green dots. Right, probability distribution of the timing of spikes relative to the phases of the LFP (blue) and V_{mo} (red) oscillations at theta frequency. Arrows indicate the average phase vector (with vector length indicated). Outer circle number indicates probability. Example selected from $n = 16$ neurons in 7 FOVs from 4 mice. **b**, As in **a**, but for an example neuron phase-locked to V_{mo} theta oscillations, but not to LFP theta oscillations. **c**, Population spike–phase vectors relative to theta oscillations of LFP (blue and light blue) and V_{mo} (red and pink). Each vector represents the average vector from one neuron (blue and red, $P < 0.05$; light blue and pink, not significant; χ^2 test, spike–phase distribution of each neuron against uniform distribution; $n = 198$–1,077 spikes per neuron; 16 neurons in 7 FOVs from 4 mice). **d**, Population spike–phase relationship. $^{***}P = 5.0 \times 10^{-5}$, two-tailed paired Student's t-test, $n = 16$ neurons in 7 FOVs from 4 mice. Box plots: 25th and 75th percentiles with notch, median; whiskers, all data points not considered outliers; plus, outliers. **e**, SomArchon fluorescence images of CA1 neurons (top) with ROIs overlaid (bottom; $n = 14$ FOV from 3 mice). Middle, zoomed-in views of the yellow boxes from the top. Yellow arrows, example spiking cells with optical voltage traces shown in **f**; blue arrows, neurons not active during the period shown. $\lambda_{ex} = 637$ nm laser at 1.5 W mm^{-2}. Scale bar, 20 μm.

imaging with SomArchon or QuasAr3 is limited mainly by the high power and illumination spot of the 637-nm excitation laser; however, our data suggest that high-powered 637-nm excitation does not induce more phototoxicity than is seen with common, lower-powered 470-nm excitation (Extended Data Fig. 3). In conclusion, SomArchon is fully genetically encoded, is compatible with conventional easily accessible one-photon wide-field fluorescence microscopes, is fully compatible with blue-light-driven optogenetics, and enables routine imaging of around 13 neurons in a single FOV. We anticipate that the practicality of SomArchon will enable its rapid deployment into a variety of contexts in neuroscience. As camera performance improves in years to come, and as further evolution of GEVIs continues, we anticipate that it might be possible to image tens to hundreds of neurons using simple one-photon optics in the near future.

METHODS

Molecular cloning. To screen candidates for the soma-localized Archon1 voltage sensor in primary hippocampal neurons, we synthesized DNAs coding for candidate localization motifs de novo with mammalian codon optimization and subcloned them with the genes for Archon1 (GenBank ID MG250280.1) and EGFP into the pAAV-CAG vector to obtain the final constructs (Supplementary Table 1; gene synthesis and subcloning performed by Epoch Life Science). For in vivo expression in the mouse brain via IUE, the genes encoding Archon1–KGC–EGFP–$K_V2.1_{motif}$–ER2, QuasAr3–PP–Citrine–$K_V2.1_{motif}$–ER2 (QuasAr3-s), paQuasAr3–PP–Citrine–$K_V2.1_{motif}$–ER2 (paQuasAr3-s) and CoChR–mTagBFP2–$K_V2.2_{motif}$–ER2 were subcloned into the pCAG-WPRE vector. The genes encoding QuasAr3–PP–Citrine–$K_V2.1$–ER2 and paQuasAr3–PP–Citrine–$K_V2.1$–ER2 were synthesized de novo (GenScript Biotech) based on the reported sequences[28]. The gene for CoChR–mTagBFP2–$K_V2.2_{motif}$–ER2 was assembled by Epoch Life Science using pAAV-Syn–CoChR–GFP (Addgene plasmid no. 59070) and pBAD–mTagBFP2 (Addgene plasmid no. 34632) as the source of the genes for CoChR and mTagBFP2, respectively; the $K_V2.2$ motifs were synthesized de novo with mammalian codon optimization (Epoch Life Science). The pAAV-Syn-Archon1-KGC-EGFP-$K_V2.1_{motif}$-P2A-CoChR-$K_V2.1_{motif}$ plasmid was also cloned by Epoch Life Science. We used the Kv2.1 motif fused to CoChR for the following reason: in our original paper on soma-targeted CoChR[18], we used the KA2 sequence, which worked best with CoChR–GFP, but in this paper we used fluorophore-free CoChR, which did not express well with KA2, and rather worked better with $K_V2.1$; we also sometimes used the corresponding sequence from $K_V2.2$ as described in the text. Plasmid amplification was performed using Stellar (Clontech Laboratories) or NEB10-beta (New England BioLabs) chemically competent *Escherichia coli* cells. Small-scale isolation of plasmid DNA was performed with Mini-Prep kits (Qiagen); large-scale DNA plasmid purification was done with GenElute HP Endotoxin-Free Plasmid Maxiprep Kits (Sigma-Aldrich). The genes for ASAP3-Kv and Voltron-ST were synthesized de novo by GenScript, based on the reported sequences[5,6], and cloned into the pCAG-WPRE vector.

Neuronal culture and transfection. All mouse procedures were performed in accordance with the National Institute of Health Guide for Laboratory Animals and approved by the Massachusetts Institute of Technology Institutional Animal Care and Use and Biosafety Committees. For preparation of dissociated hippocampal mouse neuron cultures, we used postnatal day 0 or 1 Swiss Webster mice without regard to sex (Taconic Biosciences) as previously described[13]. In brief, dissected hippocampal tissue was digested with 50 units of papain (Worthington Biochemical) for 6–8 min at 37 °C, and the digestion was stopped by incubation with ovomucoid trypsin inhibitor (Worthington Biochemical) for 4 min at 37 °C. The tissue was then gently dissociated with Pasteur pipettes, and dissociated neurons were plated at a density of 20,000–30,000 per glass coverslip coated with Matrigel (BD Biosciences). Neurons were seeded in 100 µl plating medium containing MEM (Life Technologies), glucose (33 mM, Sigma), transferrin (0.01%, Sigma), HEPES (10mM, Sigma), Glutagro (2 mM, Corning), insulin (0.13%, Millipore), B27 supplement (2%, Gibco), and heat-inactivated FBS (7.5%, Corning). After cell adhesion, additional plating medium was added. AraC (0.002 mM, Sigma) was added when glia density was 50–70% of confluence. Neurons were grown at 37 °C and 5% CO_2 in a humidified atmosphere.

For in vitro screening of candidate soma-localized Archon1 sensors, primary hippocampal neuron cultures were transfected with 500 ng plasmid DNA per well using a commercial calcium phosphate transfection kit (Life Technologies) after 4 days in vitro (DIV), as previously described[13]. After 30–60 min of incubation of cultured neurons with DNA-calcium phosphate precipitate at 37 °C, neurons were washed twice with acidic MEM buffer (pH 6.7–6.8) to remove residual calcium phosphate particles and returned to the original plating medium. All measurements on cultured neurons were taken between DIV 14 and DIV 18 (about 9–14 d post transfection) to allow sodium channel maturation (and thus spiking). No cultured neuron recordings were supplemented with all-*trans*-retinal.

Electrophysiology and fluorescence microscopy in cultured primary hippocampal neurons. Whole-cell patch-clamp recordings of cultured neurons for Supplementary Table 1 were acquired via an Axopatch 700B amplifier (Molecular Devices) and Digidata 1440 digitizer (Molecular Devices). Neurons were patched between DIV 14 and DIV 18 and were bathed in Tyrode's solution (125 mM NaCl, 2 mM KCl, 3 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM HEPES, 30 mM glucose, pH 7.3 (NaOH adjusted)) at 32 °C during measurements. Synaptic blockers (2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f]quinoxaline (NBQX), 10 µM; D(−)-2-amino-5-phosphonovaleric acid, 25 µM; gabazine, 20 µM; Tocris) were added to the extracellular solution for single-cell electrophysiology. Borosilicate glass pipettes with an outer diameter of 1 mm and a wall thickness of 0.2 mm were pulled to produce electrodes with resistance of 3–10 MΩ and were filled with an internal solution containing 135 mM potassium gluconate, 8 mM NaCl, 10 mM HEPES, 4 mM Mg-ATP, 0.4 mM Na-GTP, 0.6 mM $MgCl_2$, 0.1 mM $CaCl_2$, pH 7.25 (KOH adjusted) at 295 mOsm. Measurements from primary neuron cultures were performed on the electrophysiology setup described above. Patch-clamp data were acquired only if the resting potential was below −45 mV and access resistance was <25 MΩ. Access resistance was compensated at 30–70%. Fluorescence imaging was performed on an inverted fluorescence microscope (Nikon Ti), equipped with a red laser (637 nm, 100 mW, Coherent, OBIS 637LX, Pigtailed) expanded by a beam expander (Thorlabs) and focused onto the back focal plane of a 40× NA 1.15 objective lens (Nikon).

Two-photon imaging of SomArchon-expressing neurons was performed using an Olympus FVMPE-RS equipped with two lasers for fluorescence excitation. An InSight X3 laser (Spectra-Physics) tuned to 1,150 nm at 50% transmissivity was used to excite SomArchon, and a MaiTai HP Ti:Sapphire laser (Spectra-Physics) tuned to 920 nm at 15% transmissivity was used to excite EGFP. The laser beams were focused using a 25× 1.05 NA water-immersion objective lens (Olympus). SomArchon emission was separated using a 590-nm dichroic mirror and imaged with 660–750 nm and 495–540 nm filters for near-infrared and green fluorescence, respectively, and signals were collected onto separate photomultiplier tubes. Imaging was performed at 2.0 µs per pixel sampling speed with one-way galvano scanning.

Phototoxicity and photobleaching measurements in cultured neurons. For phototoxicity and photostability measurements, primary mouse neuron cultures, prepared as described above, were imaged using an inverted Eclipse Ti-E microscope (Nikon) equipped with an sCMOS camera (OrcaFlash4.2, Hamamatsu), LED light source (Spectra, Lumencor), a 637-nm laser (637 LX, OBIS) focused on the back focal plane of a 40× NA 1.15 water immersion objective lens (Nikon), and a Polygon400 Multi-wavelength Patterned Illuminator (Mightex) with a 470-nm LED (ThorLabs). To express SomArchon, neurons were infected with AAV2-CaMKII-SomArchon or AAV2-Syn-SomArchon-P2A-CoChR-$K_V2.1_{motif}$ at DIV 5. To express ASAP3-Kv and Voltron-ST, neurons were transfected with the pCAG-ASAP3-Kv-WPRE and pCAG-Voltron-ST-WPRE plasmids, respectively, using the calcium phosphate method described above. For imaging of Voltron-expressing neurons, the cells were incubated with JF525 at final concentration 1.25 µM for 60 min at 37 °C (application of higher concentrations of JF525 resulted in marked internalization of the dye within 40 min of incubation at 37 °C, thus preventing functional imaging owing to the high background fluorescence). After incubation, the cells were washed 3 times with fresh plating medium for 3 h to removed unbound dye. The reactive oxygen species (ROS) measurements were performed using CellRox Orange dye (Invitrogen) according to the manufacturer's protocol. In brief, neurons were incubated with the CellROX Orange reagent at a final concentration of 5 µM for 30 min at 37 °C in darkness, and then washed once with fresh plating medium before imaging. Immediately before imaging, cells were supplemented with the NucGreen Dead 488 reagent for detection of plasma membrane integrity, which we used to indicate cell death. Cells that showed a more than ten times increase in green fluorescence in the nucleus over background fluorescence levels were considered dead. Neurons were imaged between DIV 14 and DIV 18 in the plating medium at 22 °C. CellROX Orange fluorescence was acquired using 510/25 nm excitation at 0.8 mW/mm^2 and 545/40 nm emission. NucGreen fluorescence was acquired using 475/36 nm excitation at 3.5 mW/mm^2 and 527/50 nm emission.

IUE, AAV injection, and acute brain slice preparation. For IUE, embryonic day (E)15.5 timed-pregnant female Swiss Webster (Taconic Biosciences) mice were deeply anaesthetized with 2% isoflurane. Uterine horns were exposed and periodically rinsed with warm sterile PBS. Plasmid DNA (1–2 µg total at a final concentration of about 2–3 µg/µl diluted in sterile PBS) was injected into the lateral ventricle of one cerebral hemisphere of an embryo. Five voltage pulses (50 V, 50 ms duration, 1 Hz) were delivered using 5-mm round plate electrodes (ECM 830 electroporator, Harvard Apparatus), with the anode or cathode placed on top of the skull to target the cortex or hippocampus, respectively. Electroporated embryos were placed back into the dam, and allowed to mature to delivery. Brain slices were prepared from electroporated mice without regard to sex at postnatal day (P)12–P22.

The electroporated mice were anaesthetized by isoflurane inhalation and decapitated, and cerebral hemispheres were quickly removed and placed in cold choline-based cutting solution consisting of (in mM): 110 choline chloride, 25 $NaHCO_3$, 2.5 KCl, 7 $MgCl_2$, 0.5 $CaCl_2$, 1.25 NaH_2PO_4, 25 glucose, 11.6 ascorbic acid, and 3.1 pyruvic acid (339–341 mOsm/kg; pH 7.75 adjusted with NaOH) for 2 min, then blocked and transferred into a slicing chamber containing ice-cold choline-based cutting solution. For mice electroporated with Voltron-ST, 50 µl JF525 dye (Janelia Farm; 12.5 nM JF525 in 10µl DMSO mixed with 10 µl Pluronic F-127 (20% w/v in DMSO; Invitrogen) and 30 µl sterile PBS) was injected into the retro-orbital sinus one day before slicing. Coronal slices (300 µm thick) were cut with a Compresstome VF-300 slicing machine, then transferred to a holding chamber with artificial cerebrospinal fluid (ACSF) containing (in mM) 125 NaCl, 2.5 KCl, 25 $NaHCO_3$, 2 $CaCl_2$, 1 $MgCl_2$, 1.25 NaH_2PO_4 and 11 glucose (300–310 mOsm/kg; pH 7.35 adjusted with NaOH), and allowed to recover for 10 min at 34 °C, followed by another 30 min at room temperature. Slices were subsequently maintained at room

temperature (22 °C) until use. Both cutting solution and ACSF were constantly bubbled with 95% O_2 and 5% CO_2.

For AAV injection, 21-day-old C57 BL/6J mice were anaesthetized with isoflurane and placed in a small animal stereotaxic apparatus (David Kopf Instruments). Animals were injected with 200 nl rAAV8-Syn-Archon1-KGC-EGFP-Kv2.1motif-ER2 using a Nanoject (Drummond Scientific) via glass pipettes with 20–30-μm diameter tips into the striatum: anteroposterior (AP) 1.2 mm, mediolateral (ML) 2.1 mm, dorsoventral (DV) 3.2 mm relative to bregma. Brain slices were then prepared from these AAV-injected mice at P30–35. Mice were deeply anaesthetized with isoflurane and perfused transcardially using cold saline containing (in mM): 194 sucrose, 30 NaCl, 4.5 KCl, 1.2 NaH_2PO_4, 0.2 $CaCl_2$, 2 $MgCl_2$, 26 $NaHCO_3$, and 10 D-(+)-glucose saturated with 95% O_2 and 5% CO_2, pH 7.4 adjusted with NaOH, 320–340 mOsm/l. Coronal slices (250–300 μm thick) were cut using a slicer (VT1200 S, Leica Microsystems) and then incubated for 10–15 min in a holding chamber (BSK4, Scientific System Design) at 32 °C with regular ACSF containing (in mM): 136 NaCl, 3.5 KCl, 1 $MgCl_2$, 2.5 $CaCl_2$, 26 $NaHCO_3$ and 11 glucose saturated with 95% O_2 and 5% CO_2, followed by at least 1 h recovery at room temperature (21–25 °C) before recording.

Concurrent electrophysiology and fluorescence imaging in acute brain slices. For the recordings shown in Fig. 1 and Extended Data Fig. 3a–c, individual slices were transferred to a recording chamber mounted on an upright microscope (Olympus BX51WI, see below) and continuously superfused (2–3 ml/min) with carbogenated ACSF at room temperature. Whole-cell patch-clamp recordings were performed with borosilicate glass pipettes (KG33, King Precision Glass) heat-polished to obtain direct current resistances of ~4–6 MΩ. For cortex recordings, pipettes were filled with an internal solution containing in mM: 120 K-gluconate, 2 $MgCl_2$, 10 HEPES, 0.5 EGTA, 0.2 Na_2ATP, and 0.2 Na_3GTP. For hippocampus and striatum recordings, pipettes were filled with an internal solution containing in mM: 131 K-gluconate, 17.5 KCl, 9 NaCl, 1 $MgCl_2$, 10 HEPES, 1.1 EGTA, 2 Na_2ATP, and 0.2 Na_3GTP. Voltage clamp recordings were made with a microelectrode amplifier (Multiclamp 700B, Molecular Devices). Cell membrane potential was held at −60 mV, unless specified otherwise. Signals were low-pass-filtered at 2 kHz and sampled at 10–20 kHz with a Digidata 1440A (Molecular Devices), and data were stored on a computer for subsequent offline analysis. Cells in which the series resistance (R_s, typically 8–12 MΩ) changed by >20% were excluded from subsequent data analysis. In addition, cells with R_s more than 25 MΩ at any time during the recordings were discarded. In some cases, conventional characterization of neurons was made in both voltage and current clamp configurations. Positive neurons were identified for recordings on the basis of EGFP expression visualized with a microscope equipped with a standard GFP filter (BX-51WI, Olympus). Optical voltage recordings were taken through a 40× water immersion objective (Olympus LUMFL N 40x/0.8W). Fluorescence was excited using a fibre-coupled 637-nm red laser (140 mW, Coherent Obis 637-140 LX), and the emission was filtered through a 664-nm long-pass filter. Images were collected on an EMCCD camera (Andor iXON Ultra 888) or sCMOS camera (Andor Zyla4.2 Plus Andor) in a reduced pixel window to enable acquisition at about 1 kHz. Each trial was about 30 s in duration. Of the 18 cortical neurons reported in Fig. 1, 4 neurons were not analysed for Fig. 1e because the electrophysiology files were inadvertently not saved, owing to a problem with the manual save process.

For optical recordings shown in Fig. 1i, j and Extended Data Figs. 1a–g, 2, 5, acute brain slices were transferred to a recording chamber mounted on an inverted Eclipse Ti-E (Nikon) equipped with a CMOS camera (Zyla5.5, Andor), LEDs (Spectra, Lumencor), a 637-nm laser (637 LX, OBIS) focused on the back focal plane of a 40× NA 1.15 objective (Nikon), and a Polygon400 Multiwavelength Patterned Illuminator (Mightex) with 470-nm LED (ThorLabs), and continuously superfused (2–3 ml/min) with carbogenated ACSF at room temperature. Positive cells were imaged under 0.8 or 1.5 W/mm^2 (55 mW) excitation light power at 637 nm from the laser. 4-Aminopyridine at a final concentration of 1 mM was added to induce neuronal activity for experiments shown in Extended Data Figs. 2c, d, g, h, 5. For Fig. 1i, j and Extended Data Fig. 5, cells were illuminated with 2-ms blue light pulses at light power in the range from 0.1 to 1.0 mW/mm^2.

Mouse surgery. All in vivo mouse procedures were performed in accordance with the National Institute of Health Guide for Laboratory Animals and approved by the Boston University Institutional Animal Care and Use and Biosafety Committees.

Virus injection surgery. All AAVs were produced by the University of North Carolina Chapel Hill Vector Core. Adult female C57BL/6 mice (Charles River Laboratories) or Chat-cre mice (Chat-cre;129S6-Chattm2(cre)Lowl/J, the Jackson Laboratory), 8–12 weeks old at the time of surgery, were used for all experiments. AAV-Syn-SomArchon (5.9×10^{-12} genome copies (GC)/ml) or AAV-syn-SomArchon-P2A-CoChR-Kv2.1 (2.19×10^{-13} GC/ml) was injected into the motor cortex (AP: +1.5 mm, ML: ±1.5 mm, DV: −0.3 mm relative to bregma, 0.5 μl virus), visual cortex (AP: −3.6 mm, ML: ±2.5 mm, DV: −0.3 mm, 0.5 μl virus), hippocampus (AP: −2.0 mm, ML: +1.4 mm, DV: −1.6 mm, 1 μl virus) or striatum (AP: +0.8 mm, ML: −1.8 mm, DV: −2.1 mm, 1 μl virus). Viral injection occurred at 50–100 nl/min (10 min total) using a 10-μl syringe (NANOFIL, World Precision Instruments) fitted with a 33-gauge needle (World Precision Instruments, NF33BL) and controlled by a microinfusion pump (World Precision Instruments, UltraMicroPump3–4). The syringe was left in place for an additional 10 min after injection to facilitate viral spread. About one week after the viral injection, mice underwent a second surgery to implant the cranial window for in vivo imaging.

Cortex imaging window implantation. The imaging window consisted of a stainless steel cannula (OD: 3.17 mm, ID: 2.36 mm, height: 1 mm, AmazonSupply, B004TUE45E) fitted with a circular coverslip (no. 0, OD: 3 mm, Deckgläser Cover Glasses, Warner Instruments, 64-0726 (CS-3R-0)) adhered using a UV curable glue (Norland Products, Norland Optical Adhesive 60, P/N 6001). A craniotomy of about 3 mm in diameter was created, with the dura left intact, over the motor cortex (centred at AP: +1.5 mm, ML: ±1.75 mm) or visual cortex (AP: −3.6 mm, ML: ±2.15 mm). The imaging window was positioned over the cortex so that it was flush with the surface of the dura. Kwik-sil adhesive (World Precision Instruments, KWIK-SIL) was applied around the edges of the imaging window to hold the imaging window in place and to prevent any dental cement from touching the brain. Three small screws (J.I. Morris, F000CE094) were screwed into the skull to further anchor the imaging window to the skull. Dental cement was then gently applied to affix the imaging window to the exposed skull, and to mount an aluminium headbar posterior to the imaging window. Supplementary Fig. 1a, b provides the window placement.

Hippocampus and striatum imaging window implantation. Hippocampal and striatal window surgeries were performed in a similar way to those previously described[11,29]. For each imaging window, a virus/drug infusion cannula (26G, PlasticsOne, C135GS-4/SPC) was attached to a stainless steel imaging cannula (OD: 3.17 mm, ID: 2.36 mm, height: 1 or 2 mm, AmazonSupply, B004TUE45E). The bottom of the infusion cannula was flush with the base of the stainless steel cannula, and a circular coverslip (no. 0, OD: 3mm, Deckgläser Cover Glasses, Warner Instruments, 64-0726 (CS-3R-0)) was adhered using a UV curable glue (Norland Products, Norland Optical Adhesive 60, P/N 6001). An additional insulated stainless steel wire (diameter: 130 μm, PlasticsOne, 005SW-30S, 7N003736501F) was glued to the viral/drug infusion cannula with super glue (Henkel, Loctite 414 and Loctite 713) and protruded from the bottom of the infusion cannula and imaging window by about 200 μm for LFP recordings.

A craniotomy about 3 mm in diameter was made over the hippocampus CA1 region (AP: −2.0 mm, ML: +2.0 mm) or the striatum (AP: +0.8 mm, ML: −1.8 mm). A small notch was made on the posterior edge of the craniotomy to accommodate the infusion cannula and LFP recording electrode. The overlying cortex was gently aspirated using the corpus callosum as a landmark. The corpus callosum was then carefully thinned to expose the hippocampus CA1 region or the dorsal striatum. The imaging window was positioned in the craniotomy, and Kwik-sil adhesive (World Precision Instruments, KWIK-SIL) was applied around the edges of the imaging window to hold it in place and to prevent any dental cement from touching the brain. Three small screws (J.I. Morris, F000CE094) were screwed into the skull to further anchor the imaging window to the skull, and a small ground pin was inserted into the posterior part of the brain near the lambda suture as a ground reference for LFP recordings. Dental cement was then gently applied to affix the imaging window to the exposed skull, and to mount an aluminium headbar posterior to the imaging window. Supplementary Fig. 1c, d provides the window placement.

In mice that did not receive a virus injection before window implantation, 1 μl of AAV-syn-SomArchon (5.9×10^{12} GC/ml) or 1 μl of AAV-syn-SomArchon-P2A-CoChR-Kv2.1 (2.19×10^{13} GC/ml), or 1 μl of AAV-CAG-FLEX-SomArchon (6.3×10^{12} GC/ml) was injected through the virus/drug infusion cannula at 100 nl/min through an internal infusion cannula (33G, PlasticsOne, C315IS-4/SPC) connected to a microinfusion pump (World Precision Instruments, UltraMicroPump3–4), one week after the window implantation surgery. The internal infusion cannula was left in place for 10 min after injection to facilitate viral spread. Mice were awake and their heads were fixed throughout the injection period.

All mice were treated with buprenex for 48 h after surgery and single-housed to prevent any damage to the headbar or window implant.

In vivo imaging in the live mouse brain. All optical recordings were acquired on a conventional one-photon fluorescence microscope equipped with an ORCA Flash 4.0 V3 Digital CMOS camera (Hamamatsu Photonics K.K., C13440-20CU) or Hamamatsu ORCA Fusion Digital CMOS camera (Hamamatsu Photonics K.K., C14440-20UP), 10× NA0.25 LMPlanFI air objective (Olympus), 40× NA0.8 LUMPlanFI/IR water immersion objective (Olympus), 20× NA1.0 XLUMPlanFL N water immersion objective (Olympus), 16× NA0.8 CFI LWD Plan Fluorite water immersion objective (Nikon), 470-nm LED (ThorLabs, M470L3), 140-mW 637-nm red laser (Coherent Obis 637-140X), a green filter set with a 470/25-nm bandpass excitation filter, a 495-nm dichroic, and a 525/50-nm bandpass emission filter, and a near infrared filter set with a 635-nm laser dichroic filter, and a 664-nm

long-pass emission filter. The near-infrared laser illuminated a circular area of about 60–80 μm, about 80–140 μm, and about 100–200 μm in diameter in brain tissue, with FOV height (limited by camera acquisition rate) 40–60 μm, 80–100 μm, and 100–120 μm under 40×, 20×, and 16× objective lenses, respectively. A mechanical shutter (Newport, model 76995) was positioned in the laser path to control the timing of illumination over the imaging window. Optical recordings were acquired at 390–900 Hz with HCImage Live (Hamamatsu Photonics K.K.) or NIS Elements (Nikon) software. HC Image Live data were stored as DCAM image files (DCIMG), and further analysed offline in Fiji/ImageJ and MATLAB (Mathworks). NIS Elements data were stored as .nd2 files and further analysed offline using the NIS Elements software.

The GFP signal of SomArchon was acquired in the green channel ($\lambda_{ex} = 470$ nm) at 1,024 × 1,024 pixels with 2 × 2 binning to show cell structure and distribution. Optical voltage recordings were imaged in the near infrared channel ($\lambda_{ex} = 637$ nm) with 2 × 2 or 4 × 4 binning. OmniPlex system (PLEXON) was used to synchronize data acquisition from different systems. In all experiments, the OmniPlex system recorded the start of image acquisition from the sCMOS camera, the acquisition time of each frame, and other experiment-dependent signals described below.

Optical imaging of spontaneous neural activity. All in vivo optical imaging of spontaneous neural activity was performed when mice were awake with their heads fixed in a custom holder that allowed attachment of the headplate at the anterior end. Animals were covered with an elastic wrap to prevent upward movement. Spontaneous neural activity recordings lasted continuously for up to 30,000 frames (about 36 s).

Eye puff. During some in vivo hippocampal imaging recordings, an eye puff was applied to evoke high-frequency local field potential responses in the hippocampus (Extended Data Fig. 9a–d). The mice had their heads fixed in a custom holder that allowed attachment of the headplate at the anterior end, and they were covered with an elastic wrap to prevent upward movement. Each experimental session consisted of 20–30 trials, with each trial lasting for 5,000 frames (about 6 s). Three seconds after the start of image acquisition, the sCMOS camera sent a TTL pulse to a function generator (Agilent Technologies, model 33210A), which triggered a 100-ms-long air puff. The air puff was 5–10 psi, and administered via a 0.5-mm cannula placed 2–3 cm away from the eye of the mouse. The puff TTL pulses were also recorded with the OmniPlex system (PLEXON). Eye movement was monitored using a USB webcam (Logitech, Carl Zeiss Tessar 2.0/3.7 2MP Autofocus).

Optopatch blue light stimulation. All in vivo optopatch (that is, optogenetics plus voltage imaging) experiments were performed when mice were awake with their heads fixed in a custom holder that allowed attachment of the headplate at the anterior end. Mice were covered with an elastic wrap to prevent upward movement. A 470-nm LED (ThorLabs, M470L3) was coupled to a Polygon400 Multiwavelength Patterned Illuminator (Mightex), and the blue light was focused through the objective lens to illuminate the centre of the FOV. At the onset of imaging, the sCMOS camera sent a TTL pulse to trigger Axon CNS (Molecular Devices, Digidata 1440A) which controlled the 470-nm LED (ThorLabs). Each trial lasted 1.1 s and consisted of a single 100-ms-long blue light pulse, 500 ms after trial onset. Each recording session consisted of 10 trials with increasing blue light power from 0.1 to 1 mW/mm^2, with a step of about 0.1 mW/mm^2 per trial. The OmniPlex system (PLEXON) recorded the timing of TTL pulses used to trigger the Axon CNS.

Head-fixed voluntary movement experiments. All voluntary movement experiments were performed while awake, head-fixed mice were freely navigating a spherical treadmill. The spherical treadmill was constructed as described[30]. In brief, a 3D spherical Styrofoam ball was supported by air, and motion was tracked using two computer mouse sensors positioned roughly ±45° from the centre along the equator of the ball. All motion-sensor displacement data were acquired at 100 Hz on a separate computer and synthesized using a custom Python script. Motion sensor displacement data were then sent to the image acquisition computer to be accumulated using a modified ViRMEn MATLAB script. The timing of each motion sensor displacement data point was also recorded using the OmniPlex system (PLEXON) to synchronize movement data with optical voltage recordings.

To determine the mouse movement speed, ball movement was first calibrated. The ball was pinned on the two sides and rotated vertically to calibrate sensor displacement.

All mice were habituated on the spherical treadmill for at least 3 days, at least 20 min per day, before image acquisition. During optical imaging, mice were imaged while freely navigating the spherical treadmill. Each FOV was recorded for at least 36 s in total. In some fields of view, we performed multiple trials, and each trial was at least 12 s in duration with an inter-trial interval of at least 30 s in duration.

Local field potential recording. Local field potentials were recorded using an OmniPlex system (PLEXON) at a 1 kHz sampling rate. To synchronize optical recordings with LFP recordings, the camera sent out a TTL pulse to the OmniPlex system at the onset of imaging and after each acquired frame.

Motion correction. In Figs. 2i, 3, 4, motion correction was performed with a custom Python script. For FOV, if multiple video imaging files were collected for the same FOV, we started with the first imaging file to ensure speedy data processing (a single video file contains a series of images). We first generated the reference image by averaging across all images within the file. We then performed a series of image processing procedures to enhance the contrast of the reference image and every image in the file to facilitate motion correction. We first removed 10% of the pixels along all edges of an image to remove any camera induced artefact. We then applied a high-pass filter (Python scipy package, ndimage.gaussian_filter, sigma = 50) to remove low-frequency components within the images. To enhance the boundaries of high intensity areas, we identified the boundaries as the difference between two low-pass-filtered images (sigma = 2 and 1). We then enhanced the boundary by adding 100 times the boundary back to the low-pass-filtered image (sigma = 2). We then limited the intensity range of the processed images within one standard deviation above and below the average intensity of the image, by setting the pixels with intensity higher than mean + s.d. as mean + s.d., and the pixels with intensity lower than mean − s.d. as zero. Finally, to counter any potential bleaching over time, we normalized the intensity of each image by shifting the mean intensity to zero and divided intensity values by the s.d. of all pixel intensities in that image. After image processing, we calculated the displacement of each image, by identifying the maximum cross-correlation coefficient between each image and the reference image, and then corrected motion by shifting the displacement in the original, unenhanced image sequence. If the same FOV was imaged over an extended period of time, during which multiple files were acquired, we motion-corrected subsequent files by aligning them to the first file, so that the same ROIs from the same FOV could be applied across the entire imaging session. Specifically, we first refined the reference frame by generating the mean intensity projection image from the motion-corrected first imaging file. The refined reference image was then used to motion-correct all files of the same FOV, including the first file, using the procedure described above. The motion-corrected, original, unenhanced image sequences were then used for subsequent manual ROI segmentation and further analysis.

ROI identification. We imported the image files (motion-corrected as above, if necessary) into Fiji/ImageJ or NIS Elements and manually segmented ROIs by examining the time-series images to identify areas with clear neuron outlines and/or intensity dynamics over time. The optically recorded voltage traces for each ROI were generated from the motion-corrected image sequences using the multiple measurement function and were then used for analyses.

The wide dynamic range (16 bit) of the raw images meant that to select dim as well as bright cells, we had to create maximum projection and standard deviation images of the entire raw video, and stretched their look-up tables to enhance visibility. For Fig. 4 and Extended Data Fig. 9e–h, cells were densely packed, so we identified and tracked ROIs semi-manually across image sequences without performing motion correction. We first visually inspected all image sequences and identified those with minimal motion and with an SNR greater than about 2 for further analysis. We then performed an iterative ROI-selection procedure to identify ROIs that best fit each cell. Specifically, we started by manually selecting ROIs from the maximum projection image of the entire image sequence. The image sequence was then visually inspected to identify frames with cells that exhibited shifts of more than three pixels from the defined ROI. We then used these frames to separate the image sequence into multiple time intervals, and obtained a new set of maximum projection images to identify new ROIs within these time intervals for these cells. This procedure was repeated iteratively until the ROI represented the cell across all image frames in their corresponding time intervals without the cell moving out of the ROI. Thus, with this procedure, we created multiple ROIs representing the same cell across different frames. For each cell, we extracted traces for every ROI during its corresponding time interval, and stitched the baseline-normalized traces for the same cell(s) in time. The fluorescence traces of each cell were then detrended for further analysis. Supplementary Fig. 2 provides an example of raw and processed traces for two cells in the same FOV.

Hippocampal spike detection. Spikes were associated with a rapid increase in intensity, followed by a rapid decrease. By contrast, occasional motion artefacts were usually associated with a decrease in intensity as a neuron moved out of the ROI. To facilitate spike detection, we first removed motion artefacts. For each time point of the fluorescence intensity trace for each ROI, we calculated the change in intensity from that of the prior time point (I_{change}). We then defined noise as the time points at which instantaneous I_{change} was 3 s.d. below the mean value of I_{change} across the entire trace. We excluded any time points at which the I_{change} of the previous time point was more than 1 s.d. above the average I_{change}, because this might have indicated a spike. These noise time points and their following three time points (as we found that motion artefacts are typically >4 ms) were then considered motion artefacts, and removed from further analysis. We then recalculated the standard deviation of I_{change}, excluding the data points related to the motion artefact. The peaks of spikes were then identified as time points that

met the following two criteria: (1) the intensity change of the time point combined with that of its preceding time point was more than 3 s.d. above the average I_{change}, and (2) the intensity change over the next two time points was less than 2 s.d. below the average I_{change}.

Hippocampal spike–phase calculation. Hippocampal spike–phase analysis was performed on 16 neurons from 7 FOVs in 4 mice. For each FOV, we analysed data collected over 10 trials (about 60 s in total) during which animals experienced an eye puff in each trial, as described above. To calculate the phase of spikes at theta frequency (4–10 Hz), we first band-pass-filtered both the optical voltage trace and the simultaneously recorded LFP at theta frequency (eegfilt, EEGLAB toolbox). The peaks of theta oscillation power were then identified using the findspike function in MATLAB. For each spike, we obtained the phase of the spike by calculating the timing of each spike relative to the period of that oscillation cycle in degrees. We averaged the phases of all spikes from the same neuron as the average phase of a given neuron.

Analysis for pairwise coherence between hippocampal neurons and LFPs. The coherence analysis was performed on nine FOVs that contained multiple neurons from four mice. Each FOV contained imaging data over a period of 6–36 s. For each FOV, we first re-sampled the LFP at the acquisition rate of the optical imaging. We then divided the optical voltage traces and LFPs into segments of 1,000 data points. We then calculated the averaged coherence, at theta frequency (4–10 Hz), with the functions in the Chronux toolbox (optical voltage trace to optical voltage trace or LFP: coherencyc, and spike to spike: coherencypt) with tapers = [10 19], fpass = [4 10] and trialave = 1. To compare V_{mo}–V_{mo} coherence with V_{mo}–LFP coherence across nine FOVs, we averaged the coherence of neurons in the same FOV to obtain the mean coherence of that FOV, and then performed statistical tests across FOVs using the mean coherences of the individual FOVs. To understand the relationships between pairs of coherence, we used the MATLAB function fitlm to perform a linear regression between coherent pairs and obtain the P and r^2 values.

To estimate background fluorescence crosstalk, we calculated pairwise coherence and correlation between background doughnut areas surrounding a neuron. To select background doughnut areas, we excluded the edges (5%) of each FOV, because the edge may be missing for a particular image frame when image frames were shifted during motion correction. The background doughnut of a neuron was determined as the area 3–10 μm from the neuron boundary, excluding any pixels within 10 μm of the boundary of another neuron. One neuron was excluded from this analysis owing to dense labelling where we could not identify its doughnut area. Fluorescence traces of the background doughnut area were then processed as for neurons, and their pairwise coherence and Pearson correlations were calculated.

Spike detection for striatum, motor cortex, and visual cortex. After motion correction, we first identified large fluorescence increases using a threshold of 4 s.d. above the baseline. The baseline was manually selected as a period of >500 ms without spiking or drifting due to z-plane shifting or photobleaching. From these large fluorescence increases, we selected those with rise times and decay times shorter than 4 ms as spikes.

Firing rate comparison of striatal neurons during high- and low-speed movement. Movement data of mice were first interpolated to the voltage imaging frame rate with MATLAB function interp1, and then smoothed using a 1.5-Hz low-pass Butterworth filter to remove any motion sensor artefacts. We calculated the average movement speed at 0.5-s intervals and defined low-speed periods as intervals during which the average speed was ≤5 cm/s and high-speed periods as intervals during which the average speed was ≥10 cm/s. The firing rates during these high- and low-speed motion periods were compared, and a two-sided Wilcoxon rank-sum test was used to identify significant differences between these periods.

SNR calculation for in vivo photostability evaluation over imaging duration in striatum and hippocampus. We defined noise as the standard deviation of the fluorescence intensity across the entire trial period. For each neuron, we first calculated the SNR for each action potential by dividing the intensity change observed during an action potential by the noise, and then calculated the average SNRs across all spikes detected in a trial as the corresponding SNR for the trial. For the striatum dataset, only neurons imaged over at least five consecutive trials were analysed. For the hippocampus dataset, all neurons were analysed.

Detrending. All optically recorded SomArchon traces reported in the manuscript (except those shown in Fig. 4a–d) were corrected for photobleaching or focus shift by subtracting baseline fluorescence traces that were low-pass-filtered and fit to a double or single exponential function.

Histology. Mice were transcardially perfused with PBS followed by 4% paraformaldehyde. The brain was gently extracted from the skull and post-fixed in 4% paraformaldehyde for 1–4 h at room temperature or overnight at +4 °C. Fixed brains were transferred to a 30% sucrose–PBS solution and rotated for 24–48 h at 4 °C for cryoprotection. Cryoprotected brains were frozen in OCT in a dry ice bath and sliced (coronally) to 50-μm thickness using a cryostat. Glial and microglial antibody staining were performed with anti-GFAP[29] (1:250, Clone N206/A8, Neuromab) and anti-IBA1[31] (1:500, 019-19741, Wako Chemicals) primary antibodies, respectively, followed by Alexa Fluor 568 (1:1,000, goat anti-mouse IgG (H+L) cross-adsorbed secondary antibody, A11004, InVitrogen) and 633 secondary antibodies (1:1,000, goat anti-rabbit IgG (H+L) cross-adsorbed secondary antibody, A21070, InVitrogen). All antibodies were used according to protocols that have been validated by their suppliers. Slice imaging was performed using an inverted Nikon Eclipse Ti microscope equipped with a spinning disk sCSUW1 confocal scanner unit (Yokogawa), 488-, 561-, and 642-nm solid state lasers, 525/25-nm, 579/34-nm, and 664LP emission filters, a 20× NA0.75 air objective lens (Nikon), and a 4.2 PLUS Zyla camera (Andor), controlled by NIS-Elements AR software. Acquired images were contrast-enhanced to improve visualization.

Brain temperature measurements. Under general anaesthesia, a craniotomy about 3 mm in diameter was made to expose the brain surface, with a small notch on the posterior edge to accommodate the insertion of a temperature probe (Physitemp, IT-1E) coupled to a Thermocouple DAQ (DATAQ Instruments, Model DI-245). An imaging window, identical to those used in all imaging experiments, was positioned on the craniotomy. Kwik-sil adhesive was applied around the edges of the imaging window to hold it in place, but not around the craniotomy notch, to allow insertion of the temperature probe. Dental cement was then gently applied to affix the imaging window to the skull and to mount an aluminium headbar. Once mice had recovered from anaesthesia, they had their heads fixed while awake and the temperature probe was inserted under the imaging window above the brain surface, through the craniotomy notch. The 637-nm laser was directed through the 40× objective under identical conditions to those used while imaging (75–95 mW laser power), and brain temperature was recorded. We noted a temperature increase of 1.88 ± 0.80 °C (mean ± s.d., n = 3 mice) over the 12-s illumination period commonly used in our experiments. These changes are similar to, or smaller than, changes commonly seen with two-photon imaging, optogenetics, and the making of craniotomies for neural imaging[32–36].

Sample size. No statistical methods were used to estimate sample size for mouse studies throughout. We did not perform a power analysis, as our goal was to create a new technology, as recommended by the NIH: "In experiments based on the success or failure of a desired goal, the number of animals required is difficult to estimate..."[37]. As noted in the aforementioned paper, "The number of animals required is usually estimated by experience instead of by any formal statistical calculation, although the procedures will be terminated [when the goal is achieved]." These numbers reflect our past experience in developing neurotechnologies.

Data exclusions. Voltage imaging datasets with significant motion or in which no spikes were detected were excluded from analysis. Significant motion was defined as a shift of more than 20 μm in any direction. In Extended Data Fig. 1i–k, data points that corresponded to overlapping neurites were excluded. Data exclusion criteria were not pre-established.

Replication. All attempts at replication were successful.

Randomization and blinding. There were no treatment conditions to compare in this study. All recording sessions were randomly performed with different voltage sensors or in different brain regions. On recording days, cultured cells or brain slices expressing specific sensors were known. On in vivo recording days, mouse conditions were known. Voltage trace extraction and subsequent analysis were performed with the investigators unaware of specific mouse conditions. For analysis of movement modulation of striatal neuron spiking, a computer algorithm was used to identify periods with different movement parameters. For analysis of spike–phase relationships, or subthreshold membrane voltage relationships, a computer algorithm was used across all conditions. For histology, sections were selected and images were taken from slides by a researcher not aware of the conditions or antibody used. Cells were also counted and quantified from these sections by a researcher blinded to the experimental conditions or antibody used.

Reporting summary. Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

Code availability

Computer code used to generate results for this study is available at https://github.com/HanLabBU/somarchon-imaging.

Data availability

The data that support the findings of this study are available from the corresponding author upon reasonable request; raw data essential to the work are available online as Source Data files. Sequences of the reported proteins are available at GenBank at the following accession codes: SomArchon MN091368; SomArchon-P2A-CoChR-$K_V2.1_{motif}$, MN091369.

Author contributions K.D.P. and E.S.B. initiated the project. K.D.P., S.B., H.T., S.N.S., X.H., and E.S.B. designed all in vivo experiments and interpreted the data. K.D.P. developed SomArchon and together with E.E.J., O.A.S., and E.C. characterized all constructs in cultured cells. K.D.P., V.G.L.-H., D.P., C.S., Z.F., and B.L.S. performed characterization of SomArchon in acute brain slices. S.B., S.N.S. and H.J.G. performed all mouse surgeries for in vivo experiments. M.F.R. assisted on imaging setups. K.D.P, S.B., H.T., and S.N.S performed all in vivo imaging experiments and analysed all in vivo imaging data. K.D.P., S.B., H.T., S.N.S, X.H. and E.S.B. wrote the paper with contributions from all of the authors. E.S.B. and X.H. oversaw all aspects of the project.

Competing interests The authors declare no competing financial interests.

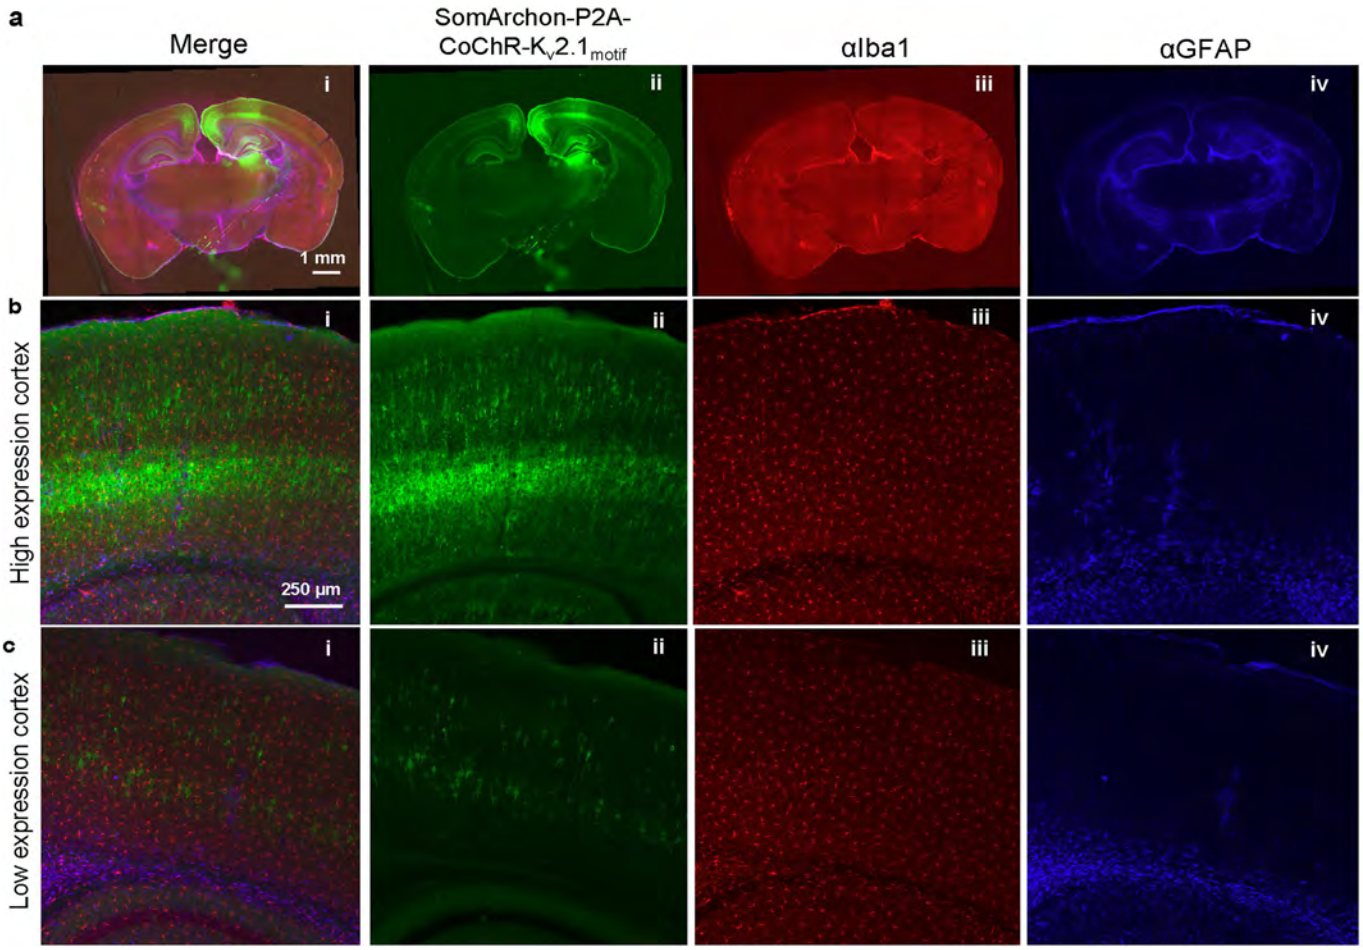
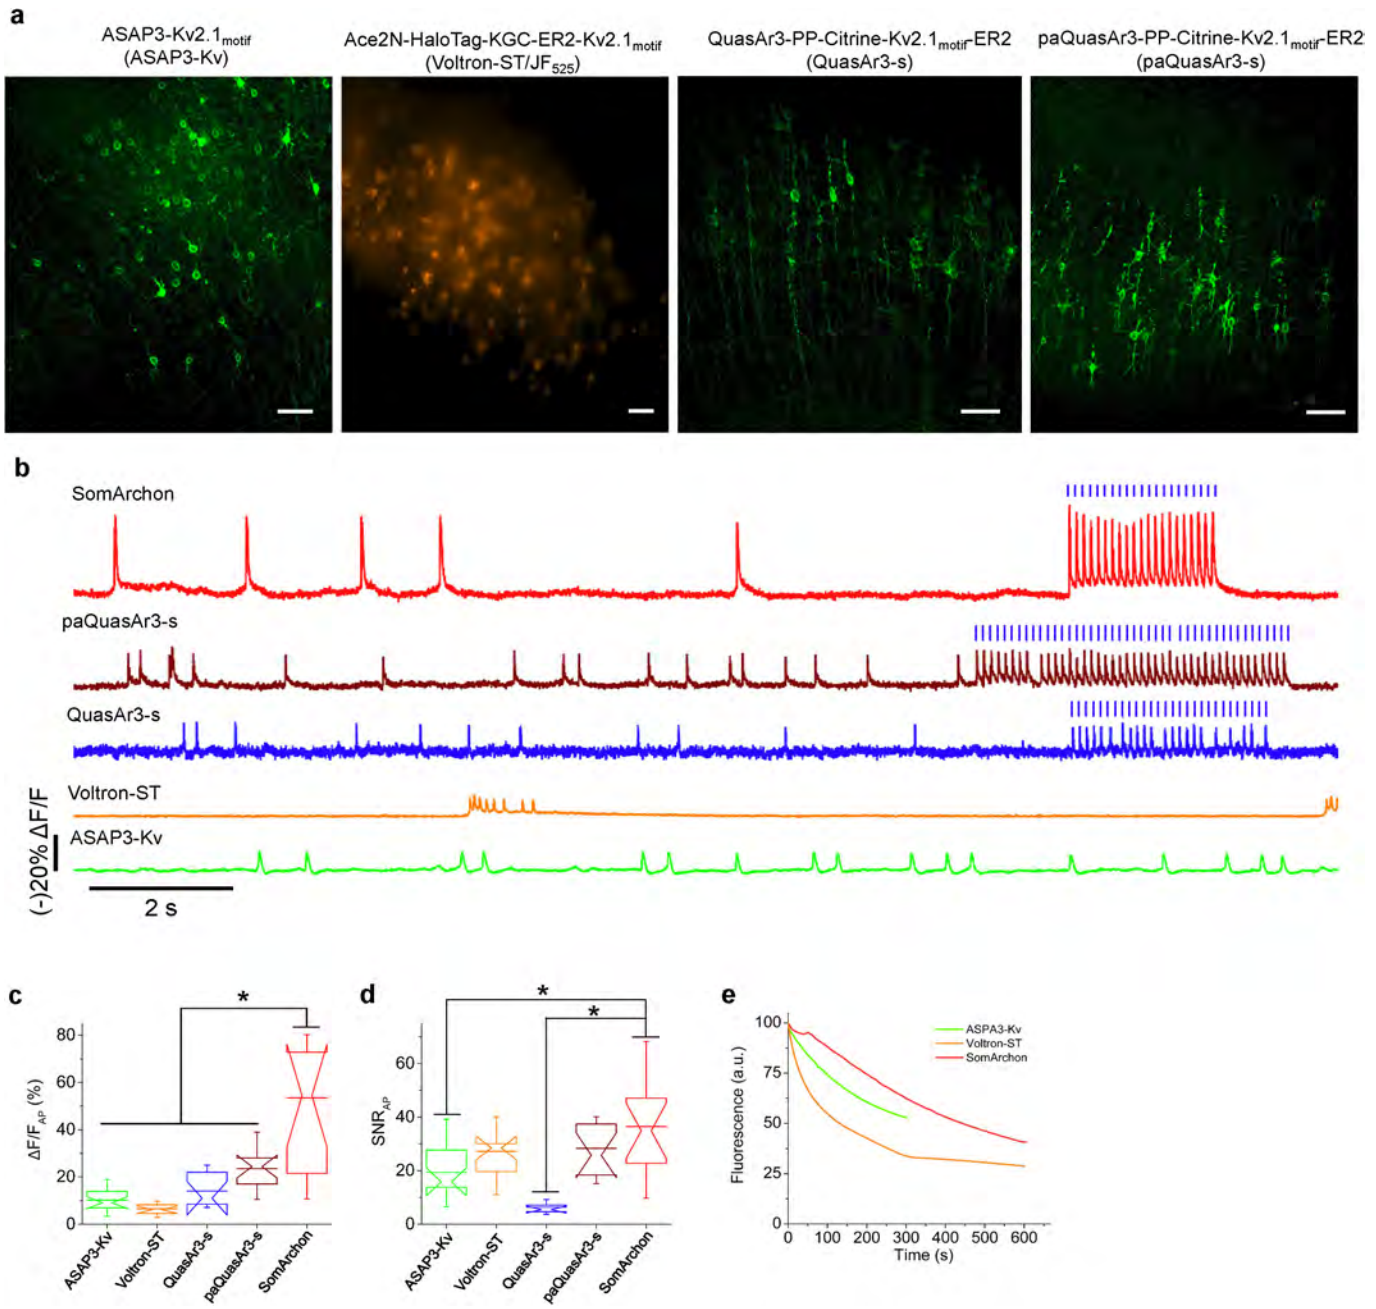
Extended Data Fig. 1 | See next page for caption.

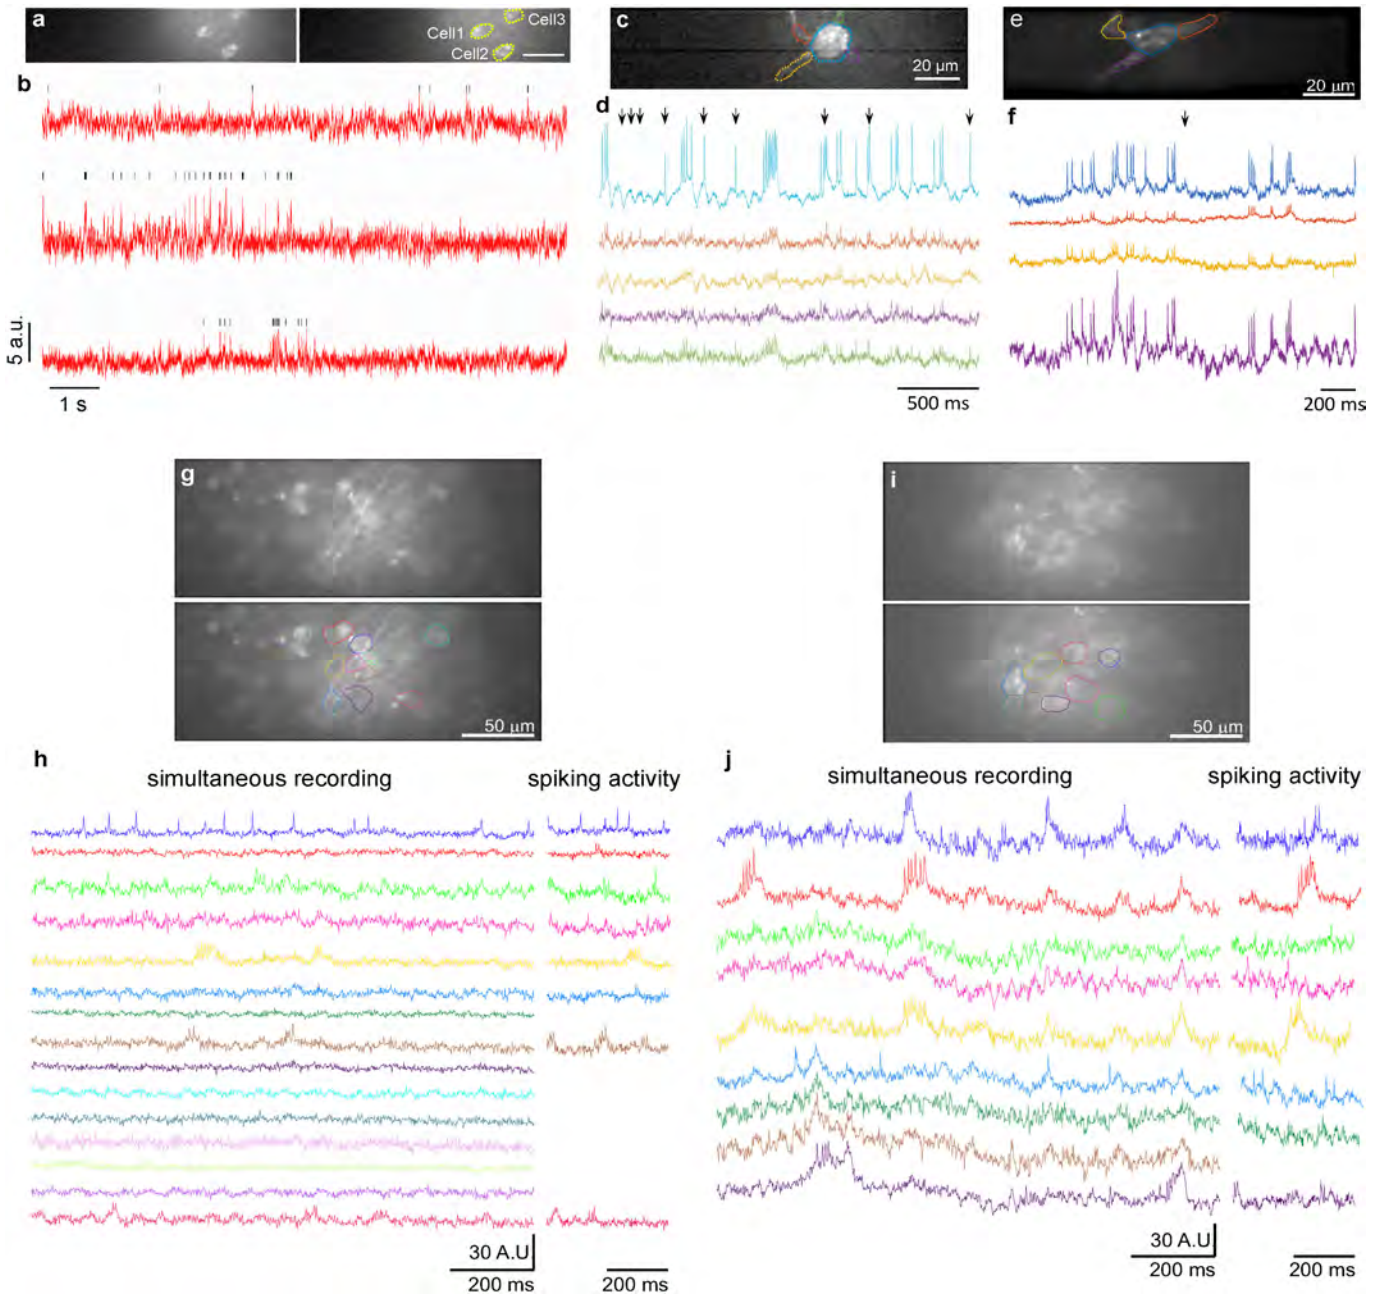
Extended Data Fig. 1 | Expression of Archon1 and SomArchon in mouse brain. a–d, Representative images of mouse brain slices expressing Archon1 (**a**, **b**) and SomArchon (**c**, **d**) (CAG promoter, via IUE) imaged with a wide-field microscope with 10× (**a**, **c**) and 40× (**b**, **d**) objective lenses (from $n = 7$ slices from 2 mice each). **e**, **f**, Normalized EGFP fluorescence along white arrows shown in **b**, **d**, respectively. Black dots correspond to resolvable cells. **g**, Number of resolvable cells per FOV for brain slices expressing Archon1 or SomArchon (2.4 ± 2.5 and 22 ± 9 neurons per FOV ($350 \times 415\ \mu m^2$) for Archon1 and SomArchon, respectively). Mean ± s.d.; $n = 7$ slices from 2 mice each; box plots as in Fig. 1. Further confocal analysis with larger FOVs of $500 \times 500 \times 50\ \mu m^3$ revealed that SomArchon can resolve around 15 times more neurons in the cortex than Archon1 ($n = 4$, 8, 9, 11, 11, 18, and 20 neurons from 7 slices for Archon1, versus $n = 180$, 187, and 137 neurons from 3 slices for SomArchon). **h**, Representative confocal images of neurons in cortex layer 2/3 (left), hippocampus (middle), and striatum (right) expressing Archon1 (top) and SomArchon (bottom). **i–k**, EGFP fluorescence along a neurite, normalized to soma, for neurons expressing Archon1 (left) or SomArchon (right) in cortex layer 2/3 (**i**, $n = 39$ and 37 neurites from 10 cells from 2 mice each), hippocampus (**j**, $n = 20$ and 34 neurites from 9 and 17 cells from 2 mice each), and striatum (**k**, $n = 17$ and 20 neurites from 7 cells from 2 mice each). Box plots as in Fig. 1. $^*P < 0.002$ compared to Archon1 at corresponding position away from the soma; n.s., not significant. Two-sample Kolmogorov–Smirnov test, see Supplementary Table 2. **l–u**, Representative confocal fluorescence images of brain slices expressing Archon (left) or SomArchon (right) via IUE (**l–q**) or AAV injection (**r–u**) in cortex layer 2/3 (**n**, **o**; $n = 8$ slices from 2 mice), hippocampus (**p**, **q**; $n = 8$ slices from 2 mice), and striatum (**t**, **u**; $n = 6$ slices from 2 mice). Green, EGFP; magenta, Nissl staining. Scale bars, 100 μm (**a–d**), 50 μm (**h**, **n–q**, **t**, **u**), 250 μm (**l**, **m**, **r**, **s**).



Extended Data Fig. 2 | Voltage imaging using SomArchon in mouse brain slices. a–**d**, Representative fluorescence wide-field images of cortex layer 2/3 neurons expressing SomArchon via AAV transduction (**a**) or IUE (**c**) with selected ROIs (bottom), and corresponding fluorescence traces (**b**, **d**; $n = 6$ and 13 slices from 2 and 4 mice for AAV transduction and IUE, respectively). Acquisition rate, 632 Hz (**b**) or 440 Hz (**d**). **e**, **f**, Representative fluorescence wide-field images of striatal neurons expressing SomArchon via AAV transduction (top) with selected ROIs (bottom) (**e**), and corresponding fluorescence traces (**f**; $n = 8$ slices from 2 mice). Acquisition rate, 733 Hz. **g**, **h**, Representative fluorescence wide-field images of hippocampal neurons expressing SomArchon via IUE (top) with selected ROIs (bottom) (**g**), and corresponding fluorescence traces (**h**; $n = 8$ slices from 2 mice). Acquisition rate, 333 Hz. **i**, **j**, Fluorescence wide-field images of thalamus neurons expressing SomArchon (top) via AAV transduction with selected ROIs (bottom) (**i**), and corresponding fluorescence traces (**j**; $n = 5$ slices from 2 mice). Acquisition rate, 333 Hz. Scale bars, 25 μm.

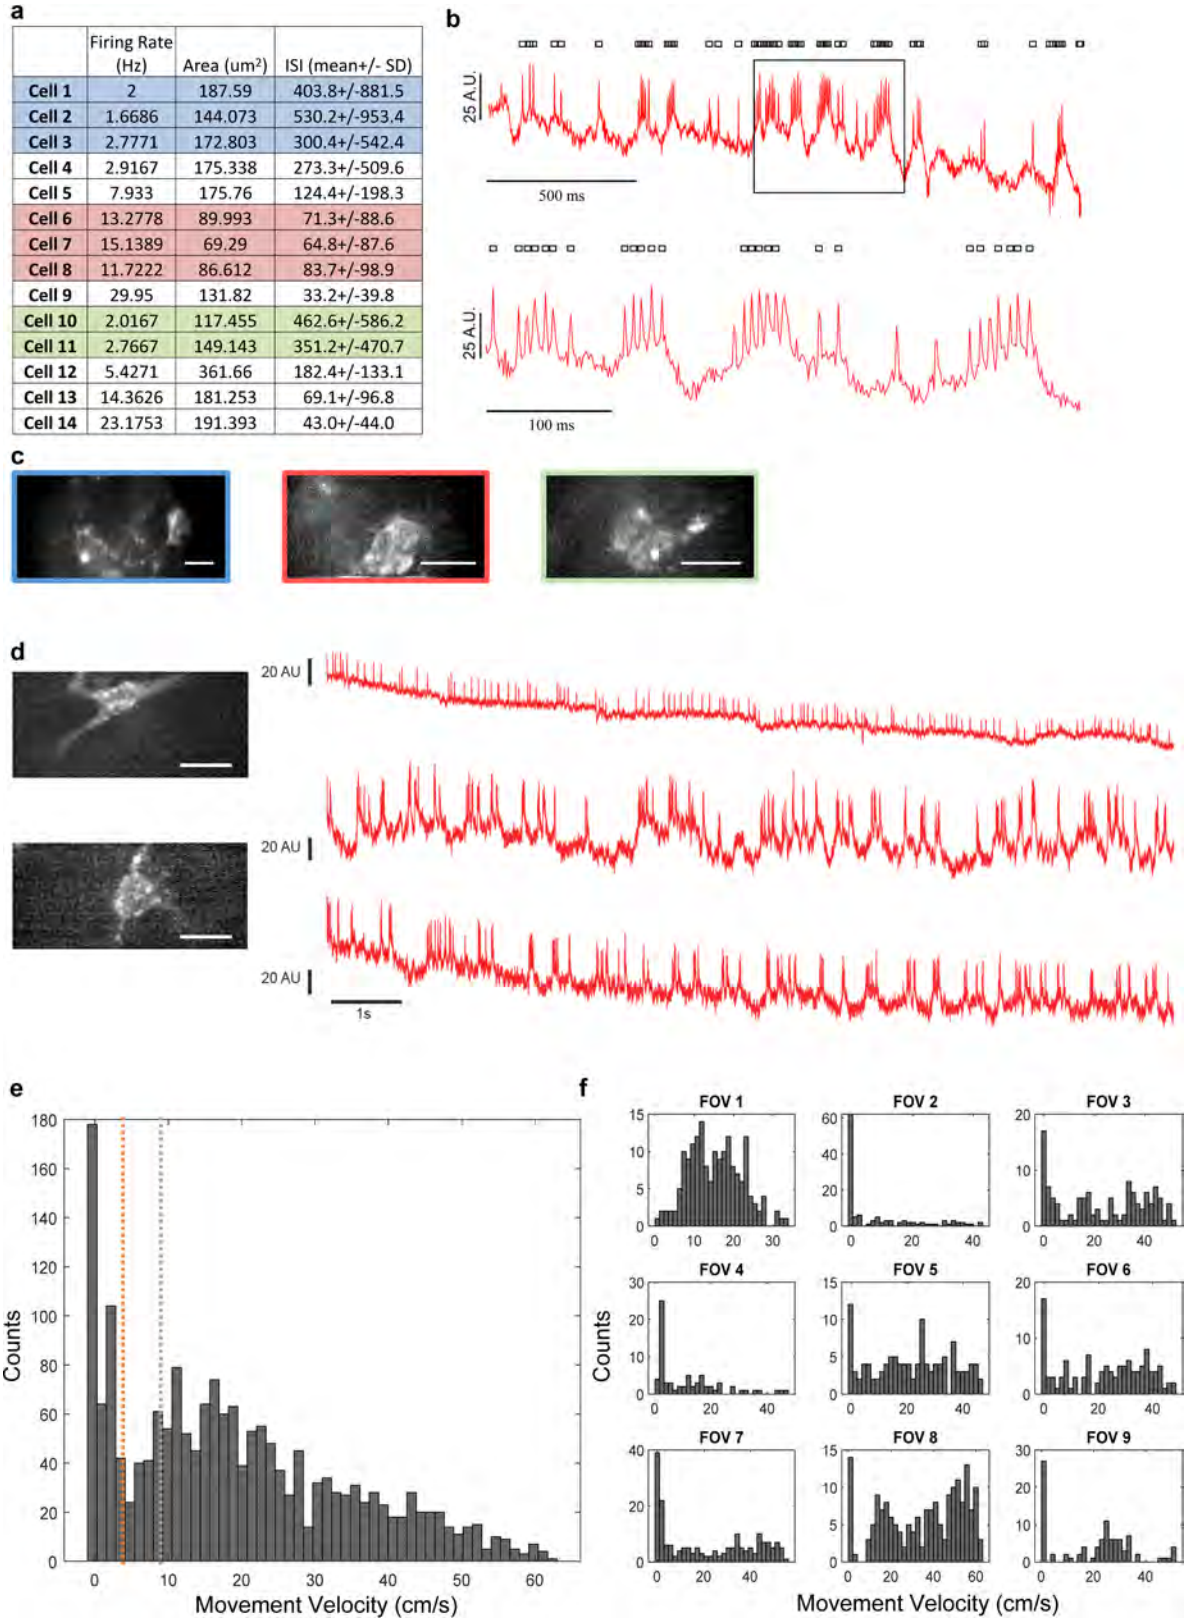


Extended Data Fig. 3 | See next page for caption.



Extended Data Fig. 3 | Expression of SomArchon and voltage imaging do not alter membrane properties or cause phototoxicity. a, Membrane properties of neurons expressing Archon (hashed boxes) or SomArchon (open boxes) in cortex layer 2/3 brain slices ($P = 0.8026$, 0.8895, and 0.8236 for resistance, capacitance, and resting potential, respectively; two-sided Wilcoxon rank-sum test comparing Archon1 versus SomArchon; $n = 8$ and 18 cells from 1 and 2 mice for Archon1 and SomArchon, respectively). **b**, Similar to **a** but in hippocampus ($P = 0.6294$, 0.9720, 0.8880, and 0.0037 for resistance, capacitance, resting potential, and FWHM, respectively; two-sided Wilcoxon rank-sum test comparing negative versus SomArchon; $n = 8$ and 7 cells from 2 mice each for negative and SomArchon for resistance and resting potential; $n = 7$ and 7 cells from 2 mice each for negative and SomArchon for capacitance; $n = 7$ and 8 cells from from 2 mice each for negative and SomArchon for FWHM). **c**, Similar to **a** but in striatum ($P = 0.7380$, 0.8357, 0.7751, and 0.0931 for resistance, capacitance, resting potential and FWHM, respectively; two-sided Wilcoxon rank-sum test comparing negative and SomArchon; $n = 7$ and 6 cells from 2 mice each for negative and SomArchon for resistance and capacitance; $n = 6$ and 7 cells from 2 mice each for negative and SomArchon for resting potential; $n = 6$ and 6 cells from 2 mice each for negative and SomArchon for FWHM). **d**, Changes in relative ROS concentration (normalized to that before illumination) over time in negative (solid line) and SomArchon-expressing (dashed line) cultured mouse neurons under various illumination protocols. **e**, Maximal increase in ROS concentration during continuous illumination for conditions performed in **d** ($n = 45$, 24, and 8 negative neurons from 2, 2, and 1 cultures for 390/22 nm, 475/36 nm, and 637 nm illumination, respectively; $n = 24$ SomArchon-expressing neurons for 637 nm illumination from 1 culture). **f**, Cell death for negative (solid line) and SomArchon-expressing (dashed line) cultured neurons at DIV 14–18 under various illumination protocols ($n = 45$, 35, 91, 40, and 27 neurons from 2, 1, 2, 1, and 1 cultures, respectively, for 390/22 nm at 2.8 mW mm^{-2}, 390/22 nm at 5.5 mW mm^{-2}, 475/36 nm at 12 mW mm^{-2}, 475/36 nm at 25 mW mm^{-2}, and 637 nm at 1,500 mW mm^{-2} illumination). **g**, Bright-field and fluorescence images of representative neurons expressing SomArchon before and after 10 min of continuous 637-nm laser illumination at 1,500 mW mm^{-2}, followed by 10 min in darkness (93% of imaged cells did not exhibit noticeable changes in morphology; $n = 27$ cells from 1 culture; non-illuminated cells did not show any changes in morphology; $n = 10$ cells from 1 cultures). Scale bar, 50 μm. **h**, Representative SomArchon fluorescence trace from neuron co-expressing SomArchon and CoChR-$K_v2.1_{motif}$. **i**, Normalized spike rates (to initial value) elicited by blue light illumination dropped after 300 s of continuous recording, owing to decrease in spike amplitude as a result of photobleaching ($n = 10$ neurons from 1 culture; plotted as mean ± s.d.). **j**, Normalized (to initial value) FWHM of spikes elicited by continuous light exposure as in **h**. Box plots as in Fig. 1.

Extended Data Fig. 4 | SomArchon expression in vivo does not cause gliosis. SomArchon was expressed in the mouse brain by AAV2.9-Syn-SomArchon-P2A-CoChR-K$_V$2.1$_{motif}$ injection into the cortex in P0 Swiss Webster mice. Brain tissues were analysed 63 days after viral injection. Merged fluorescence images from 50-μm-thick coronal sections (i) were visualized via EGFP fluorescence of SomArchon (ii), anti-IBA1 immunofluorescence (iii), and anti-GFAP immunofluorescence (iv; $n = 4$ slices from 2 mice). **a**, Expression throughout the coronal section. **b**, Zoomed-in view of the virally injected area (high-expression cortex). **c**, Zoomed-in view of the non-injected contralateral hemisphere (low-expression cortex). The commonly used glial and microglial markers GFAP and IBA1 appeared similarly in both hemispheres, suggesting that expression of SomArchon did not cause gliosis. Scale bars, 1 mm (**a**), 250 μm (**b**, **c**).



Extended Data Fig. 5 | Side-by-side comparison of next-generation voltage indicators in mouse brain slices. a, Representative fluorescence images of mouse cortex layer 2/3 neurons expressing ASAP3-$K_V2.1_{motif}$ (ASAP3-Kv), Ace2N-HaloTag-KGC-ER2-$K_V2.1_{motif}$ (Voltron-ST/JF_{525}), QuasAr3-PP-mCitrine-$K_V2.1_{motif}$-ER2 (QuasAr3-s), and paQuasAr3-PP-mCitrine-$K_V2.1_{motif}$-ER2 (paQuasAr3-s). ASAP3-Kv, QuasAr3-s and paQuasAr3-s were visualized via cpGFP, mCitrine, and mCitrine fluorescence, respectively, using laser excitation at 488 nm and emission at 525/50 nm under a confocal microscope. Voltron-ST/JF_{525} was visualized via JF525 fluorescence using LED excitation at 510/25 nm and emission at 545/40 nm under a wide-field microscope. Scale bar, 50 μm. **b**, Single-trial optical recordings of ASAP3-Kv (green) and Voltron-ST/JF_{525} (orange) fluorescence responses during neuronal activity evoked with 4-aminopyridine, and QuasAr3-s (blue), paQuasAr3-s (brown), and SomArchon (red) fluorescence responses during neuronal activity evoked with CoChR-mTagBFP2-$K_V2.2_{motif}$. Acquisition rate, about 500 Hz. Blue light pulses (470/20 nm, 2 ms per pulse, 10 Hz; vertical blue bars) were used to activate CoChR to evoke spiking. **c**, **d**, Quantification of $\Delta F/F$ (**c**) and SNR (**d**) per action potential across all recordings ($n = 18$, 14, 9, 13, and 14 neurons from 1, 2, 2, 2, and 2 mice for ASAP3-Kv, Voltron-ST/JF_{525}, QuasAr3-s, paQuasAr3-s, and SomArchon, respectively). Box plots as in Fig. 1. *$P < 0.01$, Wilcoxon rank-sum test; see Supplementary Table 2 for statistics. **e**, Photobleaching curves of ASAP3-Kv, Voltron-ST/JF_{525}, and SomArchon under continuous illumination ($n = 11$, 8, and 17 neurons from 1 culture, respectively).

Extended Data Fig. 6 | SomArchon enables both local dendritic and population imaging of neurons in multiple brain regions in vivo. **a**, Fluorescence images of selected FOV in motor cortex (left) with selected ROIs corresponding to somas of 3 neurons (right) ($n = 1$ FOV from 1 mouse). Scale bar, 50 µm. **b**, Representative fluorescence traces from **a** with detected spikes (black ticks). **c**, Fluorescence image of a hippocampal neuron expressing SomArchon with ROIs selected at the soma and on 4 proximal dendrites ($n = 1$ neuron from 1 mouse). Scale bar, 20 µm. **d**, Optical voltage traces from the selected ROIs shown in **c**. **e**, Fluorescence image of a striatal neuron expressing SomArchon with ROIs selected at the soma and on 3 proximal dendrites ($n = 1$ neuron from 1 mouse). Scale bar, 20 µm. **f**, Optical voltage traces from the selected ROIs shown in **e**. Black arrows in **d**, **f** highlight instances in which dendritic voltages differed visibly from those on the soma. **g**–**k**, In vivo population voltage imaging in the hippocampus CA1 region ($n = 14$ FOVs from 3 mice). **g**, **i**, Average intensity projection image for each video (top), with identified ROIs (bottom). **h**, **j**, Optical voltage traces for each neuron shown in **g**, **i**, respectively, with colours matching corresponding ROI colours. Panels show 1.2 s of simultaneously recorded voltage for all neurons (left), and a period with prominent spikes (right). Image acquisition rate for all recordings, 826 Hz.

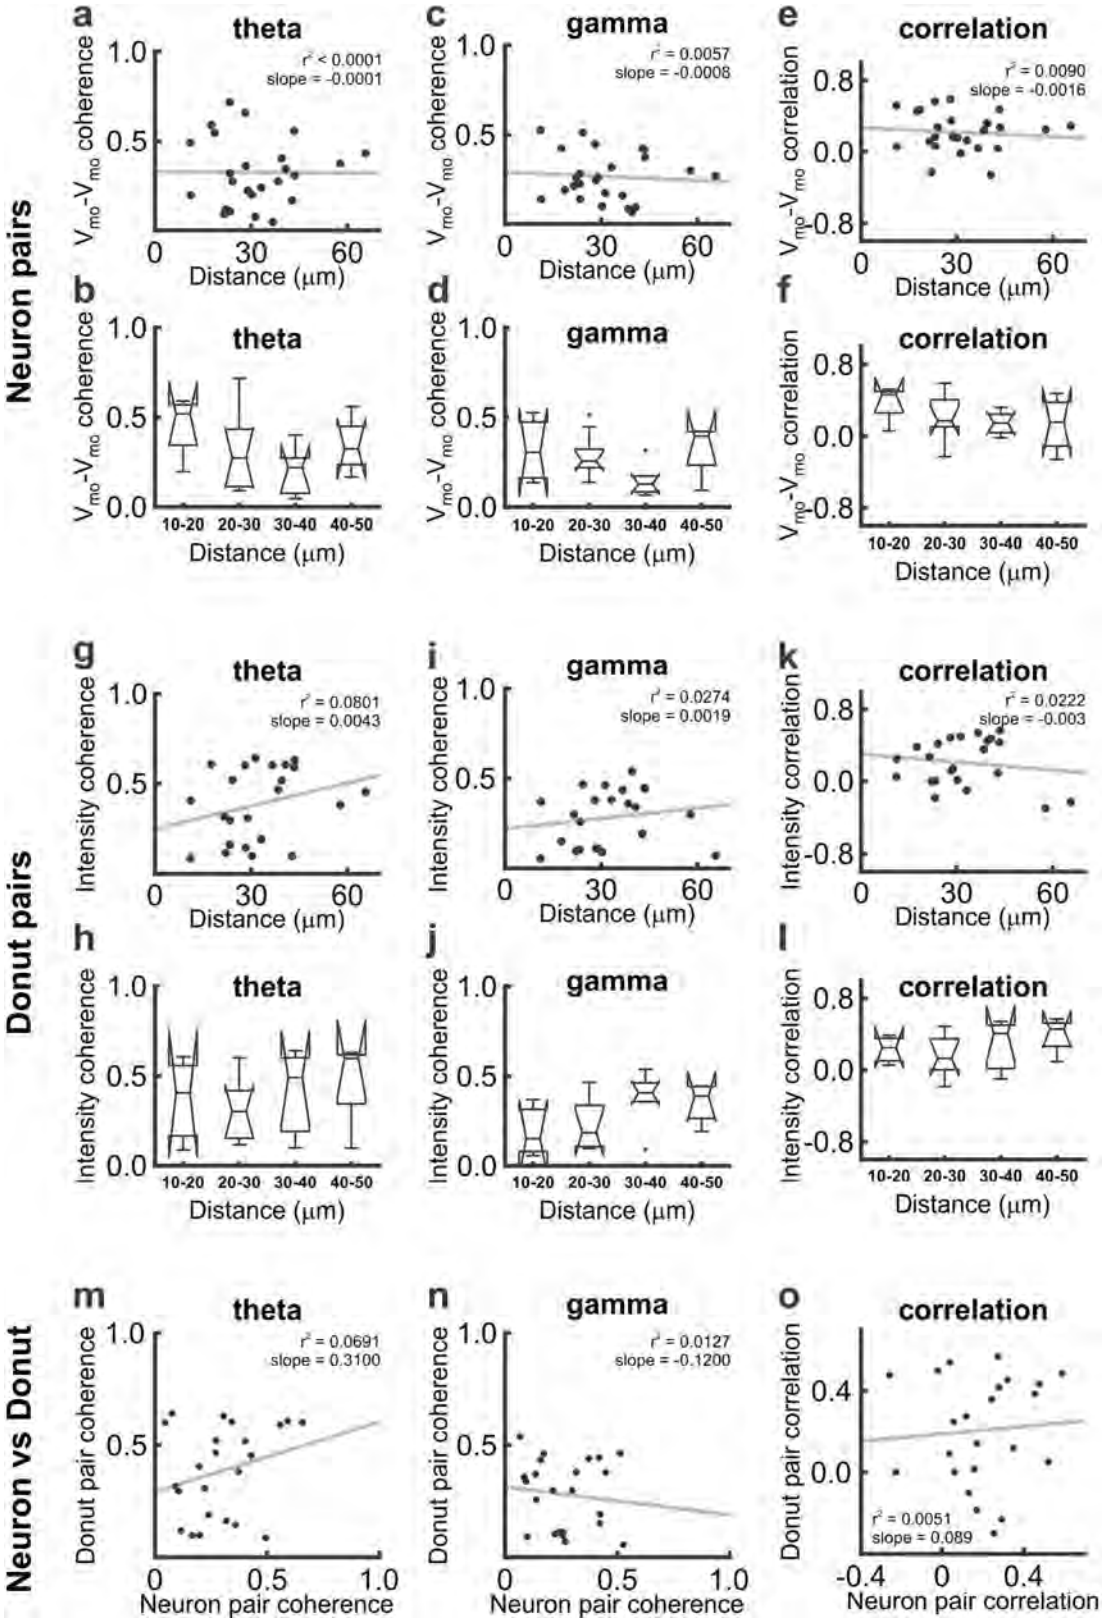
Extended Data Fig. 7 | See next page for caption.

Extended Data Fig. 7 | Properties of striatal neurons and movement thresholds. a, Average firing rate, size, and interspike interval (ISI) for 14 neurons recorded in 9 FOV in 2 mice. Cells simultaneously recorded in the same FOV are colour-coded (blue, red and green). Cells in rows with a white background were recorded individually. **b**, Selected trace from cell 9 exhibiting spike bursting (top), and a zoomed-in view of the boxed region (bottom). A.U., arbitrary unit. Identified spikes are indicated by the marks on top of the trace. **c**, Single frame images for FOVs with multiple neurons, colour-coded as in **a**. Scale bars, 20 μm. **d**, Representative optical traces from two Cre-dependent SomArchon-expressing striatal cholinergic interneurons in a ChAT-Cre mouse (left; scale bar, 20 μm), recorded in 3 sessions, while mouse was awake with head fixed and navigating a spherical treadmill ($n = 2$ neurons from 1 mouse). Top trace corresponds to top neuron on left; two bottom traces correspond to bottom neuron. Image acquisition rate, 826 Hz. **e**, Histogram of instantaneous movement speeds for all FOVs shown in Fig. 3 (nine FOVs in two mice). Instantaneous movement speed was calculated as average speed during each 0.5-s time interval. Red line, threshold for low movement speed identification; green line, threshold for high movement speed identification. **f**, Histogram of instantaneous movement speed for individual FOVs analysed.



Extended Data Fig. 8 | See next page for caption.

Extended Data Fig. 8 | In vivo SomArchon performance over time in the striatum and hippocampus of awake mice. a–h, Average fluorescence intensity, SNR per spike, and firing rates of neurons in the striatum and hippocampus of awake mice, over multiple trials. **a–c**, In each striatal recording session, we performed 5 trials, each 12-s long, with inter-trial intervals of 30–60 s. Average fluorescence intensity (**a**) decreased slightly; spike SNR (**b**) and firing rates (**c**) remained constant throughout the recording session (repeated-measures analysis of variance (ANOVA), $n = 6$ neurons in 5 FOVs from 1 mouse). **d–h**, In each hippocampal recording session, we performed 10 trials, each 6-s long, with inter-trial intervals of 20–30 s. Average fluorescence intensity (**d**) showed a slight but significant decrease across trials. SNR (**e**) decreased between the first and second trials but not afterwards, and firing rate (**f**) remained constant. Spike amplitude (**g**) fluctuated randomly over trials, and there was a significant increase in baseline noise (**h**) between the first and second trials (repeated-measures ANOVA; $^*P < 0.05$, post-hoc test: Tukey's HSD test, $n = 16$ neurons in 7 FOVs from 4 mice, Supplementary Table 2). Measurements were normalized to the first trial for each neuron. Box plots as in Fig. 4. **i–m**, A representative continuous optical trace of a hippocampal neuron over 80 s in an awake, head-fixed mouse (**i**), with zoomed-in views (**j–m**) at the beginning and end of the recording highlighting comparable firing rates and SNRs ($n = 16$ neurons in 7 FOVs from 4 mice).

Extended Data Fig. 9 | Analysis of LFP and subthreshold membrane voltage oscillation in the hippocampus. a, Example hippocampal LFP recordings from a session with ten trials, aligned to the onset of an air puff (green shading) directed to one eye in awake, head-fixed mice. **b**, LFP power spectrum shows strong theta oscillations. Mean ± s.d., $n = 10$ trials in 1 session. **c**, Oscillation power at high frequencies (100–250 Hz, red) and at theta frequencies (blue), aligned to puff onset. Each thin line represents an individual recording session, and the thick lines denote means ($n = 7$ sessions in 4 mice). **d**, Eye puff evoked a significant increase in LFP power at high frequency, but not at theta frequency (theta frequency $P = 0.5966$; high frequency $P = 0.0004$; two-tailed paired Student's t-test, $n = 7$ sessions in 4 mice). Box plots as in Fig. 4. **e**, Fluorescence image of a representative FOV (top) with selected ROIs (bottom). **f**, Membrane voltage recorded optically (V_{mo}) from neurons identified in **e**, and simultaneously recorded LFPs. Black vertical ticks above V_{mo}s denote spikes. Spike–spike coherence values between neurons are shown on the left and V_{mo}–V_{mo} theta coherence values are shown on the right. **g**, Theta-frequency-filtered LFPs and V_{mo}s for the four traces shown in **f**. V_{mo}–LFP coherence values are shown on the right. **h**, Scatter plot of V_{mo}–V_{mo} theta frequency coherence and spike–spike coherence from all neuron pairs, fitted with a linear regression ($n = 25$ pairs, $P = 0.08$, t-statistic, $r^2 = 0.12$).

Extended Data Fig. 10 | See next page for caption.

Extended Data Fig. 10 | Pairwise coherence and correlation measures over spatial distance. To investigate the potential of background fluorescence signals under wide-field imaging to produce shared crosstalk signals on neuron pairs, we examined the relationship of various coherence and correlation measures between neurons and background fluorescence over spatial distance. **a**, **b**, Pairwise coherence at theta frequencies between neurons. V_{mo}–V_{mo} coherence did not decrease significantly with spatial distance. (**a**, $n = 25$ pairs analysed with spatial distance of 11–66 μm, centre to centre; **b**, $n = 23$ pairs within 50 μm of each other; $F = 1.44$, $P = 0.26$, one-way ANOVA). **c**, **d**, Pairwise V_{mo}–V_{mo} coherence at gamma frequencies (30–50 Hz) was not dependent on spatial distance (**c**, $n = 25$ pairs; **d**, $n = 23$ pairs within 50 μm of each other; $F = 2.10$, $P = 0.13$, one-way ANOVA). **e**, **f**, Pairwise correlation between neurons did not decrease significantly with spatial distance (**e**, $n = 25$ pairs; **f**, $n = 23$ pairs within 50 μm of each other; $F = 1.00$, $P = 0.42$, one-way ANOVA). **g**–**l**, Same analysis as in **a**–**f** performed in background doughnut ROIs surrounding each neuron (Methods). Similar to results from neuron pairs, we found that theta frequency coherence between background doughnut ROIs was not dependent on spatial distance (**g**, $n = 23$ pairs; **h**, $n = 21$ pairs; $F = 0.65$, $P = 0.59$, one-way ANOVA), nor was gamma frequency coherence (**i**, $n = 23$ pairs; **j**, $n = 21$ pairs; $F = 1.93$, $P = 0.16$, one-way ANOVA), or the correlation coefficient (**k**, $n = 23$ pairs; **l**, $n = 21$ pairs; $F = 1.02$, $P = 0.41$, one-way ANOVA). **m**–**o**, The coherence between neurons and their corresponding doughnuts was not correlated at theta frequency (**m**), at gamma frequency (**n**), or for the Pearson correlation coefficients (**o**). Box plots are as in Fig. 4.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed
☐	☒ The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒ A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒ The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐ A description of all covariates tested
☐	☒ A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒ A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒ For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐ For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐ For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☒	☐ Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	Data were recorded using NIS-Elements Advance Research software v4.60.00, HC Image 4.5, OmniPlex system 1.6.0, and MATLAB 2014b.
Data analysis	Data were analyzed offline using NIS-Elements Advance Research software v4.60.00, OriginPro 8 (OriginLab), C, Excel 2016 (Microsoft), ImageJ(Fiji) 1.52i, Python 3.6.8. and 3.7.1, BoxPlotR, and MATLAB 2017a, 2018a, 2018b.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

Code availability. Computer codes used to generate results for this study are available at https://github.com/HanLabBU/somarchon-imaging.
Data availability. The data that support the findings of this study are available from the corresponding author upon reasonable request; raw data essential to the work is avalible online at nature.com. Sequences of the reported proteins are available at Genbank at the following accession codes: SomArchon MN091368; SomArchon-P2A-CoChR-KV2.1motif, MN091369.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/documents/nr-reporting-summary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	No statistical methods were used to estimate sample size for animal studies throughout. We did not perform a power analysis, since our goal was to create a new technology; in the reference (Dell, R. B., Holleran, S. & Ramakrishnan, R. Sample size determination. ILAR. J. 43, 207–213 (2002)), as recommended by the NIH, "In experiments based on the success or failure of a desired goal, the number of animals required is difficult to estimate..." As noted in the aforementioned paper, "The number of animals required is usually estimated by experience instead of by any formal statistical calculation, although the procedures will be terminated [when the goal is achieved]." These numbers reflect our past experience in developing neurotechnologies.
Data exclusions	Voltage imaging datasets with significant motion or where no spikes were detected were excluded from analysis. Significant motion was defined as a shift for more than 20 µm in any direction. In Extended Data Figure 1i,j,k data points that corresponded to overlapping neurites were excluded. Data exclusion criteria were not pre-established.
Replication	All attempts at replication were successful. The detailed experimental protocols are provided to facilitate replication by others.
Randomization	There were no treatment conditions to compare in this study. All recording sessions were randomly performed with different voltage sensors or in different brain regions. On recording days, cultured cells or brain slices expressing specific sensors were known. On in vivo recording days, mouse conditions were known. Voltage trace extraction and subsequent analysis were performed with the investigators unaware of specific mouse conditions. For analysis of movement modulation of striatal neuron spiking, a computer algorithm was used to identify periods with different movement parameters. For analysis of spike-phase relationships, or subthreshold membrane voltage relationships, a computer algorithm was used across all conditions. For histology,- sections were selected and images were taken from slides by a researcher not aware of the conditions or antibody used. Cells were also counted and quantified from these sections by a researcher blinded to the experimental conditions or antibody used.

Front. Neurosci. 13:128. doi: 10.3389/fnins.2019.00128

Extracellular recordings of electrical activity in freely moving rats are fundamental to understand brain function in health and disease. Such recordings require a small-size, lightweight device that includes movable electrodes (microdrive) to record either a new set of neurons every day or the same set of neurons over time. Ideally, microdrives should be easy to implant, allowing precise and smooth displacement of electrodes. The main caveat of most commercially available microdrives is their relatively short half-life span, in average ranging from weeks to a month. For most experiments, recording days–weeks is sufficient, but when the experiment depends on training animals for several months, it is crucial to develop new approaches. Here, we present a low-cost, reusable, and reimplantable device design as a solution to extend chronic recordings to long-term. This device is composed of a baseplate that is permanently fixed to the rodent's skull, as well as a reusable and replaceable microdrive that can be attached and detached from the baseplate, allowing its implantation and reimplantation. Reimplanting this microdrive is particularly convenient when no clear neuronal signal is present, or when the signal gradually decays across days. Our microdrive incorporates a mechanism for moving a 16 tungsten-wire bundle within a small (∼15 mm^3) lightweight device (∼4 g). We present details of the design, manufacturing, and assembly processes. As a proof of concept, we show that recordings of the nucleus accumbens core (NAcc) in a freely behaving rat are stable over a month. Additionally, during a lever-press task, we found, as expected, that NAc single-unit activity was associated with rewarded lever presses. Furthermore, we also show that NAc shell (NAcSh) responses evoked by freely licking for sucrose, consistent with our previously published results, were conserved from a first implant to a second microdrive reimplant in the same rat, notably showing reimplantation is possible without overtly affecting the functional responses of the area of interest. In sum, here we present a novel microdrive design (low-cost, small size, and light weight) that can be used for long-term chronic recordings and reimplanted in freely behaving rats.

Keywords: microdrive, extracellular chronic recording, reimplantable microdrive, electrophysiology, additive manufacturing

INTRODUCTION

Electrophysiological recording of brain activity is a valuable technique to understand the neural correlates of behavior in health and disease (Esmaeili and Grace, 2013). Recordings of electrical neural activity in rodents provide useful insights into how the brain represents information about the internal and external world (Nicolelis et al., 1995; Buzsáki, 2004; Hasegawa et al., 2015), uncovering the neuronal correlates from sensory and perceptual processing to decision making (Feierstein et al., 2006; Fonseca et al., 2018). In general, the methods in electrophysiology can be divided into intracellular and extracellular recordings. Unlike the former, the latter is widely used in freely moving animals, which allows stable recordings for several minutes or even hours (Ribeiro et al., 2004; Jovalekic et al., 2017). However, the loss of signal becomes a fundamental problem, especially, in studies involving either extensive behavioral training (spanning from weeks to months) or in animal models characterizing the development of chronic human diseases (Vlamings et al., 2012; Ellens and Leventhal, 2013; Sesia et al., 2013; Saddoris et al., 2016). To circumvent this issue, it is needed a reimplantable microdrive to record, the same animal, over an extended period.

Although it is not fully understood why electrical signals degrade along time, it has been speculated that the loss of signal could be caused by tiny vibrations produced by the animal's movement or by biological reasons such as tissue reaction surrounding the electrode, resulting in neuronal migration, neuronal death, or glial encapsulation of the recording tips (Muthuswamy et al., 2005, 2011; Branchaud et al., 2006). Also, researchers face the problem of oversampling the same neuropil over days, which reduces the biological replicates within a dataset. In this regard, previous microdrives were developed to move the wires and to record from a new set of neurons every day (Gutierrez et al., 2010) or record from the same neurons for a few days (Sotres-Bayon et al., 2012). In any case, most commonly movable electrodes are permanently implanted and cemented to the skull which precludes reimplantation in the same subject and thus increased the number of experimental animals needed (Fitts, 2011).

Multiple designs have been used for building microdrives. Manually movable microdrives have been used in the past decades with limited success. Morrow (1980) reported a manual mechanism which is based on four parts with a mounting sleeve, a carrier tube and an electrode drive screw that moves the electrode. Later, O'Keefe and Recce (1993) reported the use of a microdrive with a mechanism that avoids the rotation of the cannula or electrodes. Gothard et al. (1996) developed a conic and bulky microdrive able to move 14 tetrodes independently. Looking for a low-cost, low-weight, and easy-fabrication device, the "Scribe microdrive" was presented by Bilkey and Muir (1999). It is composed of the parts of a pen, a guide cannula and a screw, whose motion is transmitted using a contact point between the screw and the pen nib, allowing only forward displacement. Lansink et al. (2007) reported the development of a multi-electrode microdrive for chronic recording in two brain areas simultaneously, based on a microdrive presented by Gothard et al. (1996). This system allows reusing some parts of the microdrive. More recently, Chang et al. (2013) developed a home-made microdrive consisting of two joined brass guides. This microdrive uses four tetrodes displaced by a screw, and an electronic interface board (EIB-18, Neuralynx) for proper connections, which resulted in stable single-unit recordings for several weeks. Also, the same manuscript shows the steps for assembling a commercially available microdrive (Versa Drive 4, Neuralynx) based on a Mill-Max commercial connector and containing four drive screws (Chang et al., 2013).

The main disadvantage of manually driven microdrives is the limited precision to move electrodes and the stress to which the animal is subjected when lowering them. To solve this problem, several automatic movable microdrives have been developed. Fee and Leonardo (2001) introduced a microdrive consisting of a brushless dc micromotor. In 2007, a microdrive based on a hydraulic system was presented. This device can move 22 wires independently along 4 mm in intervals of 50 μm (Sato et al., 2007). Yamamoto and Wilson (2008) reported a motorized system with 21 drivers, each composed of five parts: a dc brushless servomotor with planetary gearbox, a threaded rod, a slotted PEEK tube, a shuttle lock, and a shuttle. A microdrive for mice containing a piezo-motor (TULA 35, Piezoelectric Technology Co., Ltd.) with 1 μm accuracy was presented by Yang et al. (2011). This motorized microdrive comprises 13 components. Another lightweight microdrive that uses a dc micromotor with threaded output was developed in 2012 by Otchy and Ölveczky, which consists of seven major components. In 2014, Caballero-Ruiz et al. (2014) proposed a high-precision displacement system based on a piezo motor (SQL-RV-1.8, New Scale Technologies Inc.) and a Hall-effect sensor (Allegro A1324 MicroSystems, Inc.) comprising six assembly parts and three more for the closed-loop positioning system. In 2017, Jovalekic et al. (2017) developed another micropositioning system consisting of a piezo motor (SQL-RV-1.8, New Scale Technologies Inc.) and a Hall-effect sensor (NSE-5310, New Scale Technologies, Inc.). These electrodes could be replaced, increasing the yield of neurons recorded. However, to further increase the number of neurons recorded, there is a need for a reimplantable microdrive for chronic recordings in freely behaving animals. This is particularly relevant in experiments in which much time and effort are devoted to training animals in tasks where reusing and reimplanting microdrives would increase the gathering of neural data.

Among the many microdrives developed so far, the power screw mechanism is the most commonly used for electrode positioning, whether it is a manual or automated mechanism. Most of the automated ones, in addition to the screw, use geared brushless dc micromotors, reaching resolutions about 1 μm. As suggested by Sato et al. (2007), and in spite of the high resolutions achieved by this kind of mechanisms, the backlash present in the gears and leadscrews introduces a significant amount of imprecision which could cause lateral deviations along the vertical displacement (as it can be seen in the work carried out by Chang et al., 2013) and, even more, the micro motion between the electrode and

the surrounding tissue, due to the natural movements (i.e., heartbeat and respiration) of the animal, could results in loss of signal (Muthuswamy et al., 2011). To address this problem, Sato et al. (2007) put forward a hydraulic system in which electrode positioning can be estimated accurately with a pre-pressurized system. Although the hydraulic microdrive can precisely displace the electrodes, it is too heavy and bulky. From another standpoint, electrode motion can be performed using piezoelectric motors. Unlike electromagnetic devices, the piezoelectric ones are electromagnetic noise-free, and their efficiency is insensitive to size (Heywang et al., 2008). Besides considering low weight, low cost, small dimensions, and high precision as important requirements for the development of microdrives, it is also important to consider the half-life of electrodes. Long-term experiments require a reliable microdrive to record neural signals over a long period able to overcome biotic and abiotic factors that could affect impedance (Sankar et al., 2014).

In this work, we present the development of a reusable and reimplantable microdrive that increases the success of electrophysiological studies in freely moving rats. Such a microdrive is based on a smooth displacement mechanism and a reimplantable system. It also accomplishes the low weight, low cost, small dimension, and high precision requirements mentioned above. The proposed mechanism prevents lateral motion along the electrode stroke, which results in stable recordings. The motion can be manually or automated performed, depending on the preference of the user. Moreover, a baseplate is fixed to the skull without using dental acrylic, and the microdrive is attached to the baseplate. Thus, it can be easily replaced. The efficiency of the microdrive was demonstrated using electrophysiological experiments in freely behaving rats. First, we characterized the stability of our microdrive. We found stable responses in a single neuron recorded in the nucleus accumbens core (NAcc) while a rat pressed a lever to obtain food. Then, in a separate rat, the spontaneous activity of two neurons was successfully recorded for over a month (40 days). Having demonstrated the stability of the microdrive, we evaluated if our microdrive could be reimplanted, in the same rat, without overtly damaging the functional activity of the brain region of interest. To this end, single-unit recordings from the NAc shell (NAcSh) were performed while rats licked for sucrose. In the same animals, we found that the signal quality between the first electrode implant and the second one was not statistically different, indicating that the proposed reimplantable microdrive can potentially extend the half-life of the electrophysiological experiments. Also, it revealed that reimplantation did not impair the normal function of the recorded brain region since our data replicated a well-known function of the NAcSh. That is, the majority of NAcSh neurons were either Lick-Inactive whereas the minority were Lick-Active during consummatory behavior, in the same proportion than previous observations (Krause et al., 2010; Tellez et al., 2012; Villavicencio et al., 2018). In sum, we demonstrated that the proposed reimplantable microdrive could be a reliable solution to extend chronic extracellular neuronal recording in freely behaving rats.

MATERIALS AND METHODS

In this section, the design, fabrication, assembly, and implementation of a reimplantable microdrive to smoothly displace electrode bundles for extracellular recordings is presented. Such a microdrive is based under the following requirements: small-size less than 15 mm × 15 mm × 15 mm; weight less than 5 g; mechanical stability; able to move a bundle of 16 microelectrodes; able to be actuated manually or by motor (for manual actuating, using a resolution between 50 and 100 μm; while for motorized actuating, employing a resolution less than 10 μm); able to be reimplanted and easy to be installed and reused.

Microdrive Design

Figure 1 depicts the exploded view of the proposed microdrive, which has eight overall components: a micropositioning mechanism, composed of an electrode shuttle system (1) able to move the electrodes by means of either a nut-screw linear motion system (2a), for manual configuration, or a piezoelectric motor (SQL-RV-1.8; NewScale Tech.) (2b), for motorized configuration; in order to obtain precise displacements, a closed-loop position control system is used based on a Hall-effect sensor (Allegro A1324 MicroSystems, Inc.) (3). Inside the housing (4), the mechanism, the actuator and the gold-plated electronic interface board (EIB; 5) are located. Also, the design has two covers, one that is designated to protect the EIB (6) and the other one to protect the electrodes (7). Finally, the entire assembly lies on top of the baseplate (8), which is the only piece permanently fixed on the skull of the rat.

In order to fulfill the requirements for high resolution and mechanical stability, the linear motion is generated by either a nut-screw system [**Figure 1(2a)**], for the manual configuration, or by a piezoelectric actuator [**Figure 1(2b)**], for the motorized configuration, which is coupled to an electrode shuttle system (see **Figure 2**). The electrode shuttle system is composed of an element acting as a piston [**Figure 2 (2a)**] through a bushing (2b) in order to constrain the displacement. A compression spring (2c) introduces a pre-load between the piston and the nut-screw system or the piezoelectric actuator, warranting cero backlash. In this way, the mechanism exhibits high stiffness, load capacity and resistance to shock and vibration. The piston works as a shuttle, in which a stainless-steel guide cannula (2e) with a polyimide tube (2d) concentrically arranged is fixed. To prevent short circuits between the microelectrodes and the cannula, the polyamide tube is used, and the cannula guide improves the shuttle system alignment. For the motorized configuration, a magnet (2f), sensed by the Hall effect sensor, is employed.

The housing element (**Figure 3**) and the two covers shape the casing. Inside the first one, the micropositioning mechanism is located, as it can be seen in the lateral view (dashed line, red square). In the housing element, two internal conduits [**Figure 3 (4a)**] permit guiding the electrodes to the EIB, protecting them from damages caused by the natural movements of the animal. In this way, the electrodes can be led from the top to the bottom of the structure in order to be finally cut and connected to the EIB. The clamping element (4g) permits a stable attachment between the connector and the headstage using an

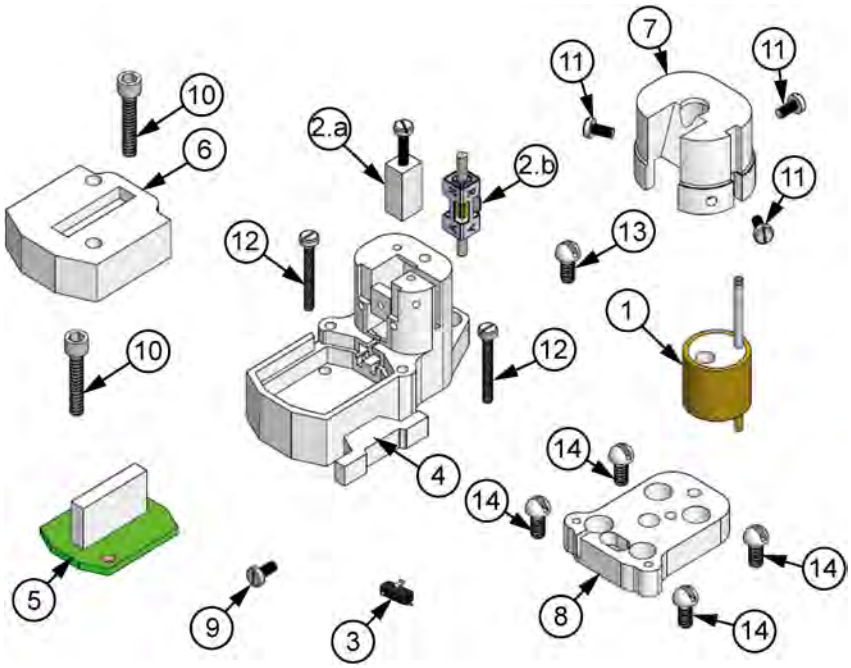

FIGURE 1 | Exploded view of the microdrive proposed. **(1)** Electrode shuttle system, **(2a)** nut-screw linear motion system, **(2b)** piezoelectric motor, **(3)** Hall-effect sensor, **(4)** housing element, **(5)** EIB-18, **(6)** EIB-18 cover, **(7)** electrode cover, **(8)** baseplate, **(9)** fixing screw of the motor or nut, **(10)** EIB cover-housing fixing screw (×2), **(11)** electrode cover-housing fixing screws (×3), **(12)** posterior housing-baseplate fixing screws (×2), **(13)** anterior housing-baseplate fixing screw, **(14)** baseplate-skull fixing screws (×4).

elastic rubber band. The EIB cover is fastened to the housing element using two screws through the holes (4f). Using three screws, the electrode cover is fixed to the housing, completing in this way the protection of the electrodes from the movements of the animal.

The baseplate (see **Figure 4**) is the element that facilitates the mounting on the skull of the rat. Such a baseplate can be easily designed for a desired position. It allows the device to be replaced in case of loss of signal, increasing the experiment time without the necessity of a second surgery. Through the fastening holes [**Figure 4 (8a)**], four screws have the function of fixing the baseplate to the skull. A groove (8b) allows joining the ground wire to the proper pin of the EIB. The alignment between the slotted guide groove (8c) and the guide wedge [**Figure 3(4b)**] makes it easier to assemble the housing element on the baseplate; also, three screws permit fixing both elements by means of an anterior fastening hole (8d) and two posterior fastening holes (8e). Also, the baseplate includes a hole (8f) through which the piston travels in a vertical path together with the bundle of electrodes in the recording site hole (8g). A microdrive design that includes such baseplate provides the opportunity to easily replace the device if there is an error during surgery.

Microdrive Fabrication and Assembly

To develop the microdrive presented, manufacturing processes criteria such as the shape of the components, type of the required materials as well as resolution and cost were considered. For the micropositioning mechanism, high resolution is a critical requirement, hence CNC manufacturing was used; through the milling process, the bushing and the piston were manufactured: the bushing was made of brass, with overall dimensions of 6 mm in internal diameter, 7 mm in external diameter, 6 mm in height and a weight of 0.29 g; while the piston was made of acrylic and has overall sizes of 2 mm in the inner diameter, 6 mm in the outer diameter, 6 mm in height and a weight of 0.069 g. The baseplate (weight: 0.52 g), the housing element (weight: 1.42 g), the covers (electrode cover weight: 0.42 g and EIB cover weight: 0.35094 g), and the nut (weight: 0.045 g) were manufactured using an additive manufacturing process (material jetting) because of the complexity of their shapes; the equipment employed was a Connex 3 by Stratasys, and the material used was VeroClear resin (RGD810). This technology has the advantage of reducing manufacturing costs when the production batch increases. The other components are commercial. The compression spring used (by Industrial Springs Corp.) is made of stainless steel and has a mean diameter of 2 mm, a free length of 5 mm and a weight of 0.01 g. The polyimide tube (Polyimide 0.0135 ID by Neuralynx) has a length of 18 mm and weighs only 0.002 g, while the guide cannula (20G by Lanceta HG) has a length of 13.5 mm and weighs 0.37 g. The magnet (R063-063 by Amazing Magnets LLC) weights 0.023 g and has overall sizes of 1.59 mm diameter and 1.59 mm length. The Hall-effect sensor (A1324LLHLT-T by Allegro MicroSystems) has overall sizes of 2 × 3 × 1 mm and weighs 0.015 g. In order to avoid rust problems, stainless steel screws were used which, according to

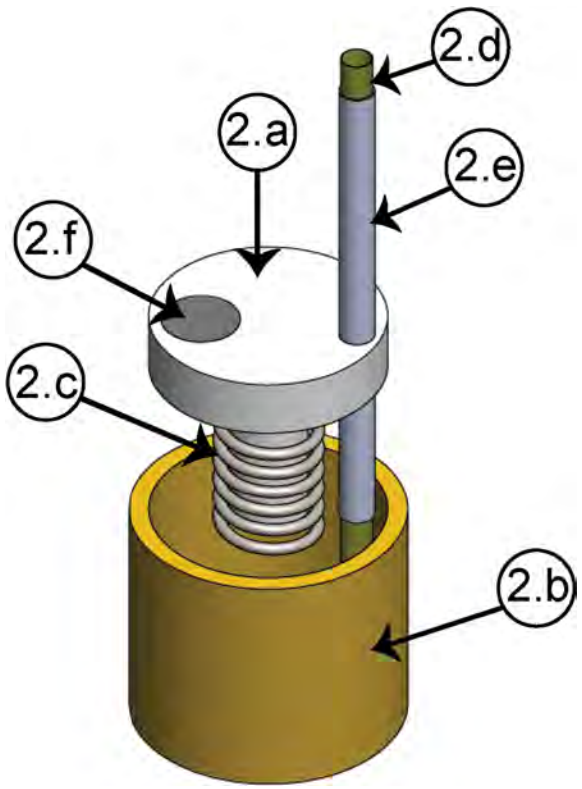

FIGURE 2 | Electrode shuttle system. **(2a)** Piston, **(2b)** bushing, **(2c)** compression spring, **(2d)** polyimide tube, **(2e)** cannula guide, **(2f)** magnet.

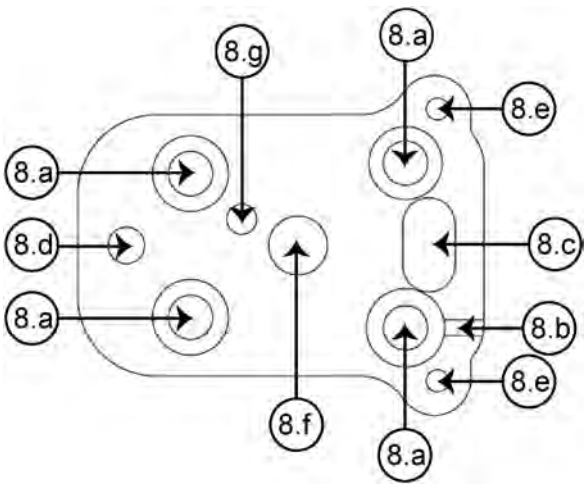

FIGURE 4 | Superior view of the baseplate. **(8a)** Baseplate-skull fastening hole (×4), **(8b)** groove for the ground wire, **(8c)** slotted guide groove, **(8d)** anterior fastening hole, **(8e)** posterior fastening hole (×2), **(8f)** piston blind hole, **(8g)** recording site (for the right NAcSh).

their application on the microdrive design, can be classified into three types: power screw, housing fixing screws and skull fixing screws. The first one (#21475 by MetricScrews) is M1-0.25 × 10 mm and weighs 0.045 g. The second one is composed of three different screws: four pieces of M1-0.25 × 3 mm (#20694 by MetricScrews) with a weight of 0.07760 g, two pieces of M1-0.25 × 8 mm (#21474 by MetricScrews) screws with a weight of 0.068 g and one 0–80 × 1/8 (by Plastics One Inc.) screw with a weight of 0.058 g. Finally, the skull fixing screws consist of four 0–80 × 1/8" screws with a weight of 0.23332 g. For the automated microdrive, a piezoelectric SQL-RV-1.8 actuator by New Scale Technologies is used, such an actuator has overall sizes of 2.8 × 2.8 × 6 mm and a weight of 0.16 g.

The complete assembly can be divided into three stages: the first one is related with the assembly of the micro positioning system; the second one involves the insertion and connection of the electrodes, and the last one is concerned with the placement of the protection covers with the appropriate fixing screws. The complete process can be seen in **Figure 5**. As a first step, the electrode shuttle system is assembled by fixing the polyimide tube and cannula (**Figure 5A**) to the piston

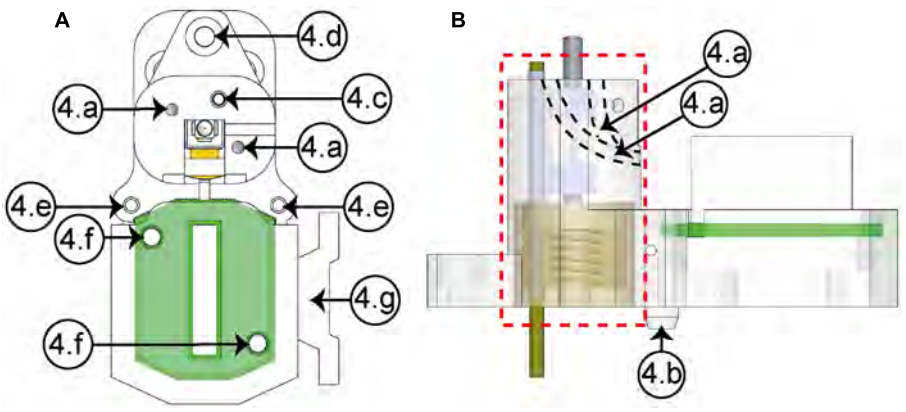

FIGURE 3 | Housing element (**A**, upper view; **B**, lateral view). **(4a)** Conduits (×2), **(4b)** guide wedge, **(4c)** cannula hole, **(4d)** anterior fastening hole, **(4e)** posterior fastening holes (×2), **(4f)** EIB's fastening holes (×2), **(4g)** headstage clamping element.

(**Figure 5B**), the polyimide tube projects 2 mm from the lower face of the baseplate. Then, the magnet is placed in the piston hole (**Figure 5C**) and the compression spring is placed concentrically to the piston rod (**Figure 5D**); after that, all these parts are put concentrically in the bushing (**Figure 5E**), which in turn is placed in the housing element (**Figure 5F**). After this, the nut-screw or the piezoelectric actuator can be placed and fixed with a screw. This stage takes about 10 min. The second stage consists in introducing the electrodes through the polyimide tube (**Figure 5G**) and the conduits (**Figure 5H**). After this, the electrodes are cut 7.5 mm from the lower face of the baseplate for the NAcSh, and 6 mm for the NAcc in order to reach the region of interest (see **Supplementary Figure S1**); next, the EIB is placed in the housing element; and finally, the electrodes are connected to the EIB by means of gold-plated pins (**Figure 5I**). **Figure 5J** shows the assembly with the piezoelectric actuator. It is important to handle the electrodes carefully, making sure they do not bend. This task takes around 30 min. The last stage consists in protecting the EIB and the exposed part of the electrodes by fixing the covers with the housing element (**Figure 5K**). At the end of this stage, the final assembly time is less than 70 min. Including the weight of the baseplate, the total weight of the reimplantable microdrive is about 4.08 g when the nut-screw is used, and 4.15 g if the piezoelectric motor is implemented. In both configurations, its overall dimensions are 27.73 × 15.95 × 21.50 mm. Finally, before the implantation, the electrodes can be gold plated and then the device is ready. **Supplementary Table S2** depicts the cost of all components to build one microdrive. In the case of the automated microdrive, the total cost of the parts is 280.2 USD. Considering that the actuator and the EIB are reusable, the total cost of each microdrive is approximately 53 USD (and it could be cheaper by producing a larger batch). All STL files are provided in the **Supplementary Data Sheet S1**.

Gold Plating of Electrodes

The impedance of the electrodes was controlled by electroplating the tip of the wires. Electroplating prevents impedance damping and improves the signal-to-noise ratio (Ferguson et al., 2009). Before implantation (and reimplantation), the 16 tungsten wires with 35 μm in diameter were electro-plated with a gold plating solution and the recommended Neuralynx stepped protocol (**Supplementary Table S1**) using a nanoZ^{TM} multi-electrode impedance tester (Plexon, Dallas, TX, United States). Impedances were reduced to 70 kΩ.

Microdrive in Freely Behaving Rats

The proposed microdrive was tested in freely behaving animals. Testing involved two separate experiments in different laboratories. In both laboratories, the activity in the nucleus accumbens (NAc) of the ventral striatum was recorded, a brain region involved with reward processing and appetitive behaviors (Castro et al., 2015). Experiments differ in the use of microdrive connectors: the first one uses the Mill-Max connector, while the second one uses an Omnetics connector. They also differ in the rat strain (Wistar and Sprague-Dawley rats) and task used to assess the microdrive: one experiment involves an instrumental task pressing-lever to obtain food while the other one involves a licking task to obtain a liquid solution.

Subjects

Two male Wistar rats (280–300 g; Instituto de Fisiología Celular's breeding colony) were housed in polyethylene cages. Rats were maintained on a 12 h light/dark cycle and fed standard laboratory rat chow in a restricted manner (18 g/day) until they reached 85% of their free-feeding weight. Rats had free access to water throughout the experiment. All manipulations and behavioral procedures were performed during the light phase. Animals were housed individually in a temperature-controlled environment

(24°C) for at least 4 days before surgery. Animals were handled daily to diminish stress responses.

Five male Sprague-Dawley rats (300–350 g; CINVESTAV bioterium). Rats were housed in polyethylene cages and maintained on a 12 h light/dark cycle (lights on 0700; and lights off 1900). These rats were under a water restriction of 23 h per day, with 1 h of access to tap water in their home-cages following each recording session (see below). Such water restriction protocol is necessary for rats to maintain high levels of motivation for operant conditioning tasks (Hughes et al., 1994), without affecting the health of the rats (Rowland, 2007). Chow food diet (LabDiet, 5008) was available *ad libitum* in their home cages. All manipulations and behavioral procedures were performed during the light phase. Animals were housed individually in a temperature-controlled environment (21–24°C) for at least 4 days before surgery.

All procedures were approved by the Institutional Animal Care and Use Committee of the UNAM and CINVESTAV, in compliance with the National Ministry of Health guidelines for the care of laboratory animals.

Surgery

Figure 6 depicts the microdrive implantation procedure. Following behavioral training, Wistar rats were anesthetized using isoflurane, and Sprague-Dawley rats with an intraperitoneal injection of ketamine (90 mg/kg)/xylazine (8 mg/kg).

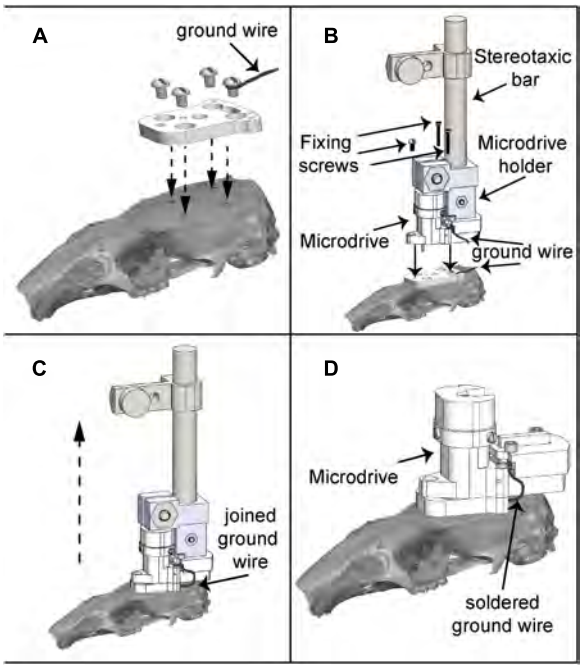

FIGURE 6 | Microdrive implantation procedure. **(A)** The baseplate is located on the cranium of the rat according to the recording site and fixed using four screws. **(B)** The microdrive holder allows a smooth and precise mounting of the microdrive, which is fixed to the baseplate using three screws. **(C)** After the ground wire fixation, the microdrive is released from the holder and ready to use. **(D)** Microdrive firmly attached on the baseplate.

The microdrive contained a 16-channel electrode bundle. For the five Sprague-Dawley rats the electrode bundle was implanted targeting the nucleus accumbens shell (NAcSh; +1.4 mm AP, −1 mm ML, and −7.5 mm DV, from bregma; Tellez et al., 2012), whereas Wistar rats aimed the NAcc (2.0 mm AP, +1.4 mm ML, and −6.0 mm DV, from bregma). Rats were positioned in a stereotaxic apparatus to perform a ∼2 × 2 mm craniotomy above the implantation site. Later, four additional Ø1.5 mm holes were made in the skull. The positions of these holes matched the holes in the baseplate where the microdrive was mounted. Then, the baseplate was fixed to the skull by screwing it through the holes. A drop of glue (cyanoacrylate, Krazy Kola Loka) was added to strengthen the fixation to the scalp. Finally, the reimplantable microdrive, positioned above the baseplate was lowered using a holder to introduce the electrode array in the brain. Once the microdrive was settled in, it was screwed to the baseplate. Following surgery, a triple antibiotic ointment was applied to the wound and enrofloxacin (45 mg/kg) was administered for three additional days. Rats were allowed to recover for 7–14 days before initiating recordings.

Behavior

Wistar rats were trained in standard operant chambers (Coulbourn Instruments, Allentown, PA, United States) located inside sound-attenuating boxes (MED Associates, Burlington, VT, United States) to press a bar to obtain food pellets (Bioserve, Inc., Frenchtown, NJ, United States) on a continuous reinforcement schedule. Recordings were performed in freely behaving rats or during lever pressing sessions.

Sprague-Dawley animals were recorded at the same time of the day between 2:00 and 3:00 p.m. Specifically, three rats were recorded while performing a brief-access test as described in Villavicencio et al. (2018). Briefly, taste stimuli consisted of reagent-grade sucrose (Sigma-Aldrich, Mexico) dissolved in deionized water. For the brief-access taste test, four semi-logarithmically spaced sucrose concentrations were used: 3, 5.8, 10.7, and 20 wt./vol. % (0.087, 0.168, 0.31, 0.58 M, respectively). For the brief-access test, in each trial, rats licked the spout to receive one randomly selected sweet concentration during a 5-s reward period. Moreover, the other two Sprague-Dawley rats performed an *ad libitum* freely licking sucrose test, in which only a sucrose solution of 10 wt./vol. % was available at all times (Tellez et al., 2012). Sweet tastants were prepared daily and used at room temperature. The behavioral box contained a V-shaped licking port where the spout was located (Med Associates, St. Albans, VT, United States). The licks given to the spout were recorded with a photobeam diode (Med Associates), and each lick delivered a 10-μL drop directly onto the rats' tongue as described in Gutierrez et al. (2010).

Data Analysis

Custom-made Matlab (The MathWorks Inc., Natick, MA, United States) codes were used to analyze behavioral and single unit activity. To identify neurons whose activity was modulated while the rats licked for sucrose in both licking tasks (**Figure 9D**), the rhythmic licking behavior was first segmented into bouts. A lick bout was considered to be a train of contiguous licks

with inter-lick intervals <500 ms (Spector et al., 1998; Tellez et al., 2012). Then, the neuronal firing rate was calculated during a baseline period encompassing −1 to −0.5 s before the onset of every lick bout and the firing rate during the lick bouts. Finally, to determine whether each neuron was modulated by licking or not, the firing rate in the baseline was compared with that in the licking period (lick bout) with a one-way ANOVA ($\alpha = 0.05$). All neurons with a significant difference were classified as modulated by licking and the difference between the firing rate during the two periods was used to classify the direction of the modulation into Lick-Active (increases in firing rate) or Lick-Inactive (decreases). The proportion of Lick-Active and Lick-Inactive neurons found during the first and second implant was compared against that previously reported in Tellez et al. (2012), using the chi-squared test ($\alpha = 0.05$; **Figure 9E**).

Furthermore, to compare the performance between two consecutive implants in the same animal, we performed the following statistical analyses. We counted the number of neurons recorded in each session using either a First or Second implant and compared among them with a Kruskal–Wallis test ($\alpha = 0.05$; **Figure 9B**). Also, we counted the number of days each microdrive recorded unitary activity and compared between First and Second implants with a Kruskal–Wallis test ($\alpha = 0.05$; **Figure 9C**). To control for the lower number of repetitions (implants), we modeled the number of recording days for either the First and Second implants by resampling. To achieve this, we bootstrap the data 10,000 times with replacement. Then, we calculated the confidence intervals (CI's) centered at the 95% from the resulting distributions and looked if CI's from the First and Second implants overlapped, to determine significant differences.

Multi-Channel Unit Recording

For the Wistar rats, individual neurons were recorded extracellularly using the present microdrive (with a Mill-Max connector), in freely behaving rats or while they pressed for food. Extracellular waveform signals exceeding a voltage threshold were amplified (gain × 100), digitized at 40 kHz using an OmniPlex Neural Data Acquisition system (Plexon, Dallas, TX, United States), and stored on a disk for further off-line analysis. Waveforms were recorded during 10 min periods of spontaneous activity. Single units were isolated using principal component analysis and template matching (Offline Sorter; Plexon, Dallas, TX, United States). We applied semi-automated (automated followed by manual correction) processing techniques to sort spikes from single units in clusters. Automated processing involved using a valley-seeking scan algorithm (Offline Sorter; Plexon, Dallas, TX, United States), one channel at a time, and then evaluated using sort quality metrics. For manual verification of automated clustering techniques, a cluster was considered to be generated from a single neuron if the cluster was distinct from clusters for other units in the principal component space. Also, the cluster had to exhibit a clear refractory period (>1 ms). Only stable clusters of single units during recording were considered for analysis. Timestamps of neural spiking and flags for the occurrence of bar-pressing were imported to NeuroExplorer (NEX Technologies, Littleton, MA, United States) for analysis. Long-term single-unit stability isolation was evaluated using Wavetracker (Plexon, Dallas, TX, United States) in which principal component space-cylinders were calculated from a 10 min segment of data spontaneously recorded session. Straight and overlapped cylinders or tubes suggest that the same single unit was recorded over different sessions (as in Herry et al., 2008).

For the Sprague-Dawley rats, extracellular single-unit activity from the NAcSh was recorded using a Multichannel Acquisition Processor (Plexon, Dallas, TX, United States). Specifically, voltage signals were sampled at 40 kHz and digitalized at 12-bit resolution. Single unit timestamps were extracted from the raw signal by using an online band-pass filter with a low cutoff of 154 Hz and high cutoff of 8.8 KHz. Only single neurons with action potentials having greater than 3:1 signal to noise ratio were analyzed. The action potentials were isolated online using voltage-time threshold windows and a three principal component contour template algorithm. Furthermore, for all recordings, off-line spike sorting (Plexon offline sorter) was performed, and only single units with stable waveforms across the entire session were included in the analysis (Gutierrez et al., 2010). As electrodes tips were positioned in the dorsal region of the NAcSh, we sampled neuronal responses across the dorsoventral axis by lowering down the electrodes every day. To this end, the lead screw driving the micro positioning system was turned one rotation before each experiment, pushing down the electrode bundle ∼250 μm. As the total displacement length of the reimplantable microdrive is 2.5 mm, after 10 days of recording (thus, traveling all the way down) the microdrive was replaced. For that purpose, rats were anesthetized and positioned in the stereotaxic frame. Once there, the microdrive was unscrewed and removed, leaving the baseplate fixed to the skull of the rat. A new microdrive was immediately reimplanted in the NAcSh using the same brain coordinates and screwed to the baseplate. During the following 3 days, rats had access to water in their home cages. Note that the reimplantable microdrives were lowered each day to test their capability to record single-unit activity all the way down and to replace the microdrives rapidly. However, of course, the experimenter can decide to lower and replace the microdrives, when considered necessary, depending on the intended duration of the experiment and the quality of the extracellular recordings.

Microdrive Placement and Electrode Location

To identify the location and integrity of the microdrive implant, a computed tomography (CT) was performed of the head of the rat using a Nikon CT, model XT H 225. **Figure 9B** is a representative X-ray image of the rat's head with the microdrive implant in place. Upon completion of all experiments, rats were transcardially perfused with 0.9% saline solution followed by an overdose of pentobarbital (150 mg/kg, i.p.). Brains were extracted and fixed in a 30% sucrose/10% formalin solution (Sigma-Aldrich, St. Louis, MO, United States). Electrode placements were verified by cutting coronal sections 40–50 μm thick using a cryostat (Leica, CM1520), subsequently mounted on slides and stained for Nissl bodies with cresyl violet. Only rats with electrode locations within the borders of the target structure were included in the statistical analysis.

RESULTS

Microdrive Assessment

To evaluate the implantation and reimplantation procedures of the microdrive, the time required for each procedure was measured. For the first case, the procedure consists in the surgery for attaching the baseplate by means of four screws, one of these with a silver ground wire soldered (**Figure 6A**); to place the microdrive at its final position, a customized microdrive holder was attached to the stereotaxic incisor bar; once the microdrive was on the baseplate, it was fixed by means of three fastener screws (**Figure 6B**); after this, the microdrive holder was released (**Figure 6C**); finally, the silver ground wire had to be soldered to the microdrive ground wire (**Figure 6D**).

For microdrive reimplantation, the procedure consists in releasing three fastener screws to remove the old microdrive (using the microdrive holder), cutting the ground wire in half (leaving at least 2 cm of ground wire from the ground screw attached to the skull to ground the EIB pin), cleaning the baseplate top and, after that, the procedure followed for implantation must be repeated (see **Figure 6**). We found that the average temperature on the ground screw after five soldering iterations (3 s per iteration) was 23.2°C (see **Supplementary Figure S3**). Even if soldering lasted as much as 10 s, we found that heating only reached 32°C, suggesting that heating due to re-soldering does not damage the underlying brain tissue.

The total weight of the reimplantable microdrive, including the weight of the baseplate, is about 4.08 g when the nut-screw is used, and 4.15 g if the piezoelectric motor is implemented. In both configurations, its overall dimensions are 27.73 × 15.95 × 21.50 mm. The microdrive offers a travel range of 2.5 mm, which is a reasonable distance to cover most brain regions in a rat. To assess the movable mechanism proposed in the microdrive, two different characterizations were performed. The first one was related with assessing the smoothness of the displacements for demonstrating the reliability of the micropositioning system to record neural activity to a certain depth without lateral motions of the tip of the wire. The second one was focused on assessing the position capabilities of the microdrive. For both evaluations, an optical comparator NIKON Profile Projector V-16D with an ×20 magnification was employed, which is a precise instrument suitable for measuring different shapes of workpieces with a resolution of 0.1 μm. Both evaluations were performed in manual and open-loop motorized configurations. Once the microdrive was fixed on the profile projector stage, for the manual system, the screw was rotated 22 times in half-turn increments to generate forward and backward displacements with a theoretical value of 125 μm in each event. Three experiments were performed, and the experimental displacements were plotted versus the theoretical position (see **Figure 7A**). The mean displacements for the three experiments were 123, 122.1, and 122.5 μm, respectively. While the mechanism was displaced forward and backward, it was noticed that the electrodes have minimal, if any, lateral motion, which warranties a smooth displacement. The same procedure was performed using the automated microdrive with open-loop control. To generate the control signals, the NSD-2101 piezo motor driver by Austria Microsystems was employed. The actuator works by voltage pulses. To evaluate the displacement of the automated microdrive in an open-loop control, three experiments were performed. Each experiment was composed of 64 steps, and each step was programmed with 10 pulses, duration of 1 ms, and intervals of 1 ms. For this case, **Figure 7B** shows the experimental displacement as a function of the motor steps for the three experiments, thereby obtaining an average displacements of 35.145, 33.193, and 30.919 μm, respectively. As was observed in the first experiment, lateral deviations were not present.

Long-Term Stable Neuronal Recordings in Freely Moving Rats

To assess the stability of the microdrive *in vivo*, we recorded NAcc neurons (**Figure 8**) in Wistar rats that were either in their home cage or during a behavioral task. Superimposed waveforms from two different units recorded simultaneously in the same electrode show them separated from noise. Offline sorting of two units using the voltage-time threshold, principal component time-space surface, interspike interval histogram,

Right: Histological reconstruction of the location of electrode tips in NAc of the ventral striatum. **(B)** Left top: Superimposed waveforms from two different units (green and yellow) recorded simultaneously in the same electrode and separated from noise (gray). Grid: 400 μV, 800 μs. Left bottom: Interspike interval histogram of the two units. Right: Offline sorting of two units using voltage-time threshold, principal component time-space surface (top) and 3D (bottom). **(C)** Freely behaving rats pressed a lever to obtain a food pellet, in a fixed ratio 1 reinforcement schedule. **(D)** Raster plot (top) and peri-event time histogram (bottom) for a neuron exhibiting an increase in firing rate after lever pressing (time = 0 s; the waveform of this neuron is shown in yellow in panel **B**). In the raster, a black tick indicates one action potential; the bin size was 100 ms. Arrowheads (▼) indicate the time of lever pressing (time = 0 s). **(E)** We tested the stability of recordings during spontaneous activity sessions in another freely behaving Wistar rat. Top: Waveforms of two separate neurons (yellow and green) recorded from the same single electrode for over a month (40 days). For visualization purposes, only waveforms in days 1, 3, 7, and 40 are shown. Bottom: Verification of long-term stable single-unit recordings using principal component space cylinders. A straight cylinder indicates that the same single unit was recorded in different sessions across time (days).

and 3D were used to verify they were separate units (**Figure 8B**). To validate the microdrive and evaluate its recording stability, freely behaving rats were trained in a lever-pressing task (**Figure 8C**). Spontaneous neural activity was recorded while rats were pressing a bar to obtain a food pellet. The response of one individual neuron is shown in the raster plot in **Figure 8D**. This neuron responded vigorously when pressing the lever to obtain food. This result is consistent with previous reports showing lever press response-related activity in NAcc (e.g., Morrison and Nicola, 2014). This neuron was recorded for three consecutive days (data not shown). These results indicate that the microdrive can be used for short-term (less than a week) recordings in rats performing a simple behavioral lever-press task. Further, in a different rat and to evaluate if the microdrive can be used for long-term recordings (over a month), we recorded spontaneous NAcc neuronal activity of two single neurons for 40 days. The response of these two individual neurons with a stable waveform for over 40 days is shown in **Figure 8E**. Quantitative verification of long-term stable single-unit recordings was performed using principal component space cylinders. A straight principal component space cylinder indicates that the same single unit was recorded in different sessions (days) across time. Taken together these results indicate that the microdrive is stable for short-term and, most importantly for long-term recordings in freely behaving rats. Yet, because of the limited dataset (one recording channel with two clearly isolatable units tracked for over a month), we acknowledge that implanting more rats with this microdrive would be necessary to evaluate quantitatively further the degree of long-term recording stability.

Neuronal Recordings for the First and Second Microdrive Implant

Having characterized the stability of the microdrive, we then assessed if it was feasible to re-implant it without overtly affecting the functional activity of the targeted brain region. To do this, we performed extracellular single-unit recordings in five Sprague-Dawley rats performing a sucrose licking task. In total, the activity of 262 single neurons was recorded and analyzed to test the efficacy of our reimplantable microdrive. **Figure 9** shows a representative example of two neurons recorded by the same tungsten wire. Note that the clusters of waveforms were stable and well separated in the principal component-time space, as well as in a voltage-time window (Inset) during the 1-h experiment, demonstrating once more that our microdrive can perform stable recordings in freely moving rats (in **Supplementary Figure S2** can be found the raw data of online sorting of a single recording day).

Next, we characterized the quality of the recordings in two consecutive implants, performed in the same animal. The frequency to record single neurons between the First and Second implant was not statistically different (Kruskal–Wallis, $\chi^2_{(1,9)} = 0.55$, $p = 0.45$; **Figure 9B**; 4.7 and 3.2 neurons per session, respectively). Moreover, in average the activity recorded from the Second implant lasted roughly the same number of days than the First implant (**Figure 9C**; Kruskal–Wallis, $\chi^2_{(1,9)} = 2.18$, $p = 0.14$; $n = 10$ implants), suggesting that the process of degradation of the electrode's signal was similar between both implants. To further validate this point, we resample with replacement the number of recorded days with signal. The averages of resampled data were 8.05 (CI = 1–7) and 5.33 (CI = 5–11) days with signal for the First and Second

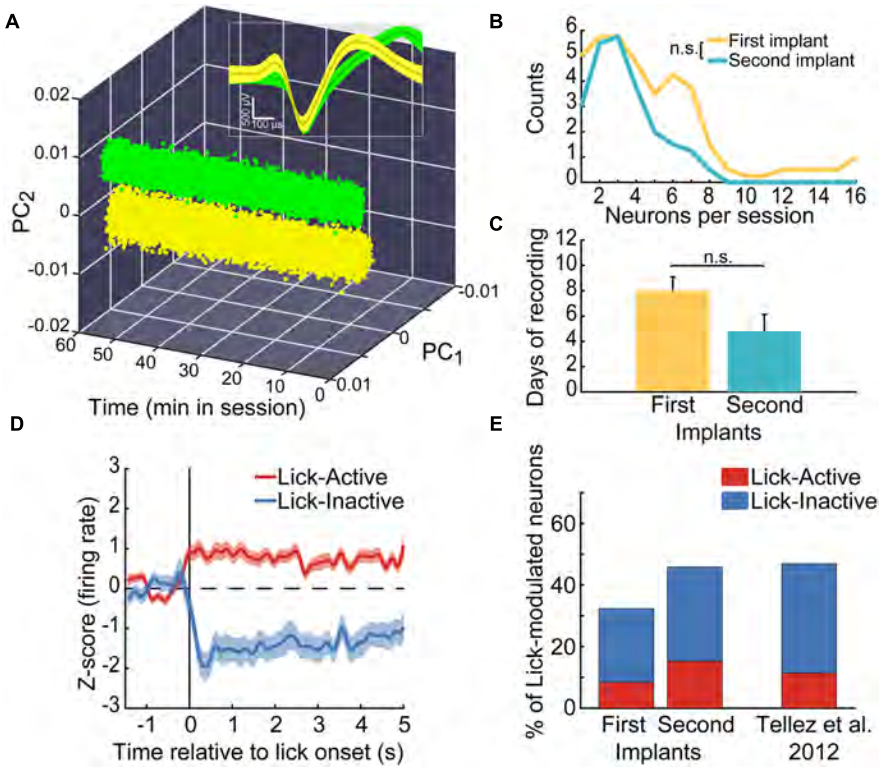

FIGURE 9 | In the same animals, we recorded a similar proportion of lick-modulated NAcSh neurons in the first and second microdrive implant. **(A)** Action potentials (dots) of two single-neurons recorded in the same channel (yellow and green, respectively) within a 1 h freely licking behavioral session. Values are plotted in a three-dimensional space built with the first two principal components (PCs) of the voltage signals vs. time. Inset: Depicts the time-voltage window showing the mean ± SEM of action potential waveforms. These neurons were recorded from the "first" implant. **(B)** Histogram depicting the number of single neurons recorded in the first and second implant across sessions. **(C)** Number of daily sessions where single-unit activity was recorded in the first and second implant. **(D)** The population activity (normalized to z-score) of neurons that were either Lick-Active (red) or Lick-Inactive (blue) around the initiation of licking (vertical line at time = 0 s). The baseline level of neuronal activity (z-score = 0) is indicated by a horizontal dashed line and was taken from –1.5 to –0.5 s relative to the lick onset. **(E)** Histograms of the percentage of Lick-Active and Lick-Inactive neurons found in the NAcSh using the first and the second implant of the microdrive and the proportion of the lick modulated neurons reported in a study published elsewhere (Tellez et al., 2012). The proportions of neurons were not statistically different relative to data from Tellez et al. (2012) (chi-square test; Lick-Active neurons of the first and second implants vs. Tellez, $\chi^2 = 0.004$, and $\chi^2 = 0.005$, respectively; Lick-Inactive of the first and second implants vs. Tellez, $\chi^2 = 0.017$ and $\chi^2 = 0.003$, respectively; all p's > 0.05).

implants, respectively. Since confidence intervals did overlap, then it indicates no statistical difference, at a 95% confidence, exists between the First and Second re-implant. Nevertheless, we do acknowledge that in our second implant, we could not record more than eight simultaneous neurons in a single session (**Figure 9B**), further studies should confirm this trend. These data suggest that good-quality recordings can be obtained from a second implant in the same rat. Also, these results demonstrate that recordings in freely moving animals can be extended for at least one more implant (perhaps more), but this remains to be tested.

To further characterize if there is any reliable advantage in the yield of neurons recorded with our microdrive, we compared the yield obtained with our reimplantable microdrive against a permanently implanted movable electrode from our previously published study (Tellez et al., 2012) (see **Table 1**). In average, in the First implant, we recorded 36.8 neurons per animal, whereas with a permanently implanted electrode 38.3 (Mann–Whitney Rank p = n.s.), producing a yield of 4.7 vs. 5.7 neurons/session, respectively (p = n.s.). Thus, our microdrive results in a similar yield than other tungsten electrodes, at least, in the First implant. As noted above, the advantage of our drive mainly resides on the ability to be reimplanted (and to be reused). As can be appreciated in **Table 1**, we recorded, from the same rats, in average 16.2 new neurons in the Second implant (see **Table 1**; Second implant). Nevertheless, we acknowledge that not in all subjects the Second implant recorded more neurons than the First implant (see for example rat R02). Nonetheless, it is important to note that we also found cases (such as in subject R01) where the Second implant improved the yield of neurons, demonstrating the advantage of using our microdrive.

After demonstrating the recording capabilities of our microdrive, we evaluated whether the two consecutive implants lead to recording the same type of functional ensembles in the NAcSh. A considerable amount of evidence has consistently shown the existence of a small proportion of Lick-Active and a larger population of Lick-Inactive neurons in the NAcSh (Roitman et al., 2005; Krause et al., 2010; Tellez et al.,

INFORME DE LABORES 2019

2012; Villavicencio et al., 2018), suggesting that these neuronal populations reflect the functional organization of the NAcSh. Thus, to address this issue, we first identified NAcSh neurons that were modulated during consummatory licking behavior. **Figure 9D** shows the populational activity of all NAcSh neurons that either increased their activity during licking (see red line) or suppressed it (blue line). Thus, the proportions of Lick-Active and Lick-Inactive neurons using our reimplantable microdrive was compared against the proportions reported in our previously published study (Tellez et al., 2012) (**Figure 9E**). For this analysis, the licking-modulated neurons from both, the brief-access taste test and the free-licking task, were pooled. No statistical differences were found in the percentage of active or inactive licking-modulated populations for the first or second implant in comparison with the data reported by Tellez et al. (2012) (chi-square test; all p's > 0.05, $n = 87$ Lick modulated neurons from our microdrive vs. $n = 124$ from Tellez et al., 2012). This result suggests that the reimplanted microdrive can record the same functional ensembles as other standard electrodes without affecting the functional activity of the NAcSh. Altogether, the data obtained indicate that the microdrive is suitable for *in vivo* recordings involving simultaneous behavioral testing and, more importantly, that it can extend recordings for an extra period, without affecting neither their quality nor the functionality of the brain region targeted.

DISCUSSION

A novel microdrive design is presented here. This microdrive met the low cost, small size, and lightweight criteria, which are ideal features for experiments involving freely moving rodents. The assembly and implantation, as well as the re-implantations, resulted easy and quick. Also, the design presented here incorporates a mechanism based on two concentric cylinders that produce smooth displacements in both the manual and automated versions. Most important, it was demonstrated that the micropositioning system could reliably advance the electrode bundle in the space without lateral motions artifacts. One of the innovative aspects of the device is that is it potentially reusable. We have indeed been reusing parts from our microdrive by cleaning, re-plating and sterilizing the device (or by simply replacing the tungsten wires). This suggests that our microdrive allows for users to potentially re-use microdrives across animals, greatly decreasing cost and time of experiments. As a proof of concept, single unit recordings using the microdrives were tested in rats performing behavioral tasks or during spontaneous activity. We found a high-quality neuronal signal that was comparable between a first standard implant and a re-implant in the same subjects. Also, it was demonstrated that such a signal could last over a month. Thus, the microdrive design proposed here is an original and useful device to facilitate the collection of neuronal activity datasets, especially for experiments where time, training, and resources employed are critical.

Micropositioning System

The microdrive presented incorporates a mechanism based on two concentric cylinders that produce smooth displacements; the mechanism is coupled to the lead screw by pressure, avoiding any backlash and system misaligning, which are the main drawbacks in mechanisms based on leadscrew and cannula guides (e.g., Fee and Leonardo, 2001; Venkateswaran et al., 2005; Otchy and Ölveczky, 2012; Jovalekic et al., 2017), in which the electrodes can be subject to mechanical drift and in consequence the loss of signal. The microdrive proposed exhibited good stability over several recording days. Another advantage of the microdrive presented is the possibility to choose between a manual or automated actuation. The use of the piezoelectric motor SQL-RV-1.8 allows replacing it with a nut and a screw with the same geometrical characteristics decreasing the microdrive's cost. The mechanical characterization demonstrated that there were not lateral displacements along the displacement stroke. Related to the displacement characterization, for the manual configuration, a resolution of about 125 μm per half turn was obtained; but if the user requires a lower displacement, he/she only needs to decrease the rotation of the screw; for example, a quarter of a turn represents a displacement of about 60 μm. For the automatic configuration (open-loop control), it was observed that there was no similarity in the three experiments. Such a behavior is related to the actuator and the mechanism employed: ultrasonic PZT actuators usually do not have a constant behavior because their principle work is based on friction; on the other hand, the spring employed in the mechanism produces a non-constant preload force to the motor, which changes depending on the position in the microdrive stroke. Despite this drawback, using close control loop can improve the precision of the displacement, as demonstrated in Caballero-Ruiz et al. (2014), where a resolution of 1.3 μm with an average error of 2.2 μm was obtained with

the prototype of the presented mechanism, making it a high-performance system.

Manufacturing

The use of additive manufacturing technologies helps us to generate a microdrive housing with internal conduits to protect the microelectrodes form possible damages caused by the natural behavior of the animal; this is an important issue in extracellular recording experiments with rodents. Also, we incorporated a baseplate and a holder that permits the easy installation of the microdrive and the possibility of reimplanting a new one in case of loss of signal. This represents an advantage when trained animals are used for the experiment. The microdrive presented can displace a bundle of 16 microelectrodes, which makes it impossible to determine the specific location of each of them, individually. It is necessary to work on a proposal that allows moving a microelectrode array with a specific distance between the electrodes to avoid the possible crosstalk phenomena and to know the specific location of each electrode. The recording experiments were performed in the NAc of the ventral striatum, but the design can be easily modified to target other brain regions. The additive manufactured baseplate allows for a flexible recording location, located between AP ± 3.5 mm and ML ± 2.5 mm; with some minimal modifications in the 3D model, it is possible to achieve more distant regions; however, not for all brain regions, for example, this design cannot offer recordings in very lateral areas such as in the posterior insular cortex (ICp); therefore, designing a universal baseplate that can be used on any region of the brain can be considered. The final weight and dimensions of the proposed microdrive are appropriate for extracellular recording in rats. For smaller rodent species, such as mice, it will be necessary to miniaturize its components and redesign the baseplate and the microdrive. Another caveat of our microdrive is that all electrodes are moved in a bundle rather than an independent placement of each electrode individually. Nevertheless, this limitation allows us to reduced device weight and, for a future version, it could save space to introduce a second driver to record two simultaneous brain regions.

Gold Plating of Electrodes

Sixteen tungsten wires with 35 μm in diameter were gold-plated in order to reduce the impedance to 70 kΩ. However, the user can flexibly choose electrodes with other diameters and materials. It has been demonstrated that tungsten is a good choice of material for chronic implants since it is a stable and inert metal (Freire et al., 2011), and it has been successfully used in single unit recordings (Gutierrez et al., 2010). This diameter is stiff enough to maintain stability and rigidity at lengths <7 mm. We note that larger diameters >50 μm are not optimal for isolating single unit activity. Furthermore, in Patrick et al. (2011), it was demonstrated gold-plated in tungsten electrodes. Additionally, Prasad et al. (2014) reported that with tungsten electrodes, the best yield is for the impedance range 40–150 kΩ. Further studies should analyze different materials and diameters in order to characterize the best option of electrodes and impedance range.

Datasets Collection

The main advantage of using the microdrive is, of course, reducing the number of experimental subjects, which is a fundamental ethical issue as expressed by Institutional Animal Care and Use Committees (Fitts, 2011). We believe that our microdrive will be especially valuable for preparations for which extensive behavioral training is needed (Erlich et al., 2011; Jaramillo and Zador, 2014; Liu et al., 2014; Fonseca et al., 2018); or in animal models for chronic diseases that take months to develop, such as diet-induced obesity (Benedikz et al., 2009; Avena, 2012). We expect our reimplantable microdrive to become a critical implementation for extracellular recordings that facilitate the collection of larger neuronal activity databases over long periods.

In sum, here we presented the design of a novel microdrive that resulted in stable recordings over days to a month, and more important, when necessary it could be reimplanted, in the same animal, with the intent to extend the half-life of extracellular recordings. Altogether, the structural and functional features of the present microdrive make it ideal to further study the neuronal correlates of behaviors, in health and disease, from perception to decision making that requires stable recordings across several weeks and give the opportunity to reuse it and reimplant it if there is an error during surgery.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

LR-H, FS-B, RG, and AC-R designed the research. LP-C, LR-L, MV, MM, and EI-H performed the research. AC-R, LR-H, RG, and FS-B analyzed the data. LR-H, MV, FS-B, RG, LP-C, and AC-R wrote the manuscript.

FUNDING

This work was supported by grants CONACyT LN280867 and DGAPA PE-106417 (given to LR-H); CONACyT CB176639 and APN 2463, DGAPA IN205417, and the International Brain Research Organization, Return Home fellowship (given to FS-B). The project was also supported by Productos Medix (3247), Fundación Miguel Aleman, and CONACyT: grants FOINS 63 and APN 464 (given to RG).

ACKNOWLEDGMENTS

The authors would like to thank Fabiola Hernandez-Olvera for her invaluable assistance with animal care; Gerardo Ruiz Botello for the assistance during the positioning characterization process; and Nora E. Reyes-Rocafuerte for proofreading.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fnins.2019.00128/full#supplementary-material

FIGURE S1 | Distance from baseplate to end of electrode bundle (7 mm). **(A)** Length of electrodes without the baseplate. **(B)** Same as in **(A)** but with the baseplate in place.

FIGURE S2 | Single-unit activity recorded from the reimplantable microdrive. Screenshot of the acquisition system's user interface software showing single-unit activity recorded during an ongoing experiment (online sorting). At the right, it is seen different time-voltage windows corresponding to different channels from where single-unit activity was recorded. Yellow and green traces distinguish different neuronal signals recorded in a single channel. At left side of the screenshot, it is shown an expansion of the channel "4" seen at the left (see window framed by a magenta rectangle).

FIGURE S3 | Soldering process and temperature measurement. **(A)** Temperature measured with an infrared thermometer before soldering. **(B)** The ground wires have been joined. **(C)** The ground wires have been soldered and an average temperature of 23.2°C has been obtained.

TABLE S1 | NanoZ stepped protocol used to perform the electroplating in the electrodes. This protocol was applied to each channel. The interval is the time between bi-phasic pulses within a run. Runs are the maximum number of attempts per step to reach a target impedance. n/a, not applicable.

TABLE S2 | Costs for microdrive parts. For the automated microdrive, the total cost of the parts is 280,2 USD, while for the manual configuration is 155,2 USD. Both estimations were made considering the cost of the electronic interface board (101.65 USD), which is reusable. Without the cost of the electronic interface board, the total cost of each microdrive is 53,55 USD.

DATA SHEET S1 | STL files and G code for manufacturing the parts of the microdrive.

ABSTRACT

Prolactin (PRL) is a pleiotropic hormone secreted by several cells and tissues in the body, such as mammary glands, T-lymphocytes, hypothalamus, among others. This hormone possess neuroprotective properties against glutamate-excitotoxicity through the activation of NF-kB, suggesting it could exert an antioxidant action. However, the role of PRL on the antioxidant defense during glutamate-induced excitotoxicity is not clear to date. Therefore, in the present study, we have evaluated the effect of PRL on SOD activity and protein content of both of its isoforms (Mn^{2+}-SOD and Cu^{2+}/Zn^{2+}-SOD), as well as, its action on mitochondrial activity in primary culture of hippocampal neurons of rats. Additionally, we have evaluated the possible antioxidant effect of PRL through the determination of lipid peroxidation products (LPO), measured as malondialdehyde (MDA). Results show that PRL enhances the activity and the protein content of Mn^{2+}-SOD and Cu^{2+}/Zn^{2+}-SOD in neurons exposed to glutamate-induced excitotoxicity. Moreover, our results demonstrate that PRL prevents mitochondrial dysfunction induced by glutamate and significantly decreases the levels of LPO products. To our knowledge, this is the first time that a potential antioxidant effect of PRL has been described in hippocampal neurons exposed to glutamate excitotoxicity, opening questions of its potentiality for therapeutics.

1. Introduction

Glutamate (Glu) is the primary excitatory neurotransmitter in the brain [1]; under physiological conditions, astrocytes maintain Glu concentration in the extra-synaptic space in a low concentration (≈1 μM) preventing excitotoxicity [2]. However, in some neurodegenerative disorders astrocyte function is compromised leading to Glu-induced excitotoxicity [3]. One of the main characteristics of this condition is the overstimulation of the glutamate receptors which leads to the intracellular calcium ($[Ca^{2+}]i$) overload and concomitantly the mitochondrial dysfunction. High intracellular concentrations of Ca^{2+} induce the opening of the mitochondrial permeability transition pore, which impairs the energy balance and enhances reactive oxygen species production (ROS). As a result, the release of pro-apoptotic factors to the cytoplasm, such as cytochrome c is favored, leading to apoptosis.

Moreover, oxidative stress recognized as the dominant player in the pathology of several neurological disorders, such as Parkinson's, Alzheimer's, stroke and ischemia; and has been extensively described as the major contributor to neuronal death, since ROS damage organelles and macromolecules, such as proteins, nucleic acids and lipids [4]. Mainly, lipid peroxidation resulting from the attack by free radicals on fatty acids in membranes promotes an increase in lipid peroxidation

products (LPO), such as malondialdehyde (MDA) [5]. LPO products interfered with the mitochondrial electron transport chain leading to the loss of the mitochondrial membrane potential (ΔΨm) and enhanced ROS as superoxide anion and hydrogen peroxide [6]. Although, neurons possess robust antioxidant defences, such as peroxiredoxin V, Cu^{2+}/Zn^{2+}-SOD (SOD1), Mn^{2+}-SOD (SOD2), glutathione peroxidase and catalase (in low amount), during neurodegeneration: the function of antioxidant defences is compromised [7].

On the other hand, prolactin (PRL) a peptidic hormone biosynthesised by the pituitary and by other extrapituitary tissues [8,9], has been described to exert more than 300 biological functions, including neuroprotection against Glu and kainic acid-induced excitotoxicity both *in vivo* and *in vitro* models [10–14]. Recently, our group reported, that PRL neuroprotection against Glu-induced excitotoxicity is mediated by $[Ca^{2+}]$i modulation and by NF-κB activation [11]. NF-κB plays several roles in cognition, inflammation, cell survival and cell death. Particularly in cell survival, NF-κB promotes the transcription of anti-apoptotic genes, such as *bcl-2* and inhibitor of apoptosis proteins (IAPs), in several models of excitotoxicity. Additionally, NF-κB activation induces the expression of both SOD isoforms in neurons [15]. However, few studies have investigated the antioxidant actions of PRL.

In this context, Melendez-García et al. suggested that PRL promotes cell survival in retinal pigment epithelium cells *via* anti-apoptotic and antioxidant actions, the latter associated to the inhibition of the oxidant-induced sirtuin 2-dependent activation of TRPM2 channels [16]. Nevertheless, in hippocampal neurons, the antioxidant action of PRL against excitotoxicity is not clear to date. Here, we evaluate whether PRL prevents apoptotic cell death *via* the stimulation of SOD antioxidant defence. Our results demonstrate that PRL treatment prevents apoptosis and mitochondrial dysfunction in primary cultures of hippocampal neurons through the increase in the protein content of both isoforms of SOD (SOD1 and SOD2) and the SOD activity, even during glutamate exposure. Interestingly, this results correlates with a decrease in LPO produced during Glu-induced excitotoxicity.

2. Materials and methods

2.1. Cell culture

Primary cultures of hippocampal neurons were obtained from Wistar rat embryos from 17 to 18 days of gestation as described by [11]. Briefly, neurons were suspended in Neurobasal medium supplemented with B-27 minus antioxidants (1%, Gibco, NY, USA), gentamicin (20 μg/mL, Gibco, NY, USA) and L-glutamine (0.5 mM, Sigma-Aldrich, Missouri, USA). For protein isolation, TBARS determination and SOD activity assay, neurons were cultured at a density of 3×10^5 cell/cm^2 in 35 mm cell culture plates (Costar, NY, USA), previously precoated with Poly-L-lysine (5 μg/10 mL, Sigma-Aldrich, Missouri, USA). For TUNEL and mitochondrial activity assays, cells were cultured in 12-well plate (Costar, NY, USA) on rounded coverslips (18 mm diameter) at a density of 185×10^3 cells/cm^2. Neurons were cultured in standard culture conditions (37 °C in a humidified 5% CO_2/ 95% O_2 air atmosphere) for ten days. At the 4 DIV, neurons were treated with cytosine arabinoside (0.8 μM, Sigma-Aldrich, Costar, NY, USA).

2.2. Cell treatment

At 8 DIV, all neurons received a partial replacement of Neurobasal medium and some cultures were treated with PRL (10 ng/mL solubilised in sterile saline solution during 72 h, Sigma-Aldrich, Missouri, USA) or with sterile saline solution alone. At 10 DIV, pre-treated neurons with PRL were exposed to Glu (100 μM) for 24 h while other culture wells were exposed to Glu alone to induce excitotoxicity as described by [11,12]. All experiments were carried out at the 11 DIV.

2.3. TUNEL assay

After treatments (11 DIV), primary cultures platted in rounded coverslips were washed with PBS and fixed with PFA (4% during 10 min) at RT. TUNEL assay (*in situ* cell death detection kit TMR Red, ROCHE, Basel, Switzerland) was performed according to the supplier´s instructions to. We counterstained nuclei with Hoechst (0.005%) and consider TUNEL-positive neurons those with condensed or fragmented nuclei, as reported by Mandelkow et al. [17]. Samples were observed under an epifluorescence microscope (Nikon H550S) using a UV-2A DM400 filter for Hoechst and Rhodamine filter for TUNEL. Images from five different fields, containing about 20–30 cells in three independent experiments, were analysed by ImageJ. Data are expressed as percent of TUNEL-positive neurons relative to the total number of nuclei labelled with Hoechst, as reported by García de la Cadena et al. [18].

2.4. Mitochondrial activity determination

Mitochondrial activity was measured with the JC-1 fluorescent marker. JC-1 is a mitochondrial transmembrane potential (ΔΨm) sensor, which emits fluorescence at 590 nm (red) when mitochondrion are polarised (active), and at 530 nm (green) when mitochondrion are depolarised (dysfunctional). Neurons cultured on coverslips and exposed to the different treatments were incubated with JC-1 (100 nM during 30 min covered from light at standard culture conditions, Thermo-Fisher Scientific, Massachusetts, USA). As a positive control of mitochondrial dysfunction, 1 μM of carbonyl cyanide-p-trifluoromethoxy phenylhydrazone (FCCP, Sigma-Aldrich, Missouri, USA) was incubated for 5 min. Afterwards, coverslips were transferred to a chamber with Lockey´s buffer at 37 °C and observed under a confocal microscope (Leica TCS-SP5) using the argon laser, at Unidad de Imagenología del Instituto de Fisiología Celular, UNAM. Images were analysed according to Lijima et al. [19], calculating the 530/590 nm ratio in the soma region.

2.5. Western blotting

Protein isolation, quantification, and Western blot assays were performed as described in [11]. Briefly, neurons cultured in 35 mm plates were washed with cold PBS and lysed with RIPA buffer supplemented with 5 mM of a protease inhibitor cocktail (mini-Complete, ROCHE, Basel, Switzerland). Protein quantification was determined with the DC protein assay kit (Bio-Rad, CA, USA), following the manufacturer's protocol and 40 μg of protein from each condition were loaded onto 12.5% SDS-PAGE and subsequently transferred to PVDF membranes (Millipore, Massachusetts, USA). Membranes were incubated with anti-SOD1 (1:100, cat. sc-11407), anti-SOD2 (1:200, sc-30080) or β-actin (1:10000, cat. sc-1615) overnight at 4 °C. Hybridised membranes were incubated with the corresponding secondary antibodies conjugated with horseradish peroxidase: anti-rabbit (1:7000, cat. 2301) or anti-goat (1:10000, cat. 2033) (Santa Cruz Biotechnology, CA, USA). The signal from each antibody was detected by chemiluminescence using the Immobilon Western Chemiluminescent HRP substrate (Millipore, Massachusetts, USA) with a blot-scanner (LI − COR, NE, USA). Densitometry analysis was performed with Image Studio 3.1. SOD1 and SOD2 content were normalised against β-actin.

2.6. SOD activity assay

SOD activity was quantified with the SOD determination kit Assay (Sigma-Aldrich, Missouri, USA) following the supplier´s instructions, based on the McCord and Fridovich´s principle. Neurons cultivated in 35 mm plates were washed with cold PBS and homogenised in lysis buffer. After centrifugation (14,000 *g* X 10 min at 4 °C), the supernatant from each condition was used for measuring SOD activity. Data represent the percentage of SOD activity.

2.7. Lipid peroxidation products determination

Lipid peroxidation (LPO) products were measured by the thiobarbituric acid reactive substances (TBARS) as described by [20]. Neurons were washed with cold PBS and subsequently homogenised in lysis buffer containing: Tris − HCl (25 mM, pH 7.5), SDS (1%), EDTA (1 mM, pH 8), mini-complete protease inhibitor and PMSF (5 mM, Sigma-Aldrich, Missouri, USA). Homogenates were centrifuged at 10,000 *g* X 10 min at 4 °C and protein content were determined by Lowry´s method. 100 µg of protein from each sample was mixed with BHT (4%, Sigma-Aldrich, Missouri, USA) and PBS at 100 °C during 30 min. Afterwards, each sample was incubated with thiobarbituric acid (0.8 M, Sigma-Aldrich, Missouri, USA) during 1 h at 100 °C. Samples were transferred to an ice bath, in order to stop the reaction, and then they were rapidly mixed with KCl (5%) and n-butanol. Finally, samples were centrifuged (400 *g* X 5 min at RT) and the aqueous phase as isolated to a measure absorbance at 532 nm.

2.8. Statistics

All data were analysed by GraphPad Prism® software by one-way ANOVA followed by a Bonferroni´s *post hoc* test. Values are expressed as the mean ± S.E.M. of 3–5 independent experiments. Significant differences were considered when $p < 0.05$ or $p < 0.01$.

3. Results

3.1. Prolactin prevents glu-induced excitotoxicity in hippocampal neurons

It has been reported that PRL induces neuroprotection against Glu-induced excitotoxicity in primary cultures of hippocampal neurons [11–14]. As a control for following experiments, we performed TUNEL assay in primary cultures of hippocampal neurons. Results depicted in Fig. 1S (supplementary material), show that PRL treatment does not alter the percentage of TUNEL positive neurons with condensed nuclei, in comparison with the control (Ctrl) group. However, in the PRL/Glu group, PRL reduces 50% of the TUNEL positive cells as compared with those exposed only Glu (Fig. 1S A and B, panel g–i and j–l), meaning that PRL induces neuroprotection against Glu-induces excitotoxicity as reported previously.

3.2. Prolactin-induced neuroprotection is associated with the preservation of the mitochondrial activity

Glu-induced excitotoxicity alters the intracellular calcium homeostasis leading to mitochondrial damage affecting the electron transport chain and the OxPhos [21,22]. Once we reproduce the neuroprotective effect of PRL against Glu-induced excitotoxicity, we aim to evaluate whether PRL treatment prevents the mitochondrial dysfunction during excitotoxicity. Since the ratio between 530 nm and 590 nm is more than 1 after Glu exposure (Fig. 1B), data suggest that Glu treatment collapses the mitochondrial potential in a similar proportion as showed in the neurons stimulated with FCCP (Fig. 1 A; panel k and n), as expected. On the other hand, neurons pretreated to PRL and then insulted with Glu, showed a ratio similar to the vehicle-treated neurons, indicating that PRL preserves the mitochondrial function during excitotoxicity. Additionally, we evaluated if PRL induces *per se* alterations in mitochondrial function and interestingly, our data showed a significant increase in the red fluorescence, which results in a significant decrease in the 530/ 590 nm ratio (Fig. 1 A; panel e, and Fig. 1. B), suggesting that PRL sustains mitochondrial membrane potential.

3.3. Prolactin enhances total SOD activity and both isoforms of protein content

As mention above, PRL induces NF-κB p65 activation in hippocampal neurons, and several studies report that this activation induces the expression of several proteins involved in neuroprotection, survival and the antioxidant defense. In this context, we evaluated whether PRL affects the protein content and the total activity of both isoforms of SOD in primary cultures of hippocampal neurons. Our results showed that PRL treatment during 72 h increases the protein content of both, SOD-1 and SOD-2 significantly, in contrast with the vehicle. Interestingly, this effect is also observed in the PRL/Glu group in comparison with the neurons that were only treated with Glu, which show a significant decrease in both isoforms, as expected (Fig. 2 A and B). Additionally, we evaluate whether PRL modifies the total SOD activity since the protein content evaluated by Western blot does not reveal their activity. As seen in Fig. 2C, PRL treatment doubles the total SOD activity, from 20% to 40%, as compared with the control and maintain this effect even in the neurons from the PRL/Glu condition (30%). While neurons treated only with Glu decreases to 10%, the total SOD activity compares with the PRL/Glu group.

3.4. Total SOD activity and protein content increase correlate with a low concentration of LPO products

LPO products increase significantly during Glu-induced excitotoxicity as result from mitochondrial dysfunction [23–25]. Since we observed that PRL maintains the mitochondrial membrane potential and increases the activity and the protein content of SOD, we quantified the LPO products concentration in hippocampal neurons treated with PRL or Glu alone or as a mixture (PRL/Glu), in order to determine indirectly the effect of PRL on lipid oxidation induced by ROS during excitotoxicity. As depicted in Fig. 3, LPO products concentration increase significantly in neurons treated only with Glu alone (100 µM). However, PRL pretreatment prevented this effect in PRL/Glu group, as the LPO products concentration decrease to 2µM/ µg of protein. Regarding the PRL-treated group, the LPO products concentration remained close to control values (Fig. 3).

4. Discussión

Excitotoxicity is implicated in neuronal death during ischemia, stroke and neurodegenerative disorders, among other neuropathological conditions [26]. This process caused by a rise in the extracellular Glu concentration is characterized by the impairment of mitochondrial activity and a significant increase in ROS production, mainly. Besides, excitotoxicity is accompanied by the decline in the antioxidant defences, such as catalase, glutathione peroxidase and SOD, among others [7,27]. Previously, we reported that PRL-induced neuroprotection against excitotoxicity is mediated by NF-κB activation [11]. Hence, in the present study, we have evaluated whether PRL mediates neuroprotection *via* the induction of the antioxidant enzymes SOD1 and SOD2.

First, we evaluated whether PRL prevents the cell death induced by Glu, in order to confirm the neuroprotective effect displayed by PRL previously reported by our group [11,12]. Our results demonstrate that PRL significantly decreases the percentage of TUNEL-positive neurons, which correspond mainly to apoptotic cells. Interestingly, other groups have also described that human PRL (hPRL) increases cell survival and decreases the number of apoptotic cells in human retinal pigment epithelial cells (ARPE-19) exposed to H_2O_2 [16].

Once we confirm that PRL decrease the percentage of TUNEL-positive cell, we demonstrated for the first time that PRL-induced neuroprotection is associated with the enhanced activity and a significant increase in the content of both SOD isoforms. These data are following those in rat luteinized granulosa cells exposed to PRL treatment (1 ng/mL for four days), in which both, the protein content and the mRNA of SOD1 and SOD2 increases significantly [28]. Moreover, in another study in pancreatic β-islets exposed to PRL (1 µg/mL for 24 h), it has been reported that PRL increases 8-times SOD1 mRNA, probably

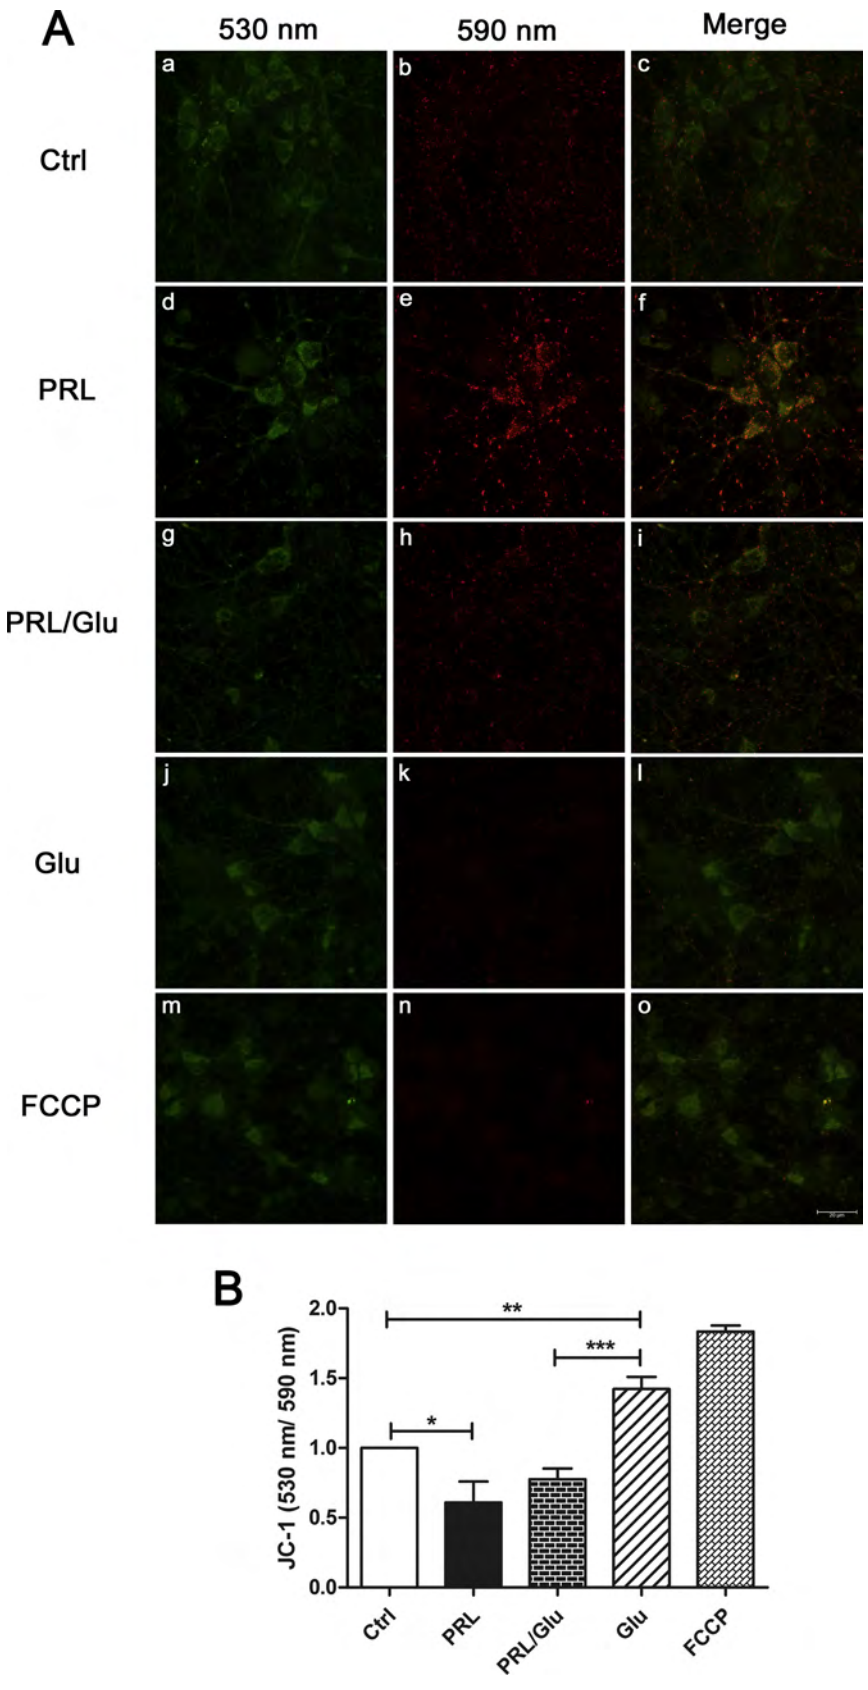

Fig. 1. Prolactin-induced neuroprotection is associated to the preservation of the mitochondrial activity. (**A**) Representative images from the hippocampal neurons stained with the JC-1 dye, treated with Control (saline solution); PRL (10 ng/mL); PRL/Glu (10 ng/mL and 100 μM, respectively), Glu (100 μM) and FCCP (1 μM for 5 min). (**B**) JC-1 ratio between both wavelengths (530 nm/590 nm), depolarized neurons show increased green fluorescence while neurons with active mitochondria increases the red fluorescence resulting in a decreased JC-1 ratio. Bars represent the mean ± SD of the JC-1 ratio from four independent experiments. Data were analyzed by one-way ANOVA followed by a Bonferroni´s post hoc test ** $p < 0.01$ PRL/Glu *vs.* Glu and Ctrl *vs.* Glu. Scale bar: 20 μm.

through the MAPK and STAT-3 activation [29]. However, contrary to these observations, another study showed that PRL induce antioxidant effects in retinal epithelium cells by SOD-independent mechanisms [16], suggesting that further experiments are required to investigate the effects of PRL on other antioxidant defense systems in hippocampal neurons.

Our results also demonstrate that PRL enhances total SOD activity, while Glu significantly decrease it, as compared with control values.

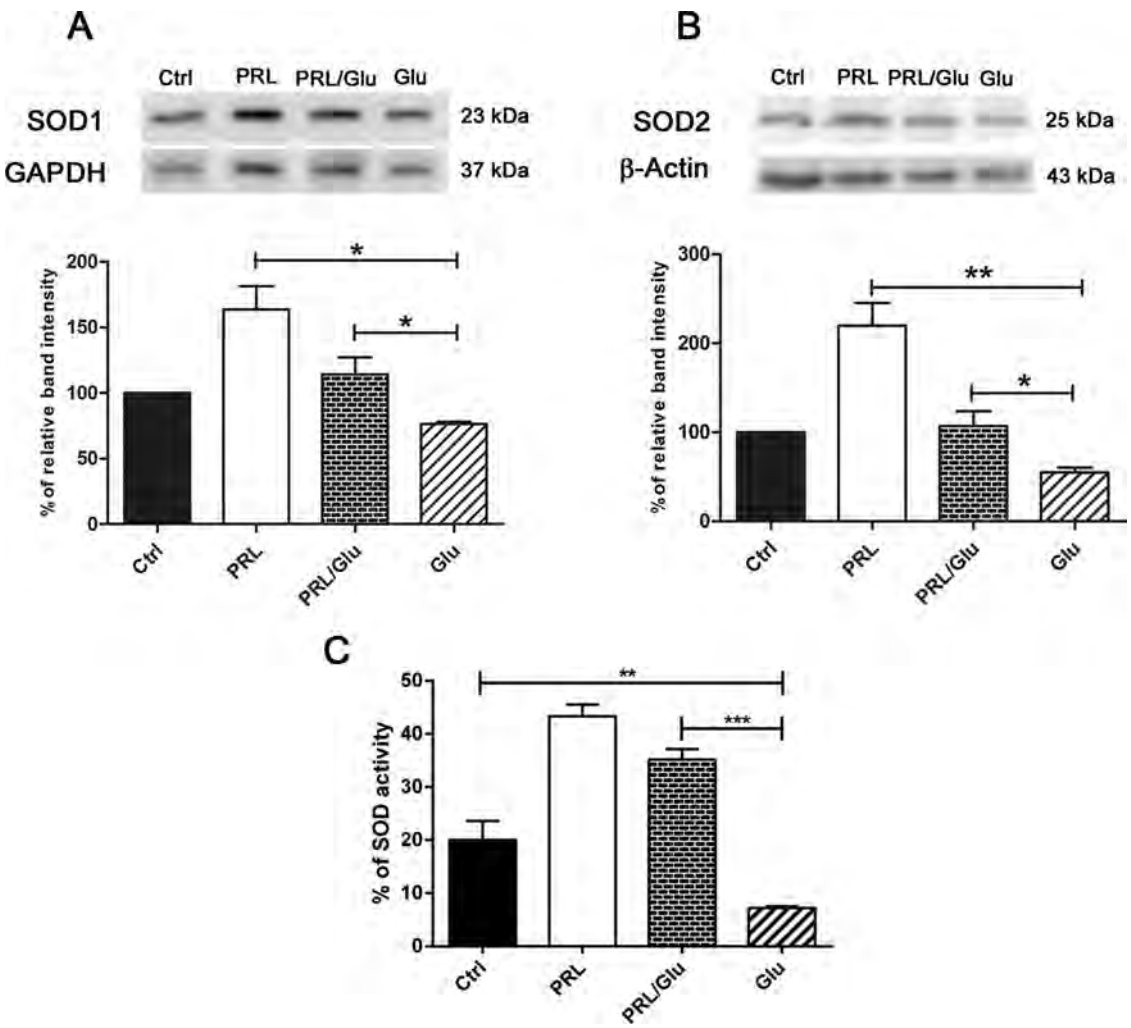

Fig. 2. Prolactin enhances SOD activity and protein content. (**A-B**) Representative western blots from both SOD isoforms. Densitometry analyses represent the relative ratio SOD1 or SOD2 normalized against GADPH or β-Actin, respectively. (**C**) Percentage of SOD activity in hippocampal neurons treated with PRL (10 ng/mL), PRL/Glu (10 ng/mL and 100 μM, respectively) and Glu alone. Bars represent the mean ± SD of five independent experiments. Data were analyzed by one-way ANOVA followed by a Bonferroni´s post hoc test *p < 0.05 PRL vs Glu; ** p < 0.01 PRL *vs.* Glu and Ctrl *vs.* Glu, *** p < 0.001 PRL/Glu *vs.* Glu.

These are in accordance with the literature. For instance, Bolzán et al. demonstrated that PRL positively regulates the SOD activity in liver and thymus in 29-month-old Sprague-Dawley female rats in a dose-dependent manner [30]; and Sun et al. reported that Glu-induced excitotoxicity impairs SOD activity in human neuroblastoma SH-SY5Y cells 24 h after Glu treatment [31]. Interestingly, our results demonstrate for the first time that enhanced PRL-induced SOD activity also occurs during Glu exposure, suggesting the increase in this antioxidant system even during the excitotoxic insult. This correlates with the increased protein content of SOD1 and SOD2, suggesting that PRL can augment both the constitutively expressed SOD1 [32] and the PI3K/Akt pathway-dependent SOD2 [15,33]. We hypothesize that PI3K/Akt pathway might induces SOD 2 expression, since PRL is able to activate this pathway through PRL receptor (PRLR) and hippocampal neurons express the long and short isoforms [12]. In fact, the PI3K/Akt pathway activation induced by PRL is under study in our group. The significant increase of both activity and protein content of SOD-1 and SOD-2 is probably *via* NF-kB activation; however, to address this effect to this transcriptional factor we are currently performing experiments with selective inhibitors of this pathway such as SN-50, PDTC.

Other interesting findings from this study is the effect of PRL on LPO products and the ΔΨm. We report for the first time that PRL prevents the increase in LPO and mitochondrial depolarisation induced by GLU, suggesting the preservation of mitochondrial function. PRL effects in the hippocampus have been poor studied only a few studies have focused on its antioxidant effects and none on the direct effect of PRL on lipid peroxidation, or mitochondrial function. However, a large number of studies are available regarding the antioxidant effect of growth hormone (GH), a protein hormone that belongs to the same protein family protein as PRL that exhibits antioxidant effects in several models. For instance, the human growth hormone (rhGH) prevents mitochondrial dysfunction and excitotoxicity, through the down-regulation of the mRNA of the NMDA receptor subunits GluN1, GluN2a and GluN2b [34]. Based on this finding we suggest that PRL could also modulate the expression and activity of the NMDA receptor complex, leading to a decrease in the intracellular Ca^{2+} overload and the concomitant preservation of the mitochondrial function. Actually, our group is on the effect of PRL on the expression, function and Glu binding affinity to AMPA, NMDA and KA ionotropic Glu receptors.

The mechanism underlying the decrease in LPO concentration by PRL is still not precise. In contrast, the effect of GH in the LPO products has been widely explored. It is known that patients with severe GH deficiency exhibit a high LPO serum concentration [35]. Likewise, GH decreases LPO products levels in the liver, heart, kidney and spleen of ovariectomized aged female rats, through the restoration of reduced glutathione and the increase in the reduced/ oxidised glutathione ratio [36]. This observation suggests that PRL induce a similar effect in the present conditions. Further LPO determinations in our *in vivo* model of

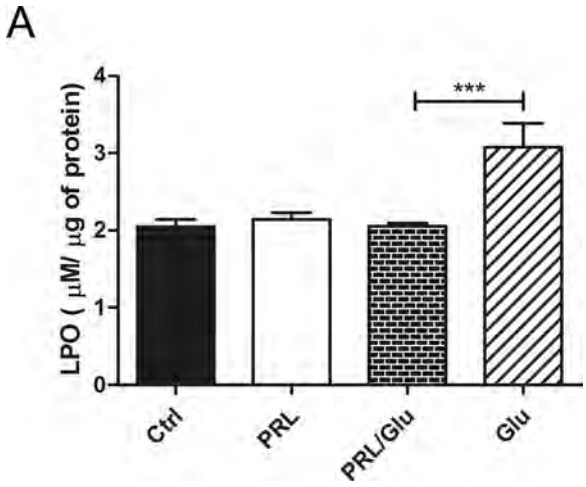

Fig. 3. SOD protein content and activity correlates with a decrease in the LPO products concentration induced by Glu. Bars represent the LPO products concentration correct per μg of protein from the hippocampal neurons exposed to PRL (10 ng/mL); PRL/Glu (10 ng/mL and 100 μM, respectively) or with Glu alone (100 μM). Each bar represent the mean ± SD of four independent experiments. Data were analyzed by one-way ANOVA followed by a Bonferroni´s post hoc test *** $p < 0.001$ *vs.* Glu.

neuroprotection induced by the exogenous administration of PRL, are required.

Finally, the present study provides evidence for the first time of the antioxidant effect of PRL during Glu-induced excitotoxicity in hippocampal neurons, suggesting novel properties for this hormone in the brain, which have been neglected for a long time, and offers new knowledge supporting the potentiality of PRL for the treatment of multiple targets affected by excitotoxicity.

Abstract: Triosephosphate isomerase is the fifth enzyme in glycolysis and its canonical function is the reversible isomerization of glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. Within the last decade multiple other functions, that may not necessarily always involve catalysis, have been described. These include variations in the degree of its expression in many types of cancer and participation in the regulation of the cell cycle. Triosephosphate isomerase may function as an auto-antigen and in the evasion of the immune response, as a factor of virulence of some organisms, and also as an important allergen, mainly in a variety of seafoods. It is an important factor to consider in the cryopreservation of semen and seems to play a major role in some aspects of the development of Alzheimer's disease. It also seems to be responsible for neurodegenerative alterations in a few cases of human triosephosphate isomerase deficiency. Thus, triosephosphate isomerase is an excellent example of a moonlighting protein.

Keywords: Triosephosphate isomerase, moonlighting, cancer, antibody, virulence factor, allergen, cryopreservation, Alzheimer's disease, neurodegeneration.

1. INTRODUCTION

Glycolysis is a catabolic pathway involving ten steps, in which one glucose molecule is converted to two pyruvate molecules, consuming two ATPs, but gaining four molecules of ATP for each transformed glucose [1]. Triosephosphate isomerase (TIM) catalyzes the fifth step of glycolysis, reversibly isomerizing glyceraldehyde-3-phosphate (GAP) and dihydroxyacetone phosphate (DHAP). Even though TIM is not a regulatory enzyme, it is in charge of providing metabolites that connect with other metabolic pathways including (i) the pentose phosphate pathway, in which complex sugars can be formed from GAP [2]; (ii) the de novo synthesis of NAD+ via the synthesis of quinolinic acid (QA): here aspartate is oxidized to iminoaspartate, which condenses with a molecule of DHAP to form QA; QA is then phosphorylated to be converted into nicotinic acid mononucleotide, one of the precursors of NAD+ [3]; (iii) gluconeogenesis, in which GAP or DHAP may be formed starting from pyruvate or oxaloacetate [4] and (iv) biosynthesis of triacylglycerols in adipose tissue, where DHAP is used for the synthesis of triacylglycerols [5].

TIM is present in all organisms [6, 7] and, in most known cases, has approximately 250 amino acids per monomer chain (molecular mass ~ 27,000 Da), even though the length of the protein, and the molecular mass, can vary considerably in different species. The first crystallized structure of TIM revealed it had a $(\beta/\alpha)_8$-barrel topology [8], currently known as the TIM barrel. This is the most frequent structural motif in soluble proteins. Close to 10 % of the enzymes with known structure are TIM barrels [9, 10]. TIM does not require any ion or cofactor to perform its catalytic function [11, 12]. TIM is only active as a dimer, but both monomers have all catalytic residues. From an evolutionary and kinetic point of view, TIM is considered a perfect catalyst, since only the velocity of diffusion of the substrate to the active site is the limiting step for catalysis. Both, the function and the catalytic mechanism of TIM have been conserved in all species throughout evolution [1, 10, 11]. TIM is a well-studied glycolytic enzyme that has been thoroughly characterized from an enzymatic point of view.

After years of research on many enzymes, new functions, which are not related to their catalytic function, have been discovered [13]. Some examples can be found in glycolytic enzymes, which besides their main function, also regulate the activity of other proteins. For example, aldolase helps in the assembly and function of the vacuolar-type ATPase, hexokinase regulates the function of the apoptotic proteins Bax, Bak, and Bad, glyceraldehyde-3-phosphate dehydrogenase regulates the transcription of the gene of histone H2B during the progress of the cellular cycle, and glucose-6-

INFORME DE LABORES 2019

phosphate isomerase participates in inducing cellular motility through secretion and binding to the tumor autocrine motility factor receptor gp 78 [6].

This review focuses on new non-catalytic functions of TIM in multiple biochemical systems, most of them medical and one of them of veterinary importance. It has been reported that, depending on its location and oligomeric state, TIM can have different functions. For example, TIM expression levels are associated and seem to be important markers of different types of cancers [14]. TIM is also involved in the cellular cycle via its interaction with cyclin 2 dependent kinase (Cdk2) [15-17]. In other cases, TIM secreted to the surrounding medium may function as a virulence factor [18]. TIM may also function as an allergen that easily elicits immune responses [19]. Modification of TIM allows adequate signaling for the maturation of highly specialized cells like spermatozoa [20]. It has also been proposed that TIM must be assembled correctly for an optimal function of neurons. And finally, TIM also seems to play an important role in Alzheimer's disease [7] and in neurodegeneration problems in some cases of the rare human TIM deficiency disease [21, 22].

2. TIM AND CANCER

2.1. Variation in the Degree of TIM Expression

The incidence of cancer seems to be increasing in recent years and is becoming more prevalent in its numerous varieties (https://www.cancer.gov/about-cancer/understanding/statistics). Many tools for early detection and diagnosis of different types of cancers lack sensitivity and often positive confirmation of its presence occurs only in the advanced stages of the disease [23]. The dysfunction of tumor suppressors and oncogenes produce modifications in several intracellular signaling pathways, which reprogram the metabolism of tumor cells to favor their survival and growth. Glycolysis is a central degradation pathway in eukaryotes, but in the majority of cases, cells acquire their ATP stores from oxidative phosphorylation. In several cancers, metabolic alterations trigger the transformation of healthy cells into diseased cells. One of these alterations, called the Warburg effect, is when the cancer cell uses glycolysis as its main pathway to produce ATP. Depending on the cell type, the mRNA expression of TIM increases 5 to 20-fold when the cells start proliferating [24, 25]. The deregulation of the levels of expression for TIM is one of the characteristics of cancer [14]. The level of expression of this enzyme in different cells and its clinical implications are not defined and, in some cases, result in beneficial effects and in other cases they become deleterious [25-27].

The expression of TIM is associated with the suppression of the development of the tumor and metastasis in some types of cancers like hepatocarcinoma and carcinoma of the stomach [24, 25]. In liver cancer, the effect of suppression of the tumors has been described both *in vitro* and *in vivo* in YY-88103, Hep3B, and Huh7 cells and in tumors extracted from patients with hepatocarcinoma. Even though the mechanism of how TIM affects the progression of the disease is not well understood, it has been shown that the overexpression of TIM, in this type of cancer, inhibits cellular growth arresting the cells in phases G1/S of the cell cycle [25]. Some of the genes that participate in the modulation of phases G1/S are P53, P16, P27, cyclin D1, and Rb. The alteration of their levels increases cell growth and the risk of tumor formation [28]. Additionally, high levels of TIM, modify the expression patterns of regulatory proteins like P53, P16, P27, cyclin, Rb, and β-catenin. The increase in the expression of P53 and P27 produces a decrease in the expression of cyclin D1, which leads to a cellular arrest and stops propagation, while β-catenin, an enzyme closely related to metastasis, reduces its expression [25].

TIM expression is deregulated in all cases of gastric cancer [27]. Overexpression of TIM in gastric carcinoma cells with phenotype SGC7901/VCR, which are multi-resistant to the drugs used to treat the illness, helps reduce this multiresistance. Similarly, a reduction of the expression of TIM favors resistance to those drugs [24]. This indicates that overexpression of TIM helps in the treatment of gastric cancer.

Another TIM that has a suppressor effect on the growth of cells is the TIM from a species of mollusk called *Arca inflata*. It has a toxic effect on adenocarcinoma cells with A549 and SPC-A-1 phenotypes and also on HEP G2 liver carcinoma cells [29].

In different ways, expression of TIM in different types of gastric cancers is related to an increase in invasion, metastasis and the proliferation of tumor cells [26]. In gastric carcinoma cell lines with the BGC-823 phenotype, overexpression of TIM promotes cellular proliferation, migration, and invasion, but does not generate any changes in the cell cycle. However, when TIM expression is suppressed in cells with phenotype MGC-803, proliferation decreases and an apoptosis signal is turned on, producing an arrest of the cell cycle in phase G2/M [14, 23, 27]. Thus, the intracellular concentration of TIM in these cells is of great importance for their disease-producing behavior.

Additionally, the levels of expression of TIM are also altered in other types of cancers such as cancer of the urinary tract [14], carcinoma of the ovaries [30], lung adenocarcinoma [14], cancer of the colon with a high metastatic potential [23], gastric carcinoma [26], thyroid cancer [31], breast cancer [32, 33], squamous cell carcinoma of the esophagus [34], pancreatic cancer [31], kidney cancer [35, 36], esophageal carcinoma [26] and squamous lung cell carcinoma [14, 23, 25]. In all cases, TIM is related to the metastatic and invasive behavior of the diseases.

2.2. TIM Expression Levels as Markers for the Prognosis of Different Cancers

The differential expression of TIM in cancerous cells and in normal cells has an important diagnostic value and relates to the prognosis of the patient. The possibilities of survival can be predicted depending on the type of cancer, the size of the tumor, the presence of metastasis, the degree of histologic differentiation of the cells and the overexpression of TIM [26, 37].

In gastric cancers, survival is diminished in patients with high levels of TIM expression and who have tumors larger than 5 cm, in comparison with those who have tumors of the same size but low expression levels of TIM [26]. In cases of

INFORME DE LABORES 2019

papillary and follicular cancer of the thyroid, a differential expression of this enzyme has been found [31]. It has been observed that this expression, together with that of other proteins such as A2, cofilin1, PCNA, and HSP27, allows differentiation between both types of cancer, helping in its timely and appropriate treatment [31]. In breast cancer cells expression of TIM is also elevated in comparison to healthy cells, making it a good biomarker for the disease [33].

Metastasis is a common complication of cancer, which typically worsens the prognosis of the patients. The detection of the places where the cancer has spread is of utmost importance for the treatment of the disease. In the case of some gynecological cancers, there are some deregulated proteins that function as biomarkers. For example, in endometrial and ovarian cancer, TIM is expressed more intensely in the secondary tumors than in the primary tumor [38]. Numerous proteins have been described that can serve as biomarkers in different types of cancer, but, interestingly, TIM seems to be deregulated very frequently in a great number of varieties of this illness and, in many cases, can be a useful marker.

2.3. Anti-TIM Antibodies

The immune response is one of the primary and fundamental lines of defense against pathogenic agents. During the first stages of tumor formation, many proteins or peptides are expressed on the surface of cancerous cells. These molecules may initiate an immune response in the patient against the tumor [39]. Humoral responses against cancer have been demonstrated with the identification of many different surface and intracellular antigens in different types of tumors. However, the concentration of antigens tends to be very low, particularly during the initial stages of the ailments [23]. Early detection and diagnosis are of vital importance in many malignancies. The detection of autoantibodies is one of the widely used approaches for the detection of these illnesses today [32].

TIM is distributed in all the cytoplasm of cells and it is overexpressed to high levels in tissues with high glycolytic activity, like cancer cells. One of the theories about why TIM may have immunogenic activity is that during the development of the tumor it produces aberrant or mutated proteins that can elicit an immune response [34]. Anti-endogenous TIM antibodies have been reported in squamous cell carcinoma of the lung [23], gastrointestinal carcinoma [26], esophageal carcinoma [34], breast cancer [32, 33], hepatoma [34] and carcinoma of the kidney [35], among others.

As mentioned before, one of the theories about the generation of autoimmune responses is the production of aberrant proteins, but the mechanism of the autoantibody response against intracellular proteins remains unknown. In some cases, the response is generated because variant proteins are expressed as results of the activation of alternative promoters after the cancerous transformation of the cells [33] or different isoforms of the protein are expressed [36, 39]. Moreover, it has been proposed that most tumor antigens are not products of damaged genes. Instead, tumor antigens are overexpressed proteins during cellular differentiation [23, 39] that change their expression level depending on the status of the tumor and direct the progression of the disease [36].

In squamous cell carcinoma of the lung, TIM is secreted to the extracellular medium assisting the recognition of the disease by the immune system. Pieper and coworkers [40] suggest that a mutation of threonine 28 for an isoleucine, produces a new epitope which increases the immune response. These autoantibodies also exist in other diseases such as hepatitis, but these antibodies are more reactive in patients with hepatic cancer than in those with hepatitis [34].

The humoral immune response against TIM is apparently dependent on certain post-transcriptional modifications such as protein glycosylation. Antibodies can recognize glycosylated TIM but not TIM without modifications [34, 39]. The high specificity with which the antibodies recognize glycosylated TIM, could yield clues to the metabolic changes that occur in the course of the disease.

In addition to cancer, anti-TIM antibodies have been detected in a variety of diseases. These include systemic lupus erythematosus, particularly its neurologic manifestation known as neuropsychiatric lupus erythematosus [41-43], in osteoarthritis, where they are associated with chronic inflammation [44] and in patients with hepatitis type A and mononucleosis, in which the antibodies cause hemolysis, the reactivation of the Epstein-Barr virus [45] and multiple sclerosis [46].

In general, each tissue or organ in the body has a different molecular composition, depending on its location and function. The mechanism of production of auto-antibodies against many of their extracellular and intracellular proteins is still not fully understood.

3. TIM AS A VIRULENCE FACTOR

Virulence factors are molecules with which a microorganism invades and colonizes other organisms and provokes sickness. Virulence factors can be proteins, carbohydrates or lipids which are usually located on the surface of the pathogen [47]. There are reports on a great number of virulence factors, and notably in some parasites and protozoans, some enzymes that are normally intracellular have been found in the extracellular matrix. Some of them are glycolytic enzymes among which are glyceraldehyde-3-phosphate dehydrogenase (GAPDH), enolase and TIM. It has been demonstrated that the function of these enzymes in the extracellular matrix is not catalytic [18, 48]. The mechanism of secretion to the exterior of the cell of these enzymes is unknown [47]. No signal sequence or anchoring motif that may help bind TIM, GAPDH or elongation factor thermo unstable (EF-Tu) to the surface of the cells has been identified [18]. Together with other proteins, TIM has been identified on the surface of Gram-positive bacteria [49]. Usually, proteins that anchor on the surface of cells with their C-terminal domain, maintain their N-terminal domain as a recognition peptide [47].

The cell surface has two types of adhesins: one type are proteins that are covalently associated with the membrane, the other type are proteins that are bound to the cellular surface using ionic interactions. In the case of *Lactobacillus plantarum*, it was shown that TIM, GAPDH, and EF-Tu were bound to the membrane with these ionic interactions [50].

INFORME DE LABORES 2019

TIM has also been reported as an external adhesion molecule in organisms like *Trichomonas vaginalis* [51], *Lactobacillus plantarum* [50] and *Paracoccidiodes brasiliensis* [48]. In these organisms, TIM interacts with the epithelial cells and with the proteins of the extracellular matrix like laminin and fibronectin. TIM from *Staphylococcus aureus* mimic lectin activity and permits binding with sugars on the surface of *Cryptococcus neoformans*. The association of *S. aureus* TIM with the glyco-capsule of *C. neoformans* triggers apoptosis, and thus elimination of this pathogen [48, 52]. Furthermore, TIM from *S. aureus* together with enolase regulates fibrinolysis and fibrinogenesis, potentiating its capacity to invade tissue [47, 53].

In some parasites, one way to evade the immune response of the host is the continuous interchange of epitopes on the surface of their cells [54]. In some parasites like *Brugia malayi*, *Schistosoma mansoni* and *Haemonchus contortus*, variations in the quantities of TIM excreted to the medium, depending on the phase of their vital cycle, have been described [55]. It has also been reported that a certain concentration of TIM secreted to the medium is necessary for the maturation *of Brugia malayi*, indicating that TIM plays a role in the evasion/modulation of the host's immune response [56].

Drastic changes in the expression levels of TIM, related to viral replication, have also been reported in viral infections [57]. After viral infection, the machinery of the cell is sequestered by the virus to favor its replication or evade the immune response. The Warburg effect has been observed during infection of the cells of *Exopalaemon carinicauda* by the white spot syndrome virus (WSSV). This includes an increase of activity of glycolysis and a redirecting of the infected cells to different replication states. The levels of TIM are particularly altered, indicating that TIM has a major role in WSSV infection [57, 58].

4. TIM AS AN ALLERGEN

Food allergies are caused by an induced abnormal immune response to certain foods. The eight great groups of foodstuffs that are capable of generating this type of response are peanuts, nuts, soy, wheat, fish, oysters, milk and eggs. Allergies have increased all over the world in the last years, due to the increased consumption of certain foods [59, 60].

Typically, all allergens are proteins and, in some cases, these proteins exist in all organisms. Allergens usually have a low molecular mass (of approximately 10-70 kDa), a high solubility, a high thermic stability, and acid isoelectric points [60, 61]. The most common allergens in the groups of foodstuffs mentioned above have been known for decades, but there are still many that have not been identified and studied. There are databases that enlist details about certain molecular, biochemical and clinical properties of some of these proteins. An example is the list of allergens of the Allergen Nomenclature Sub-Committee of the World Health Organization and the International Union of Immunological Societies (www.allergen.org).

Among numerous families of proteins present in food, it has been found that most allergens belong to a small group of proteins with restricted biochemical role [62]. Surprisingly, the TIM-barrel is the most frequent motif among the allergens [63].

TIM has been described as a new allergen, mainly in marine organisms and in certain invertebrates. Some of these species are: *Octopus fangsiao* [60], *Blattella germanica* [19], *Penaeus monodon* [64], *Procambarus clarkii* [65], *Citrullus lanatus* [59], *Forcipomyia taiwana* [66], latex (rubber) [67], *Litchi chinensis* [61], *Crangon crangon* [68], *Solea solea* [69] and *Sarcoptes scabiei* [70].

Pan-allergens are proteins that are present in all organisms and have the capacity of cross-reacting [64, 71]. Cross-reactions are immune responses against similar antigenic epitopes, which come from different sources. They generally occur with proteins that have at least 35% homology in their sequences [65]. For example, human TIM cross-reacts with TIMs from other species such as crustaceans, insects, dust mites and mollusks [64]. TIM from *B. germanica* (cockroach) has 60.7% sequence homology with wheat TIM and 19 other TIMs [19]. Thus, patients that are allergic against TIM from *B. germanica* can also react when exposed to other TIMs. Cross-reaction also occurs between TIM and other proteins. For example, TIM from *P. clarkii* has crossed-reactivity with Filamin C (FLN c), which is a protein that binds actin in this same organism [65]. It has also been proposed that hypersensitivity against watermelon (*C. lanatus*) TIM is due to cross-reactivity with the pollen of other plants. In the case of lychee TIM, cross-reaction has been seen with latex (rubber) TIM [67]. TIM from *S. scabiei* var. *canis* shows cross-reactivity with sera from rabbits that have been infected with other parasites. TIM from *S. scabiei* also shows great homology with 25 allergens of dust mites [70].

The mechanism by which TIM generates immune reactivity is not yet fully understood. Rosenberg and coworkers [72], proposed that the formation of homo and hetero-oligomeric aggregates between TIM itself or with other proteins considerably favors the humoral immune response against those proteins. An analysis of the structures of several crystallized allergens showed that 80% of them are dimers [64]. Since the oligomeric state can be important in the induction of the immune response, the treatment of the food before it is ingested is a factor that influences the generation of allergic responses. Generally, food receives treatment with heat (cooking) and is then subjected to changes in pH and enzymatic digestion when it is eaten. Most of the time there is either an increase or decrease in the hyper-reactivity caused by the proteins, in particular by TIM [60]. However, protein in its native conformation is not always the causative agent of allergic reaction [73]. In some cases, as is the case with the TIM from *O. fangsiao*, there is no decrease in the response when it is treated with heat. In contrast, TIM from *P. monodon* loses its immunogenicity under the same conditions [60].

There are two types of antigen epitopes: linear and conformational [73]. It is thought that epitopes of TIM from *O. fangsiao* are of the linear type because their conformations are not affected by hydrolysis and denaturation, but epitopes of TIM from *P. monodon* are conformational.

INFORME DE LABORES 2019

Much is unknown about the epitopes that initiate an anti-TIM allergy. Nevertheless, in the case of crustaceans and arthropods, such as the dust mite and *S. scabiei*, use of an antibody against anti-TIM IgE has been proposed as a good marker for allergy prediction [64, 70].

Due to their immense nutritional contribution to world food consumption, marine products can frequently produce allergies and hypersensitivity problems. Several common proteins that can elicit an immune response have been identified in these foods, which include tropomyosin, arginine kinase, the light chain of myosin, the sarcoplasmic calcium-binding protein, troponin C, hemocyanin and TIM [60, 73].

5. TIM AS A BIOMARKER OF CRYOPRESERVED SEMEN

Spermatozoa are highly differentiated cells which lack endoplasmic reticulum, Golgi apparatus, peroxisomes, lysosomes, and ribosomes and therefore lack transcription and translation. Expression of proteins necessary for fecundation is completed before they are ejected to the environment [74]. Cryopreservation of semen is a technique that permits the conservation and dissemination of gametes of different species. Frequently, the procedure causes structural and functional damage to spermatozoa. The increase in reactive oxygen species (ROS), osmotic stress, mechanical damage and the formation of crystals, are the main causes of the decrease in the quality of sperm during cryopreservation. Changes in any of these variables affect the mobility and potential fertility of the sperm [75]. TIM is located in the membranes of the acrosomes of the spermatozoa and it plays an important role in the capacitation reaction and the binding of sperm to the pellucid zone of the oocyte [76]. Additionally, high levels of TIM have been found in asthenozoospermia (a diminishment in the motility of sperm) in boars. In bulls, high levels of TIM are associated with a lower quantity of sperm and low fertility levels [20, 77].

Analysis of the patterns of overexpression of spermatic proteins under various conditions revealed that cryopreservation produces changes in levels of expression of 41 enzymes [74]. These proteins belong to three groups: enzymes for the organization of the flagellum, detoxification proteins, and metabolic energy proteins. Among these enzymes, TIM modifies its quantity to an important degree. In studies of the quality of sperm for cryopreservation, two populations of cells have been identified with different levels of TIM expression. Those with low quantities of TIM before freezing had a better viability after thawing and those with high TIM levels had a low survival rate [20, 77].

It is thought that after thawing the high amounts of TIM predispose the cell to an "early capacitation"; that involves all the cellular modifications that allow the sperm to bind to the oocyte [20, 78, 79]. If capacitation occurs before the right time, the motility of the spermatozoa is affected.

During freezing and thawing of sperm cells, the lipids in their membranes are rearranged. These changes increase the fluidity of the membranes, causing alterations in intracellular calcium permeability, accelerating capacitation and diminishing the viability of the spermatozoa [75, 80, 81].

Additionally, it has been observed that cryopreservation induces important changes in phosphorylation and the redox state via carbonylation of the proteins of sperm. One of the proteins most affected by this reaction is TIM. Carbonylation of proteins is the direct result of the oxidative stress caused by cryopreservation [75].

Changes in the oxidation state of the proteins cause physio-pathological conditions due to the modification of their structure and function. For example, carbonylation of TIM and other enzymes promotes early capacitation of sperm [75].

Protein carbonylation can be a crucial component of redox signaling in certain mammalian tissues. It may be a part of the mechanism for cryo-capacitation, a method commonly used for mammalian sperm [75].

In vivo, infertility is frequently associated with low sperm count (azoospermia), but it has also been found that the production of anti-TIM antibodies hinders capacitation of sperm and their binding to the pellucid zone [76].

6. THE ROLE OF TIM IN ALZHEIMER'S DISEASE

The reactive species of oxygen and nitrogen (ROS and NOS) are normally produced in small amounts in mammalian cells, where they act as physiological messengers. Changes in the cellular environment, exposure to toxins or changes in metabolism change the balance of the concentration of these species. All cells in an organism are vulnerable to the damage caused by an unbalance of ROS. In particular, neurons have increased sensitivity because of their high energy demand and low concentration of antioxidants in these cells [82-84].

One of the hallmarks of Alzheimer's disease is the presence of plaques and neurofibrillary tangles due to the accumulation of the amyloid peptide (Aβ) and paired helical filaments of Tau protein [85, 86]. The main function of Tau protein is to stabilize microtubules, which are necessary for axonal transport. TIM interacts with Tau protein under normal and also under pathological conditions. Under normal conditions, when there is little oxidative stress, Tau protein protects TIM, preventing modifications that may affect TIM's activity [85]. It is known that Aβ is capable of reducing the Cu^{2+} and Fe^{3+} ions, with the concurrent production of H_2O_2, which creates a cascade of ROS. The superoxide anion (O_2^-) reacts with nitric oxide (NO) to produce the peroxynitrite anion (ONOO-), which nitrates the tyrosines of proteins. This process is known as nitrotyrosination. This reaction, which involves the addition of a nitro (NO_2) group to a tyrosine, is irreversible and yields 3-nitrotyrosine as a product [87, 88]. In Alzheimer's disease, 45 proteins have been found that undergo this modification [84].

One of the proteins that are most affected by nitrotyrosination is TIM. TIM is the only glycolytic protein whose malfunction is associated with a loss of memory and with cerebral dysfunction and neurodegeneration [6, 7, 89]. When tyrosines of TIM are nitrated, its catalytic efficiency is decreased 15 times with respect to the wild-type enzyme [90]. Human TIM has 4 tyrosines, but the derivatization of Y164 and Y208 have a greater impact on the structure of the enzyme [90].

INFORME DE LABORES 2019

Enzymatic catalysis of TIM is usually accomplished in a special medium that enables isomerization. This setting is provided by the catalytic loop which remains open when there is no substrate and closed when catalysis is ongoing [91, 92]. Nitration of Y164 and Y208 prevents the loop from closing. Y164 interacts with T168 forming a hydrogen bond that reduces the mobility of the loop. Besides, the hydroxyl group of Y209 (of yeast TIM) is of highest importance for the stabilization of the loop in closed position. When this Y209 has nitrated the catalytic loop remains open, favoring the entrance of water to the active site and, with it, the formation of methylglyoxal (MEG) [88, 90, 93].

MEG is capable of glycosylating other amino acids in proteins and nucleic acids. Arginine is its most frequent target, producing argpyrimidine glycation of Aβ [84, 87, 88, 90, 94, 95], that accelerates the deposit of the amyloid peptide and considerably increases its toxicity [90].

The modifications brought by oxidative stress, as well as those created by the accumulation of MEG, produce compounds that are capable of modifying the permeability of the mitochondrial membrane [86]. For example, 4-hydroxy-2-trans-nonenal, a product of the peroxidation of the lipids of the membrane, interacts with some amino acids such as cysteine, lysine, and histidine which generate conformational changes in membrane proteins. The damage to the structure of the membrane can be so severe that its permeability may induce cellular death. Additionally, MEG accumulation diminishes the mitochondrial membrane potential and as a result, the amount of pro-apoptotic proteins Bax and caspase -3 are increased [88, 96, 97].

Other studies indicate that nitrotyrosinated TIM has a greater tendency to aggregate. In an alignment of the sequence of amyloid peptide and TIM, a fragment of TIM showed 20% homology with the amyloid peptide [98]. Accumulation of nitrotyrosinated TIM aggregates that cannot be degraded by the proteasome act as seeds for the fibrogenesis of other proteins.

TIM has an important functional and structural role in Alzheimer's disease. It has been shown that the modification of the structure of the dimer is enough to induce neurodegeneration [7]. Likewise, modification of its function provokes the formation of toxic structures such as neurofibrillary plaques and tangles. Another common feature of Alzheimer's disease is a low level of ATP in the cells, which also correlates with the low activity of TIM [87, 99]. Figure **1** depicts a summary of the pathological processes in which TIM plays a role in Alzheimer's disease.

7. HUMAN DEFICIENCY OF TRIOSEPHOSPHATE ISOMERASE

Human TIM deficiency is a rare autosomal recessive disease that was first described in 1965. It belongs to a class of diseases called glycolytic enzymopathies which show symptoms such as chronic hemolytic anemia, cardiomyopathy, high susceptibility to infection, neurologic dysfunction and premature death [7, 89, 100].

Thirteen mutations of the gene that codifies for TIM (in chromosome 12p13) have been described for this disease, and all of them result in a diminished enzyme activity that results in the excessive accumulation of DHAP. However, the most common mutation is in the codon for the amino acid in position 104, where a glutamic acid is substituted for an aspartic acid, producing the mutant enzyme TIM E104D. This mutation occurs in 80% of the cases. Other less frequent mutations are the substitution of cysteine 41 for tyrosine (TIM C41Y) and isoleucine 170 for valine (TIM I170V) [7, 101, 102]. Both mutations affect the dimerization of TIM and the binding of the substrate. There are other mutations that have been identified like the change of phenylalanine for leucine in position 240, glycine for arginine in position 122 or valine for methionine in positions 154 and 231 [22, 100, 101, 103, 104].

There are mainly two types of symptoms caused by this illness: the first is clearly due to the reduced catalytic function of the enzyme, which causes severe metabolic disorders and which are not in the scope of this review. The second type of symptoms, which are absent in very few patients, are associated with neurodegeneration.

7.1. Possible Causes of Neurodegeneration in Human TIM Deficiency

TIM deficiency is different from other glycolytic enzymopathies because none of these are associated with neurologic dysfunction. Although the precise causes for neurodegeneration in TIM deficiency are not known, there are some observations that could potentially explain it. When the catalytic activity of TIM is diminished there is an accumulation of DHAP in all cells [101]. For example, in patients with mutation TIM E145Stop /TIM F240L, the concentration of DHAP inside the erythrocytes is 60 times higher than normal. Even though the accumulation of high concentrations of DHAP is not toxic, the molecule tends to transform non-enzymatically to MEG, which is toxic and capable of modifying proteins and nucleic acids (see section 5 "The role of TIM in Alzheimer's disease" and Fig. **1**). Under conditions of high oxidative and nitrative stress, glyoxalases cannot cope with the accumulation of MEG [21] and the glycated proteins, together with the oxidative stress and the damaged DNA, contribute to the neuronal symptoms [22, 101].

DHAP is also a precursor of acyl-DHAP, which is an intermediary in the synthesis of alkyl glycerol ethers and plasmalogens. DHAP can also be converted to non-ether derived glycerolipids, which produces an abnormal metabolism of lipids [105]. It has been reported that plasmalogen levels in the membranes of erythrocytes and lymphocytes can influence several processes related to protection mechanisms from oxidative stress [101, 106]. Coincidentally, the plasmalogen levels in erythrocytes from patients with TIM deficiencies due to TIME104D and TIM F240L/E145stop are diminished [101]. DHAP also inhibits competitively the activity of myoinositol 3 phosphate synthase, an enzyme that involved in the de novo synthesis of inositol. A deficiency in the concentration of inositol has been described in several pathological conditions like bipolar disorder, Down's syndrome and peripheral diabetic neuropathy, which suggests that the deficit in TIM activity can contribute to neurodegeneration [101].

Other studies that could explain the development of neurodegeneration are those made by Roland *et al*., [6, 7, 89],

INFORME DE LABORES 2019

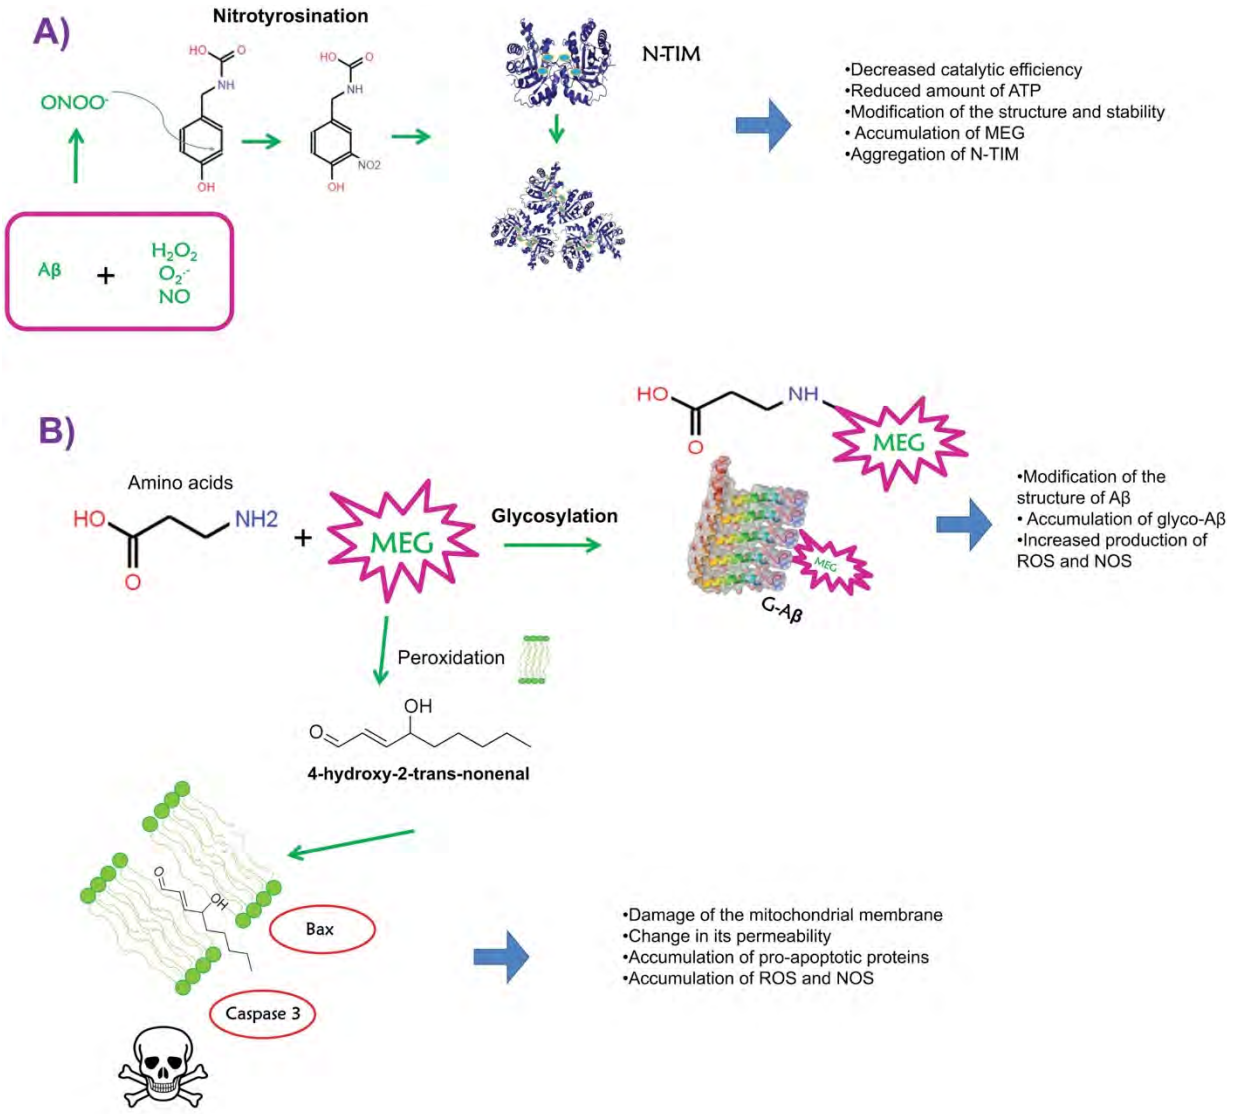

Fig. (1). Role of TIM in Alzheimer's disease. A) The accumulation of the amyloid peptide (Aβ), together with the oxidative/nitrative stress produce peroxynitrite which modifies tyrosines in proteins. During the progress of the disease, TIM is nitrotyrosinated (N-TIM), decreasing its catalytic activity, lowering ATP levels in the cells and favoring the formation of methylglyoxal (MEG), a highly toxic molecule. **B**) The accumulation of MEG generates further oxidative/nitrative stress in the cell. The contact of MEG with membranes produces 4-hydroxy-2-trans-nonenal, which damages the membrane and changes the membrane potential of the mitochondria generating apoptosis [96]. MEG can also glycosylate proteins like Aβ (G-Aβ). Accumulation of G-Aβ further favors production of reactive oxygen species and reactive nitrogen species, and N-TIM aggregates can function as seeds to form new fibrillar structures.

Ralser *et al.* [100] and Rodríguez-Almazán *et al.* [107]. These studies indicate that TIM deficiency is produced by changes in the conformation of the protein, more than because of the metabolic defects caused by the loss of activity. Specifically, problems in dimerization and/or the assembly of the enzyme are the main cause of the disease. One proposal is that TIM participates in the dynamics of the vesicles in the synapse as the main source of the ATP (through glycolysis) that feeds the process and, when this pathway is inhibited, the traffic of the vesicles stops. Another proposal suggests that TIM participates in the mobilization of vesicles as an activator of other molecules that facilitate vesicular traffic [7, 108, 109]. Recently it has been found that TIM binds to cofilin, which is a regulatory protein of actin, and that, the formation of a TIM-cofilin complex seems to regulate vesicle traffic [7, 110]. Thus, an anomaly in the structure of either protein could influence the formation of this complex, affecting neuronal communication [7].

It has also been reported that TIM can associate with the N-terminus of the transmembrane protein Band 3 from erythrocytes and that this association diminishes its catalytic activity [101, 111]. The N-terminus of protein Band 3 has great sequence similarity with the C-terminus of tubulin, which is the end with which tubulin is bound to the microtubules. It has therefore been suggested that TIM can also bind to the microtubules, which are the main component of neuronal axons, and thus provoke an energetic destabilization [87, 101].

INFORME DE LABORES 2019

8. DISCUSSION

There is a great discrepancy in the great size of the human genome and the number of synthesized proteins [13]. This difference implies the utilization of the limited amount of synthesized proteins to fulfill multiple functions. The case of TIM, as mentioned previously, is an enzyme present in all organisms, so that its reuse or moonlighting functions is a common occurrence.

TIM has several roles that are different from its traditional main function. But, relatively little is known of the properties and mechanisms that allow it to perform the varied functions described here. TIM seems to have a role in cell cycle signaling. It interacts with proteins like Cdk2, whose activity is essential in meiosis and the adequate control of cellular proliferation, repair, and death [15-17]. Its maximal activity is between phases S and G2, even though it is active in phases G1-S. It has been reported that Cdk2 is able to phosphorylate TIM, reducing its glycolytic activity and causing a disturbance in other pathways, which generate cellular arrest [96].

Cellular proliferation is strictly controlled and TIM, together with other enzymes seems to form a part of the controls. In certain types of gastric cancer, the levels of TIM are unbalanced, initiating the loss of control in cellular proliferation. This makes TIM a good biomarker for this type of ailment [24, 25].

The reason why a difference of expression levels of TIM between one type of cancer and another can vary the prognosis of the patients suffering these diseases is unknown. Yet, one of the aspects that have not been examined is that there may be several isoforms of this protein or that this enzyme may be subjected to different types of post-transcriptional modifications. In some cases, these modifications bring beneficial effects like in the maturation of sperm, where the active form of TIM is the one that is carbonylated [75]. Furthermore, there are other modifications that result in pathological processes like Alzheimer's disease [87, 88] and the formation of anti-TIM autoantibodies [34, 39]. For example, three isoforms of TIM are overexpressed in some types of pulmonary cancer, and, the clinical outcome of the disease varies depending on the isoform that is expressed. Interestingly these isoforms vary only in the type of modifications they show, with phosphorylation being the most common [112].

One of the factors that control post-transcriptional modifications in these proteins is the redox balance of the cell. Cdk2 is also related to the nitric oxide signaling pathway so that any failure in this pathway can cause important modifications in TIM and other proteins [96].

Whenever TIM suffers changes due to oxidative stress, it reduces its activity and changes its conformation favoring the production of MEG and the propagation of the oxidative damage in the cell.

As mentioned earlier, TIM expression has an impact on the prognosis of various cancer patients. The repercussions are different, depending on the type of tumor that develops. This may also be due to a high genetic variation between tumors and the way in which their metabolism varies, thus affecting the differential response in TIM expression and the prognosis of the patient. Renal tumors have the greatest genetic variation and 3 types of mutations may be found among them. Clear cell renal carcinoma cells have a specific deletion in chromosome 3P, while papillary renal cell carcinoma cells have trisomies and chromosome Y losses and chromophobe renal cell carcinoma cells have losses in chromosomes 1, 2, 6 and 10 [35].

A novel therapeutic strategy in cancer treatment is the inhibition of glycolysis. The disruption of this pathway, using Cdk2 to inactivate TIM, could produce the death of malignant cells [96].

It is interesting to note that in several diseases like cancer and Alzheimer's disease, overexpression of TIM also coincides with the overexpression of other proteins such as cofilin. This is a protein that binds actin and regulates the length of the microfilaments; it also acts in the reorganization of the microtubules for vesicle traffic. It is now known that cofilin associates with TIM so that they can be translocated by the plasmatic membrane and bind to the Na/K ATPase [110]. As described previously, the mechanisms by which TIM is transported outside the cell, or induces the formation of antibodies, or functions as a virulence factor, are unknown. Perhaps, its ability to associate with proteins related with cellular traffic (cofilin, Band 3 and microtubules) could give a clue.

The presence of TIM autoantibodies in cancer represents a type of "fingerprint" or "signature" of the immune system responding to the progression of the disease. Antibodies can sometimes be detected years or months before the main symptoms of the disease are apparent, giving signs of the dynamics of the carcinogenic process [34]. In neuropsychiatric lupus, anti-TIM antibodies appear in great quantities and they show a high specificity of 94.7%, making them a good marker for this disease [42].

It is thought that antibodies arise due to the exposure of misfolded proteins, however, misfolding is not necessary for immunogenicity. The reason could be the form in which protein is associated with itself or with other proteins [72].

Surprisingly, even though TIM is so immunogenic in certain pathologies, this enzyme also contributes to the evasion of the immune response. Certain parasites and bacteria use it as a protecting shield just for that purpose. In immune tolerance, the immune system recognizes a non-self or self-antigen, but no response is elicited. Tolerance depends on the situation in which the recognition of the antigen takes place [113].

CONCLUSION

TIM belongs to the group of moonlighting proteins, which carry multiple functions. Even though TIM is not a regulating enzyme, it seems to have an important metabolic role in the development of several cancers. The correct assembly of the protein is necessary for normal neuronal function, with structural modifications leading to neurodegeneration. Depending on the cellular environment TIM can be a potent allergen or induce immune tolerance.

New protein moonlighting functions are being discovered and may have evolved as a means of communication and

INFORME DE LABORES 2019

cooperation between different pathways necessary for fundamental functions in the complex world of different types of cells, within an organism [13].

Finally, further research is required considering TIM and its multiple functions, trying to elucidate the mechanisms by which it accomplishes all these different tasks, either to apply them biotechnologically or to prevent and treat a select group of diseases.

Abstract
Perception of our environment entirely depends on the close interaction between the central and peripheral nervous system. In order to communicate each other, both systems must develop in parallel and in coordination. During development, axonal projections from the CNS as well as the PNS must extend over large distances to reach their appropriate target cells. To do so, they read and follow a series of axon guidance molecules. Interestingly, while these molecules play critical roles in guiding developing axons, they have also been shown to be critical in other major neurodevelopmental processes, such as the migration of cortical progenitors. Currently, a major hurdle for brain repair after injury or neurodegeneration is the absence of axonal regeneration in the mammalian CNS. By contrasts, PNS axons can regenerate. Many hypotheses have been put forward to explain this paradox but recent studies suggest that hacking neurodevelopmental mechanisms may be the key to promote CNS regeneration. Here we provide a seminar report written by trainees attending the second Flagship school held in Alpbach, Austria in September 2018 organized by the International Society for Neurochemistry (ISN) together with the *Journal of Neurochemistry* (JCN). This advanced school has brought together leaders in the fields of neurodevelopment and regeneration in order to discuss major keystones and future challenges in these respective fields.
Keywords: JNC-ISN Flagship School, review, cell therapy, spinal cord, axon guidance, regeneration.
J. Neurochem. (2020) **153**, 10–32.

The first anatomical reference of the brain dates back to the ancient Egyptian mummifications. However, the tremendous complexity of this organ was revealed by the work of the world-renowned neuroscientist Santiago Ramón y Cajal. Nevertheless, his anatomical descriptions could not fully explain the cellular and molecular events at the origin of behavioral, motor or sensitive responses. Today, it is clear that the CNS is the processing center for these events. Moreover fine sensory perception and intricate motor control are orchestrated by a discrete and permanent communication

between the CNS and the PNS. In the last century, neuroscientists have investigated the mechanisms involved in the development and plasticity of this structure. To address these fundamental questions, researchers made use of simple and accessible animal models. *Drosophila melanogaster* was one of the first organisms used because of several technical advantages: amenability to genetic manipulation, short lifespan and large number of offsprings. Studies emanating from this model system paved the path toward our understanding of major neurodevelopmental mechanisms involved in vertebrate behavior, neuronal migration and differentiation among many others (Bellen *et al.* 2010). *Danio rerio* (zebrafish), quickly emerged as an attractive more complex animal model. Like the *Drosophila melanogaster*, the zebrafish model also possessed a short lifespan and a large number of offsprings. However, it provided the advantage of studying neurodevelopmental mechanisms in vertebrates (d'Amora and Giordani 2018). While findings in these two models have led to major findings in the field of neuroscience, there are still significant gaps in our understanding of human development. Over the last 50 years, *Mus musculus* and *Rattus norvegicus* are classic models in neuroscience research because of their closer phylogenetic proximity to humans (Ellenbroek and Youn 2016).

In parallel to these findings, a large number of pathologies related to the CNS have emerged over the last century. This is mainly related to the aging population, encountering previously unknown neuro-degenerative diseases. The rising prevalence of these neurodegenerative diseases has urged the need for novel and more effective therapies (Gitler *et al.* 2017). Quickly, the idea emerged that developmental processes could be reinitiated to induce regeneration and brain repair. In an effort to target these fundamental questions, the Journal of Neurochemistry organized in September 2018 a workshop in Alpbach, Austria, gathering some of the most prominent researchers in the field of developmental neurobiology and regeneration in order to discuss the most significant findings and current challenges in these fields. Trainees attending this workshop have drafted a seminar report of this workshop listing the major advances and putting forward major questions in the field.

The developing nervous system

Metazoans all possess an axis of symmetry. In contrast to *radiata* (radial symmetry), *Bilateria* possess a two-fold symmetry. Thus, *bilateria* have a front and rear as well as left and right sides. To connect its two lateral halves, the CNS of *bilateria* possesses commissural neurons. These neurons, which are born embryonically, project their axons contralaterally to connect the left and right side of the organism. Together, these commissural networks not only allow for integration and coordination of left-right neuronal activities, but are essential for the correct processing and interpretation of various sensory information, the coordination of motor responses and other brain functions (Stoeckli 2018; Gaudet and Fonken 2018; Ducuing *et al.* 2019). Many commissural tracts exist in the CNS (Chédotal 2014). Here, we will discuss the three major systems: the corpus callosum, the ventral commissure of the spinal cord, and the optic chiasm.

Forebrain

The forebrain possesses two main cortical projection neurons: cortico-cortical, that form the corpus callossum, and cortico-fugal, further subdivided into corticothalamic and coroticospinal tracts (Leyva-Díaz and López-Bendito 2013).

The corpus callosum (CC) is the largest brain commissure and develops alongside neocortex expansion. Interestingly, this structure is unique to eutherian mammals and relays information between left and right hemispheres via the midline (Gazzaniga 2000; Suárez *et al.* 2014). Corpus Callosum dysgenesis affects ~ 1 : 4000 live births that result in either partial or complete absence (agenesis) of the CC (Edwards *et al.* 2014). Initially the two hemispheres are separated, at the midline, by the interhemispheric fissure (Rakic and Yakovlev 1968). This region is lined by specialized astroglial and neuronal cells that are required for proper CC tract formation (Silver *et al.* 1982; Niquille *et al.* 2009; Gobius *et al.* 2016; Gobius *et al.* 2017). In addition to providing a permissive substrate for callosal growth cones to grow across the midline, midline cells also secrete guidance cues. Pre-crossing CC axons are sensitive to Slit2, expressed by these astroglia, which acts as a repulsive cue to constrain callosal axons expressing the Roundabout (Robo) receptors 1/2 (Unni *et al.* 2012). In contrast, netrin-1, expressed by the cingulate cortex, counteracts the Slit2 repulsive signal by attracting callosal axons expressing the transmembrane receptor deleted in colorectal cancer (Dcc) (Fothergill *et al.* 2014). Indeed, loss of Dcc or netrin-1 leads to CC agenesis (Serafini *et al.* 1996; Fothergill *et al.* 2014). In addition to netrin-1, semaphorin (Sema3C) is secreted at the midline and attracts callosal axons expressing the receptor neuropilin 1 (Nrp1, Fig. 1a) (Niquille *et al.* 2009). Once CC axons have reached and crossed the midline, this attractive signal is switched off (Mire *et al.* 2018). This coincides with an up-regulation of the transmembrane protein ephrin-B1 in post-crossing CC axons. Interestingly, ephrin-B1 possesses a unique Asparagine residue (N-139), not shared by other ephrins, which once glycosylated can allow ephrin-B1 interaction with Nrp1 and silence Sema3C/Nrp1 attraction (Mire *et al.* 2018) (Fig. 1b). These findings identify a novel mechanism involving interaction between Sema3c/Nrp1 and Ephrinb1 during midline crossing in the corpus callosum (Fig. 1).

Optic chiasm

Another critical component of the CNS is visual perception. The functional unit of the eye is the retina (Fig. 2a), which is

INFORME DE LABORES 2019

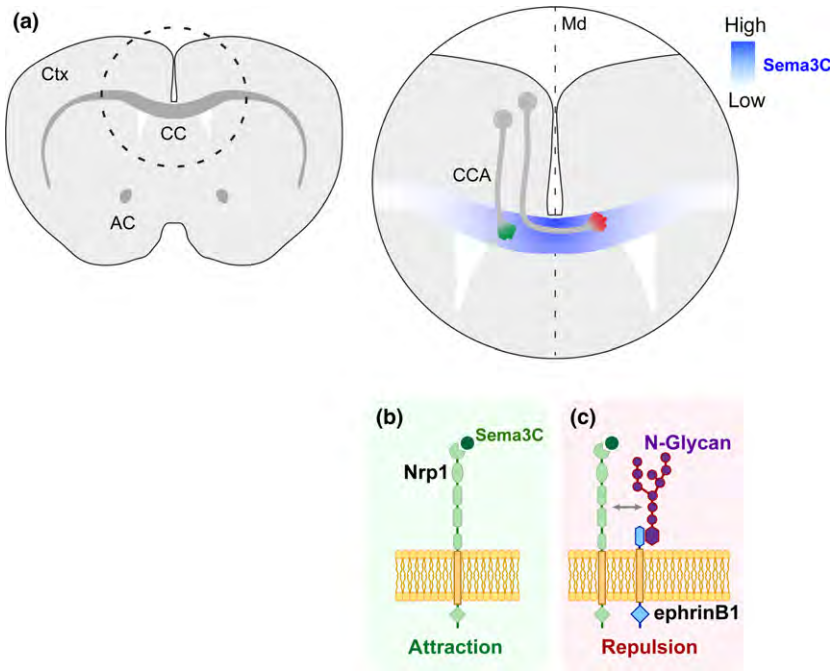

Fig. 1 Sema3C controls midline crossing in the developing *corpus callosum*. (a) The role of semaphorin in midline crossing in the *corpus callosum* has been recently elucidated. Sema3C is expressed in a gradient across the callosal midline. It binds the Nrp1 receptor on callosal axon growth cones (b) acting as an attractive cue. (c) The Sema3C/Nrp1 complex is silenced by the presence of trans-membrane protein ephrinB1. This requires an N-Glycan post-traductional modification of ephrinB1. Ctx, cortex; CC, *corpus callosum*; AC, anterior commissure; CCA, *corpus callosum* axon.

a highly organized structure. Photoreceptor cells are photosensitive cells that transform photons of light into an electrical impulse that is transmitted to bipolar cells and subsequently to Retinal ganglion cells (RGCs). RGCs relay this electrical signal to the brain along their axons that form the optic nerve. Importantly, whilst other retinal cell types can modulate the electrical signal mediated by photoreceptor cells, such as amacrine and horizontal cells, RGCs are the only output neuron from the retina and connecting it to the brain. During visual system development, retinal ganglion cells (RGCs) extend axons toward a specialized structure at the midline, named the optic chiasm (OC). At this point, RGCs will either project to the same hemisphere (ipsi-lateral) or cross the midline to project to the opposite hemisphere (contra-lateral). Therefore, two types of RGCs, ipsilateral RGCs (iRGCs) and contralateral RGCs (cRGCs) can be defined by the laterality of their projections (Williams *et al.* 2004).

This process is critical for depth perception, stereopsis. Indeed, since both eyes will obtain a "picture" of our environment, by combining these pictures we will generate a three-dimensional (3D) representation of the picture. Interestingly, the amount of overlap between each eye is directly proportional to the amount of ipsi-lateral projections. For instance, species with laterally positioned eyes, such as mice, possess only 3–5% of ipsi-laterally projecting RGCs. However, humans and primates, with more frontally positioned eyes, possess approximately 50% of ipsi-laterally projecting RGCs (Guillery *et al.* 1995; Jeffery and Erskine 2005; Herrera *et al.* 2019). Mouse iRGCs and cRGCs are characterized by specific transcriptional patterns and, in part, spatial localization, with iRGCs residing in the ventro-temporal retina, and cRGCs being dispersed across the retina (Herrera *et al.* 2003; Pak *et al.* 2004; Williams *et al.* 2006; García-Frigola *et al.* 2008; Kuwajima *et al.* 2017) (Fig. 2b and c).

In order to control the crossing of RGC axons at the OC, two processes take place: repulsion of axons with an ipsi-lateral fate, and the crossing of contralateral axons across the midline (Fig. 2d). EphB1/ephrin-B2 signaling pathway is a key component of ipsi-lateral axon repulsion. Expression of the EphB1 tyrosine kinase receptor is restricted to axons of iRGCs, while its ligand, the repulsive axon guidance molecule ephrin-B2, is expressed at the OC (Williams *et al.* 2003). When the axons reach the proximity of the OC, a chemo-repulsive gradient of ephrin-B2 leads to growth cone collapse and pausing of axonal outgrowth, eventually causing changes of trajectory and driving the axon toward ipsi-lateral visual nuclei (Petros *et al.* 2010). It was further shown that RGC axon laterality is transcriptionally regulated. The transcription factor Zic family member 2 (Zic2) was identified as a key regulator of iRGCs identity (Herrera *et al.* 2003; Wang *et al.* 2016). Furthermore, Zic2 is sufficient to induce the expression of EphB1 receptor in iRGCs (Lee *et al.* 2008; García-Frigola *et al.* 2008) (Fig. 2c). In addition, the transcription factor Forkhead box D1 was shown to be critical in maintaining iRGCs fate by promoting the expression of Zic2 (Herrera 2004). In addition to the EphB1/ephrin-B2 repulsion pathway, another pathway also controls ipsilateral RGC repulsion: Shh is expressed by contralateral RGCs and transported axonally and anterogradely to the optic chiasm (Peng *et al.* 2018). At the optic chiasm, ipsilateral

INFORME DE LABORES 2019

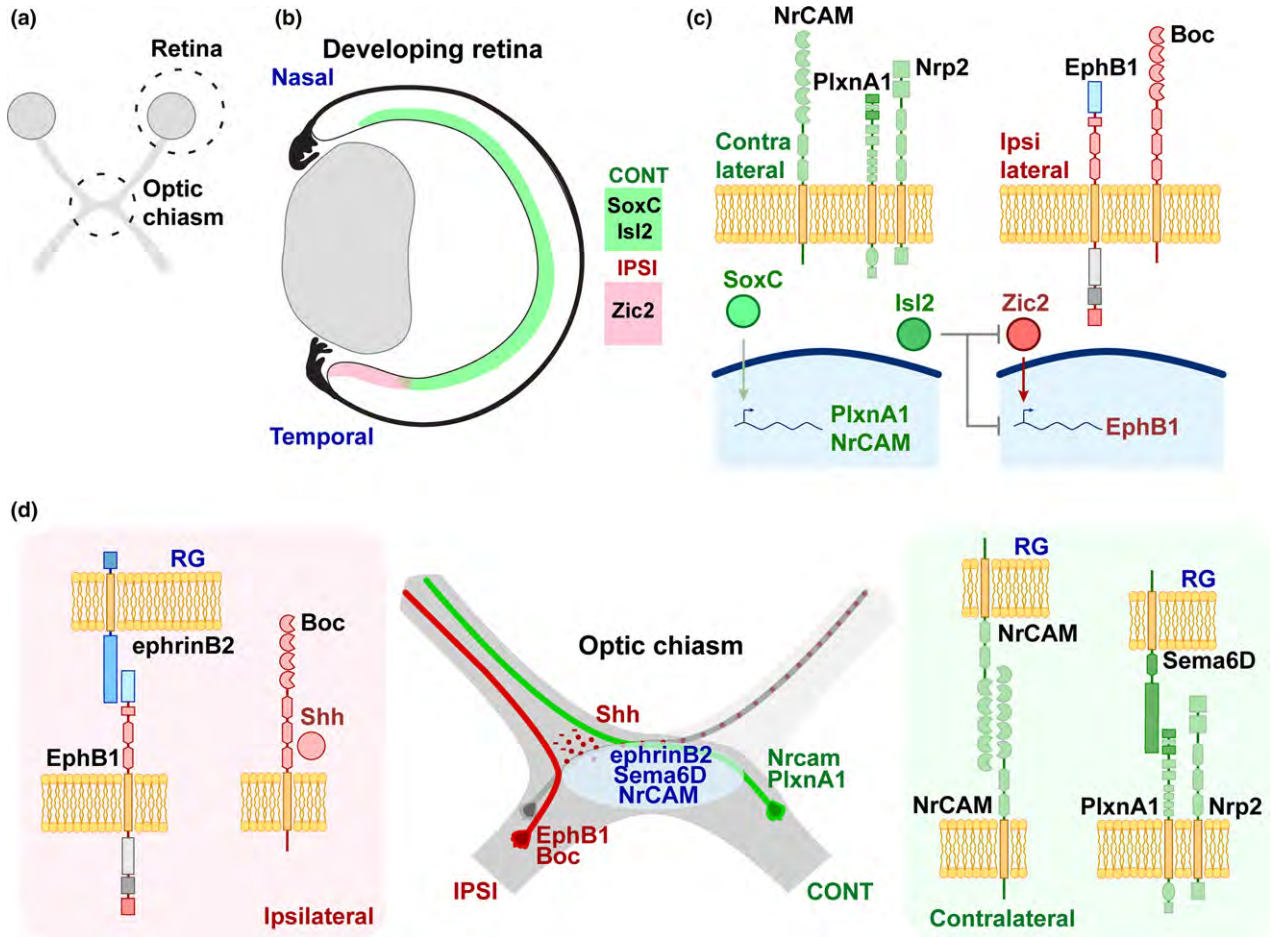

Fig. 2 Retinal ganglion cells development and their pathfinding at the optic chiasm. (a) In the developing visual system, retinal ganglion cells (RGCs) project from the retina to the brain nuclei. During this process, some RGC axons cross the midline at the optic chiasm. (b) RGCs projecting towards the contra or ipsilateral side are already specified in the retina by two sets of transcription factors: *SoxC* and *Islet2* in contralateral RGCs and *Zic2* in ipsilateral RGCs. The Sonic hedgehog (Shh) receptor Boc, is also expressed by ipsilateral RGCs. (c) These two different combinations allow the expression of guidance effectors, regulating the pathfinding choices at the optic chiasm. Moreover *Islet2* is also blocking the expression of *Zic2* and *Boc* expression in contralateral RGCs. (d) The optic chiasm is the intermediate target where contralateral RGCs (green) project towards the contralateral side of the CNS whereas ipsilateral RGCs (red) follow the visual tract on their original side. Shh, transported by the contra-lateral RGCs (gray), is released at the optic chiasm. Ipsi-lateral RGCs expressing the transmembrane receptors Boc as well as EphB1 are repelled by Shh and ephrinB2 at the optic chiasm. An attraction of contralateral RGCs to the midline is mediated by the cell adhesion molecule NrCAM and transmembrane semaphorin Sema6D, through their interaction with NrCAM and the complex PlexinA1-Neuropilin2. RG, radial glia.

RGCs, which express the Shh receptor Boc, are repelled by Shh and therefore do not cross the optic chiasm, remaining ipsilateral (Fabre *et al.* 2010; Peng *et al.* 2018) (Fig. 2d).

In contrast, cRGC axons express the L1 cell adhesion molecule, the neuronal cell adhesion molecule (NrCAM), and the semaphorin receptor Plexin-A1. Together, these molecules provide a permissive substrate for cRGCs to invade and cross the OC (Williams *et al.* 2006; Kuwajima *et al.* 2012). Transcriptionally, the Sox C family of transcription factors (Sox4, Sox11, Sox12) was identified as key regulators for cRGC fate by regulating NrCAM and PlexinA1 expression (Kuwajima *et al.* 2017) (Fig. 2c and d). In addition, the transcription factor Islet2 is expressed by ~ 30% of cRGCs, mainly expressed by late-born cRGCs (Pak *et al.* 2004; Kuwajima *et al.* 2017). Furthermore, the leucine-rich repeat receptor Islr2 has been shown to be expressed on cRGCs and its deletion leads to aberrant ipsi-lateral projections in *Danio Rerio* (Panza *et al.* 2015).

Interestingly, binocular vision is impaired in patients with albinism (an absence of melanin production of the retinal pigmented epithelium). This led researchers to study the role of pigmentation on iRGCs. It was found that albino mice have less iRGCs, but a normal number of cRGCs (Rebsam *et al.* 2012). This appears to be linked to the timing of RGC

INFORME DE LABORES 2019

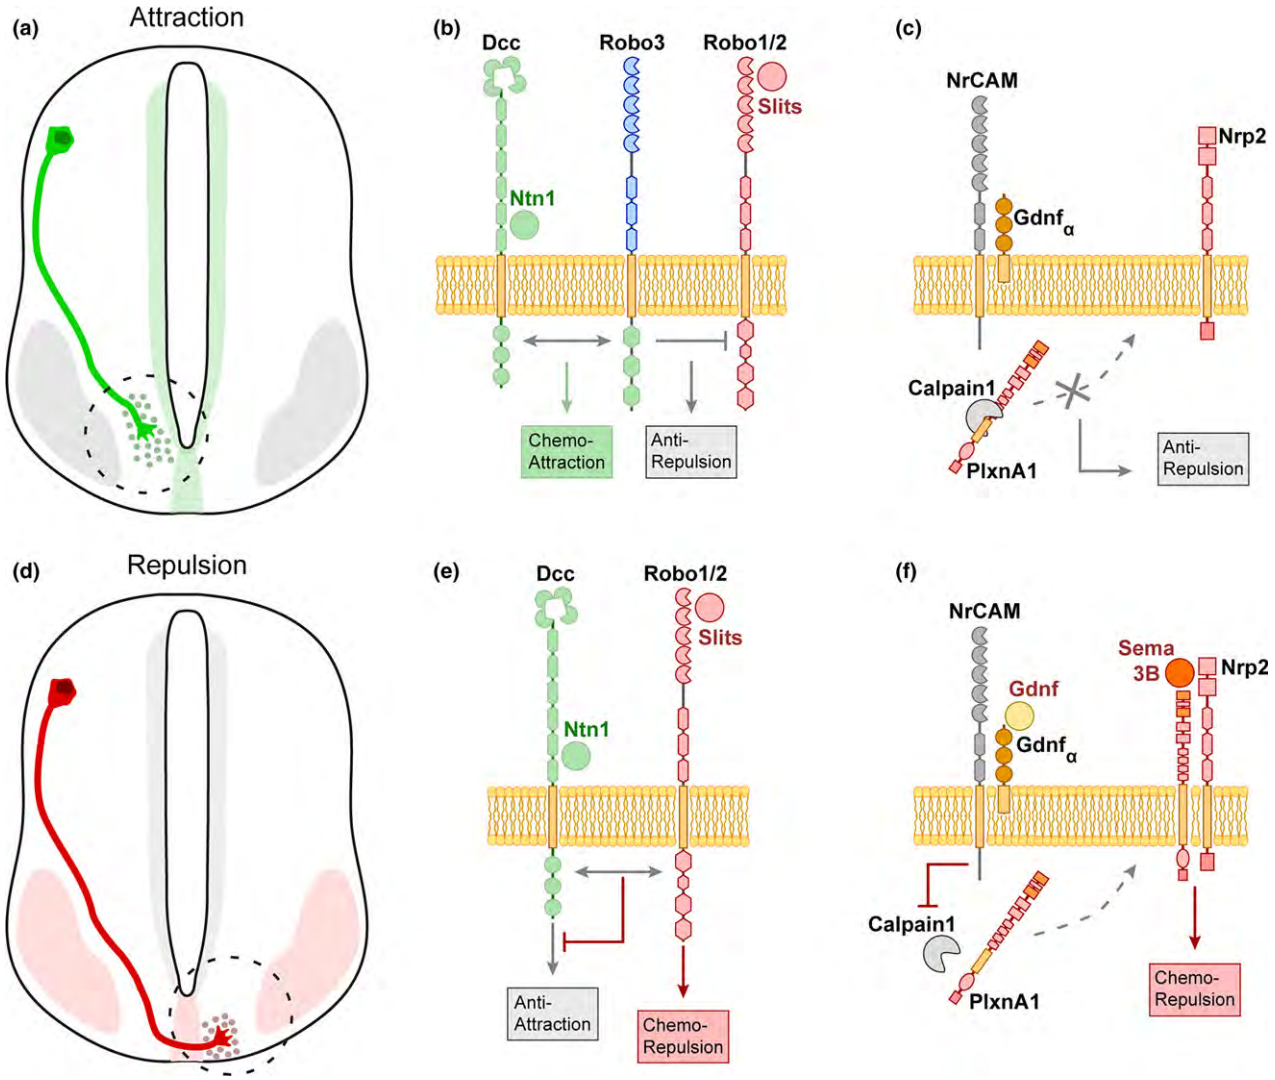

Fig. 3 Spinal cord commissural axons development: pre and post-crossing guidance mechanisms. (a) Commissural axons arise from the dorsal portion of the spinal cord. To cross the midline, they first have to be guided to the floor plate. This first process involves several guidance receptors that trigger the axon outgrowth toward the ventral midline. (b) Pre-crossing axons express the Roundabout 3 (Robo3) receptor. Robo3 interacts with deleted in colorectal cancer (Dcc) receptor and both promote axon extension to the floor plate in response to Netrin-1. Netrin-1 was first thought to act as long-range cue but recent studies suggest that it acts as short-range cue. Robo3 might also prevent Slit repulsion by interacting with the Robo1/2 receptors. (c) Moreover in pre-crossing commissural axons, the presence of calpain induces a cleavage of the PlexinA1 receptor, inactivating this repulsive signalling pathway. (d) After midline crossing, commissural axons switch from midline attraction to repulsion. They become sensitive to repulsive cues secreted by floor plate cells which prevent midline re-crossing. Axon then start to extend rostrally toward their final targets. (e) At the floor plate, Robo3 is down-regulated, and Robo1/2 interaction with Slits blocks the Dcc-Netrin-1 attractive signalling. (f) In addition, the expression of Gdnf by floor plate cells inhibits calpain activity on crossing fibres, allowing PlexinA1 to reach the membrane where it interacts with Neuropilin2, where this receptor complex triggers midline repulsion upon binding Sema3B.

differentiation: albino animals have a shorter time window during which iRGCs are born which is compensated by an increased number of cRGCs (Bhansali *et al.* 2014). Furthermore, the functional comparison of gene expression in albino and pigmented retinas, showed that the Wnt-pathway, which controls iRGC differentiation and cell proliferation, is dysregulated in albino animals (Iwai-Takekoshi *et al.* 2018). Rescue of ipsi-lateral deficit via blockage of Nr-CAM may improve visual capability in albino animals, thereby providing a paradigm for functionally investigating the consequences of natural ipsi-lateral depletion (Williams *et al.* 2006).

Interestingly, the existence of another population of RGCs has been described to project between the two retinas (retino-

retinal projection) in various vertebrate species (Müller and Holländer 1988; Tóth and Strznicky 1989; Nadal-Nicolás *et al.* 2015). More recently, it was described that this population resides in the ventro-nasal retina and is transient (E16.5 to postnatal day 4) (Murcia-Belmonte *et al.* 2019). These late-born RGCs were shown to express Unc5c, a netrin-1 receptor. Upon reaching the optic chiasm, Unc5c-positive RGCs are repelled by netrin-1 and project into the contralateral optic nerve. Indeed, Unc5c is both sufficient and necessary for retino-retinal projections (Murcia-Belmonte *et al.* 2019). However, the precise connection and function of this projection remains to be characterized. Moreover the implication of this projection in co-ordinating spontaneous activity remains to be studied.

Spinal cord

In the developing spinal cord, midline crossing takes place ventrally through a structure named the floor plate (FP). The FP is a crucial patterning center composed of specialized cells that contribute to the specification of the neuronal lineages of the neural tube and adjacent territories.

Moreover the FP is a source of both growth-promoting and growth-repulsive cues for commissural axons, such as netrin-1 and Slits (Chédotal 2019). In vertebrates, spinal commissural axons navigate first ventrally toward the floor plate (Fig. 3a), cross the midline and then turn rostrally or caudally (Fig. 3d). According to the current model, the sensitivity to midline repellents is silenced in pre-crossing commissural growth cones as they navigate toward the FP. However, during FP crossing, commissural growth cones gain responsiveness to FP repulsive cues. The post-crossing commissural neurons are thus expelled from the midline, and also prevented from re-crossing the FP. At later stages, they follow rostro-caudal gradients of guidance cues, turning rostrally or caudally in the ventral or lateral funiculi (Gaudet and Fonken 2018; Ducuing *et al.* 2019; Chédotal 2019).

Commissural axon guidance before midline crossing

The earliest born spinal commissural neurons will extend their axons toward the pial surface of the spinal cord and ventrally toward the FP (Fig. 3a). For many years it was thought that a long-range gradient of the secreted protein netrin-1 is generated by the FP and attracts commissural neurons ventrally upon binding the receptor Dcc (Hiramoto *et al.* 2000; Finci *et al.* 2015). However, recent studies have challenged this model and rather support a local and haptotactic function of netrin-1. Indeed, netrin-1 is not only expressed by FP cells but also by the neural progenitors of the ventricular zone of the spinal cord and brainstem. In support to this model, specific deletion of netrin-1 at the FP, does not perturb commissural axon crossing in the hindbrain (Dominici *et al.* 2017; Yamauchi *et al.* 2017). Interestingly, in the spinal cord, midline crossing appears slightly delayed (Moreno-Bravo *et al.* 2019) and some axons are misguided before crossing (Varadarajan *et al.* 2017; Moreno-Bravo *et al.* 2019; Wu *et al.* 2019). These results suggest that floor plate-derived netrin-1 is dispensable for commissural axon crossing, but also highlight a different mechanism of action of netrin-1 between the hindbrain and the spinal cord. Importantly, ablating netrin-1 expression in ventricular zone progenitors severely perturbs midline crossing in the brainstem (Dominici *et al.* 2017; Yamauchi *et al.* 2017) but only mildly in the spinal cord (Moreno-Bravo *et al.* 2019). However, the simultaneous deletion of ventricular and FP derived netrin-1 prevents midline crossing (Moreno-Bravo *et al.* 2019). Therefore, in the spinal cord, both sources of netrin-1 cooperate to guide commissural neuron at the midline. Other secreted proteins such as VEGF (Ruiz de Almodovar *et al.* 2011) and Shh (Charron *et al.* 2003; Bovolenta and Sanchez-Arrones 2012; Sloan *et al.* 2015; Wu *et al.* 2019) are expressed at the floor plate and act redundantly with netrin-1 to attract axons as they get close to the FP.

Robo3, a member of the Roundabout (Robo) family, plays a key role in midline guidance. This receptor is expressed transiently by commissural axons in mouse spinal cord, midbrain and hindbrain and then is rapidly down-regulated after the axons have crossed the FP (Belle *et al.* 2014; Zelina *et al.* 2014). It is expressed in human pontine neurons (Jen *et al.* 2004) and in hindbrain and spinal cord commissural axons of birds (Philipp *et al.* 2012; Escalante *et al.* 2013; Friocourt and Chédotal 2017) and other vertebrate species (Friocourt *et al.* 2019). The absence of Robo3 leads to a complete loss of several commissures in mice and in humans (Jen *et al.* 2004; Marillat *et al.* 2004; Sabatier *et al.* 2004; Renier *et al.* 2010; Michalski *et al.* 2013). The mechanism through which Robo3 controls commissure development is not completely understood. However, it was proposed that Robo3 expression in pre-crossing commissural neurons repress Slit/Robo repulsion (Fig. 3b), thus allowing commissural axons to reach, enter, and cross the ventral midline in response to netrin-1 attraction (Sabatier *et al.* 2004; Jaworski *et al.* 2010; Chédotal 2011). This mechanism has been validated in the spinal cord and lateral reticular nucleus. Interestingly, the inferior olivary nucleus does not seem to follow the same mechanism (Di Meglio *et al.* 2008). However, it was initially proposed that Robo3 may facilitate attraction of commissural neurons to the floor plate, independently of Slit/Robo signaling (Sabatier *et al.* 2004; Di Meglio *et al.* 2008; Jaworski *et al.* 2010). More recent studies support this notion. Indeed, whilst non-mammalian Robo3 retained its ability to bind Slits, the mammalian orthologue of Robo3 has lost key residues in the Slit/Robo binding domain (Zelina *et al.* 2014). Instead, it possesses the ability to bind to netrin-1, by creating a receptor complex between Dcc and Robo3 via Src kinases, on a conserved tyrosine residue and contributes to the attractive actions of netrin-1 (Zelina *et al.* 2014). Therefore, Robo3 might

promote attraction to the ventral midline rather than counteract repulsion.

To date, several transcription factors have been associated with the most dorsal commissural population, dI1, which arises from the *Atoh1*$^{+}$ domain (Chédotal 2014). These interneurons are divided in two different subtypes depending on the location of their targets: ipsilateral (dI1i) or contralateral (dI1c) (Wilson *et al.* 2008). Interestingly, their projection pattern relies on the balance between the expression of two transcription factors *Lhx2* and *Lhx9* (Lim homeobox) and their upstream activation by the transcription factor *Barhl2* (Ding *et al.* 2012). Lhx2 is able to directly bind to the regulatory region of *Robo3* and modulate its expression in a dose-dependent manner. Moreover in *Lhx2/9* knockouts, most of dI1 interneurons fail to cross the midline and project ipsilaterally (Wilson *et al.* 2008; Marcos-Mondejar *et al.* 2012).

Furthermore, the transcription factor Zic2 triggers an ipsilateral transcriptional program but also inactivates a contralateral one (Escalante *et al.* 2013). Indeed, down-regulation of *Zic2* by *in utero* electroporation of siRNA induces an abnormal up-regulation of Robo3 and a contralateral projection of dorsal horn neurons. A *Zic2* gain of function has the reverse effect, reducing *Robo3* expression and an increase of ipsilateral projections. In addition to modulating Robo3 expression, Zic2 is necessary and sufficient to induce EphA4 expression and commissural neuron repulsion in response to midline ephrinB's.

Commissural axon guidance after midline crossing

Upon FP crossing, commissural axons become sensitive to a myriad of repulsive guidance molecules expressed at the FP. However, prior to midline crossing, commissural axons do not express the receptors (at the surface) required to sense this repulsive environment. One such example is the repulsive receptor, PlexinA1, which is down-regulated at the surface of commissural neurons prior to midline crossing (Fig. 3c). PlexinA1 down-regulation at the growth cone involves the protease, Calpain-1 (Nawabi *et al.* 2010; Charoy *et al.* 2012). However upon FP entry, commissural neurons become exposed to the NrCAM that inhibits calpain-1 activity (Fig. 3f). As a result, PlexinA1 can accumulate at the growth cone which becomes sensitive to the repulsive cue Sema3B (expressed at the FP) (Nawabi *et al.* 2010; Charoy *et al.* 2012). In addition to PlexinA1, the semaphorin receptor Neuropilin 2 (Nrp2) is also expressed at the growth cone following FP entry. Indeed, Sema3B and Nrp2 double mutants display FP stalling as well as post-crossing misrouting (Nawabi *et al.* 2010; Parra and Zou 2010).

Slits are other repulsive cues expressed at the FP (Brose *et al.* 1999). As with PlexinA1 and Nrp2, commissural axon growth cones start expressing the Robo 1 and Robo2 receptors only after midline crossing, and become sensitive to Slit repulsion (Fig. 3e). Indeed, deletion of Robo receptors results in commissural axons stalling at the FP (Long *et al.* 2004; Garbe and Bashaw 2007; Blockus and Chédotal 2016). However, Silts can also function independently of Robo receptors. In vertebrates, Slits can be cleaved into two separate fragments (Brose *et al.* 1999; Wang *et al.* 1999). The shorter fragment (Slit-C) is able to bind to PlexinA1 in commissural neurons to induce growth cone collapse (Delloye-Bourgeois *et al.* 2015).

Once commissural axons have exited the FP, they are then guided by other cues to continue either rostrally or caudally. Little is known about the cues guiding postcrossing axons along the midline. However, Wnt signaling has been shown to be critical in this process (Onishi *et al.* 2014). An expression gradient of several Wnt family proteins controls the rostral turning of post-crossing commissural axons through an attractive mechanism involving the Frizzled3 (Fzd3) receptor (Lyuksyutova *et al.* 2003; Yoshikawa *et al.* 2003). The disruption of the Wnt gradient, results in a randomization of the growth of post-crossing commissural axons, which randomly turn toward the anterior or posterior part (Yoshikawa *et al.* 2003; Zou 2004). Recently, a mechanism orchestrating Wnt activation has been proposed. During FP crossing, commissural neurons expressing Smoothened (Smo) are exposed to the morphogen sonic hedgehog (Shh). This interaction leads to the reduction in mRNA translation of Shisa2, a well-known Wnt signaling inhibitor. Shisa2 inhibits the Wnt receptor Frizzled (Fzd3) trafficking to the cell surface by interfering with its glycosylation, inactivating Wnt signaling (Onishi and Zou 2017). Moreover it has been shown that components of the planar cell polarity signaling pathway mediate Wnt attraction and the anterior turning of commissural axons (Lyuksyutova *et al.* 2003; Zou 2012; Onishi *et al.* 2014). In addition to the planar cell polarity pathway, the canonical Wnt signaling pathway is critical in mediating post-crossing commissural neuron turning. Indeed, down-regulation of both Lrp5 and Lrp6 (Low density lipoprotein receptor-related protein, co-receptors for Frizzled), which are required in the β-catenin-mediated canonical Wnt pathway, lead to major defects in post-crossing commissural neurons (Avilés *et al.* 2016).

Shh also guides post-crossing commissural axons (Bourikas *et al.* 2005; Yam *et al.* 2012). After crossing, commissural axons become repelled by Shh and project anteriorly along a posterior-high Shh and anterior-high Wnt4 gradients. However, instead of mediating its action through Patched or smoothened, Shh acts through the Hedgehog interacting protein. Further experiments showed that this switch in Shh responsiveness depended on the levels of 14-3-3 proteins, which are low in pre-crossing and high in post-crossing commissural neurons, and modulate Protein Kinase A activity (Yam *et al.* 2012).

Peripheral nervous system development

The bilaterian nervous system is subdivided in two main components: the central and the peripheral nervous systems

(CNS and PNS). Permanent cross-talk between the CNS and PNS is critical for integration of sensory inputs. In the 4th century BC, *Alcmaeon of Croton* (Goddard *et al.* 1996) (Zolog 1994) proposed the first theory about channels ("poroi" in ancient greek) that would connect the senses and the brain, this last one being the center of human perception. Later, it became clear that all sensory perception being mechanical, auditory, gustatory, and olfactory were relayed to the CNS through the "nerves" (Mazengenya and Bhikha 2017). Indeed, the precise interplay between these two networks develop in parallel during embryonic development (Ben-Arie *et al.* 2000). Additionally, it has been demonstrated that both axon guidance and neuronal activity can strongly modulate connections between the PNS and the CNS (Bonanomi and Pfaff 2010; Wang and Bergles 2015). Nevertheless, the PNS is itself formed by different components, each specialized in the transmission of a specific signal to the CNS. These signals are transmitted by mechanosensory, chemical or thermal receptors projecting to the mammalian spinal cord via nociceptive afferents.

Drosophila bristles are sensory organs that are tightly distributed and contain one single mechanosensory neuron that specifically projects to the CNS. These axons can be guided by cell adhesion molecules, such as Neuroglian or Flamingo (Martin *et al.* 2008; Steinel and Whitington 2009), but also by other guidance molecules, such as Plexins or semaphorins (Wu *et al.* 2011). Down syndrome cell adhesion molecule (DSCAM) is a transmembrane receptor of the immunoglobulin-superfamily (Chen *et al.* 2006). DSCAM has since been described to regulate cell targeting, axon branch specification, and dendrite patterning (Schmucker *et al.* 2000; Wang *et al.* 2002a; Dascenco *et al.* 2015). The repulsive molecule, Slit, has been shown to bind and signal through DSCAM1 independently of Robo receptors (Chen *et al.* 2006). Indeed, local binding to Slit drives spatial specificity of axon collateral formation. Furthermore, Chen *et al.* (2006) report that many DSCAM isoforms exist and particular DSCAM isoform mosaicism in a specific growth cone appears to dictate local guidance decisions, such as the formation of axon collateral projections.

The inner ear is essential for the transmission of sounds and their integration by the CNS. This complex sensory organ is composed of bipolar spiral ganglion neurons (SGN) that connect the ipsilateral cochlear nucleus and the mechanosensory inner and outer hair cells located in the organ of Corti (Nayagam *et al.* 2011). SGNs project to both the inner (IHC) and the outer hair cells (OHC). During the course of development, both type I and II project to the OHC but type I SGNs appear to refine in later stages and only project to the IHC (Huang *et al.* 2012; Safieddine *et al.* 2012; Druckenbrod and Goodrich 2015). The use of molecular markers to target single spiral ganglia has revealed key morphological differences between type I and type II SGNs as well as their specific projection patterns to the IHC or outer hair cells OHC (Druckenbrod and Goodrich 2015; Coate *et al.* 2015). Indeed, type I and II SGNs were shown to be molecularly different. Type I SGNs express the semaphorin receptor Nrp2 and its co-receptor PlexinA3 (Coate *et al.* 2015). Upon binding Sema3F, secreted by the OHC, type I SGNs are repulsed and restrict their projections to the IHC (Coate *et al.* 2015). More recently, the use of single sequencing has allowed a more in depth characterization of SGNs. In this study, Shrestha *et al.* (2018) identified that type I SGNs can be further classified into three different subtypes. These data suggest a growing complexity of the auditory system formation and integration of external signals.

These examples underline the complexity of PNS development. With the aim of understanding the surrounding environment, each of these systems seems to have its own guidance mechanisms, which through a tight and orchestrated regulation, establish an essential pathway between sensory neurons and superior brain areas. Novel genetic and technical approaches also highlight the cellular heterogeneity in these systems, most of them considered quite homogeneous until recently. The understanding of the molecular differences between cell types in a determined structure is a key element in establishing therapeutic approaches such as stem cell therapy. Moreover these molecular differences can also help to understand the possible effects of different known guidance mechanisms. Lastly, several groups have tried to understand the role of spontaneous activity in these structures. Neural activity has been observed to happen randomly in most structures, since early development (Shrestha *et al.* 2018). This neuronal activity could be essential to pattern and reinforce synapses, as was shown in the visual system (Ackman and Crair 2014).

Non-traditional roles of axon guidance molecules

Axon guidance molecules have been extensively studied during axonal development but have also been shown to be critical in many diverse biological processes such as angiogenesis and cell migration (Castets and Mehlen 2010; Aberle 2019). Undeniably, cortical development is dependent on cellular migration. A fundamental question for the past decades has been the emergence of the neocortex, a specific feature of the mammalian brain (Finlay and Darlington 1995; Northcutt 2006). Cortical development begins with the division of radial glial progenitor cells (RGPCs), which gives rise to all cortical neurons and glia. RGPCs are aligned at the cortical ventricular zone and undergo mitosis to either self-renew (symmetric division = indirect neurogenesis), or differentiate into cortical neurons (asymmetric division = direct neurogenesis). However, in mammals RGPCs can also divide symmetrically to give rise to an intermediate progenitor cell (IPCs) (Haubensak *et al.* 2004; Noctor *et al.* 2004; Miyata *et al.* 2004). IPCs can either self renew or differentiate into cortical neurons.

Thus, IPCs have been proposed to serve as the main determinant for cortex expansion in mammals (Malatesta *et al.* 2000; Noctor *et al.* 2001; Smart 2002; Noctor *et al.* 2004; Kriegstein *et al.* 2006; Hansen *et al.* 2010). Recently, Cárdenas *et al.* (2018) have identified a novel role for Robo 1/2 in regulating radial glia cortical migration. By comparing the mouse olfactory bulb (OB) (reminiscent of the reptilian paleocortex) to the cortex (Cx), Cárdenas *et al.* (2018) observed that the OB solely developed by direct neurogenesis whereas the Cx was developed mostly by indirect neurogenesis. Interestingly, Robo1/2 were expressed in a gradient, with a high-low expression in the OB compared to the Cx. Furthermore, it was shown that Robo1/2 can regulate the notch canonical signaling pathway via Delta-like 1 as well as the ligands *jagged* 1 (*Jag1*) and *Jag2*. The mechanism put forward is that high Robo1/2 expression in the OB reduces Delta-like 1 expression and increases *Jag1* and *Jag2* expression, resulting in asymmetric division and direct neurogenesis. Indeed, gain of function experiments showed that high Robo1/2 expression is sufficient to induce direct neurogenesis in the mouse Cx (Cárdenas *et al.* 2018). Interestingly, amniotes deprived of a neocortex, such as birds and reptiles, show high Robo1/2 expression in the cortex (Cárdenas *et al.* 2018). Thus, the authors propose silencing of Robo1/2 as an evolutionary switch giving rise to indirect neurogenesis in mammals.

The Fibronectin Leucine Rich-repeat Transmembrane (FLRTs) proteins have also been identified as axon guidance molecules. For instance, thalamocortical axons expressing Dcc are not sensitive to the netrin-1 gradient present in the thalamus because of Robo1 silencing (Leyva-Díaz *et al.* 2014). However, FLRT3 can sequester Robo1 to allow for Dcc expression at the surface of thalamocortical neurons, thereby activating netrin-1 responsiveness (Leyva-Díaz *et al.* 2014). More recently, FLRTs have also been implicated with cortical progenitor migration (del Toro *et al.* 2017). In mammals the cortex initially forms as a laminar sheet. Whilst some mammals (mice and rats) will retain this smooth cortical development (lissencephaly, Fig. 4a), other mammals (primates and ferrets) develop cortical folds (gyrencephaly, Fig. 4b). FLRT1/3 have recently been shown to be critical players in this process (del Toro *et al.* 2017). Interestingly, genetic ablation in mice of FLRT1/3 promotes cortical folding (del Toro *et al.* 2017). Whilst the proliferation rate of radial glia cells was unchanged, their migratory patterns were significantly perturbed. Indeed, loss of FLRT1/3 increased neuronal clustering and radial migration rate. This creates columns of migrating progenitors, inducing an asymmetric proliferation across the surface of the cortex and as a result creating sulci. Of note, FLRT1/3 expression is reduced in gyrencephalic species, suggesting that the abundance of FLRT1/3 during evolution promoted cortical smoothing (lissencephaly).

Whilst typical axon guidance proteins such as Slits and ephrins have been largely discussed, a growing body of literature has shown that some lipids could be atypical guidance molecules. Phospholipids are considered the major components of cell membranes and they have the ability to form amphipathic lipid bilayers. Their role in axon guidance was first proposed by some in vitro experiments in which Lysophosphatidic acid, an intermediate substance of lipid synthesis, was shown to be able to induce growth cone collapse, neurite retraction and cell rounding in neuroblastoma-derived neuronal cell cultures (Jalink *et al.* 1993). Later on, further evidence highlighted their role on primary cultured chick embryo neurons and on isolated retinal growth cones (Saito 1997; Campbell and Holt 2001). Additional *in vivo* evidence of the axon guidance role of lysophospholypids were obtained in the *Xenopus* visual system. In absence of sphingosine 1-phosphate, retinal projections were misguided and invaded abnormal areas (Strochlic *et al.* 2007). Recently, a novel role for phospholipids on axon guidance was brought to light: Phosphatidyl-B-D-Glucoside (PtdGlc) is localized in radial glia and nascent astrocytes *in vivo* (Nagatsuka *et al.* 2006; Kinoshita *et al.* 2009). PtdGlc can be hydrolysed in *lyso*PtdGlc and released into the extracellular environment (Guy *et al.* 2015). In the embryonic chick and mouse spinal cord, TrkA and TrkC dorsal root ganglion axons enter the CNS through the dorsal root entry zone. Only TrkC axons get into the primordial dorsal funiculus where *Lyso*PtdGlc is found (Guy *et al.* 2015), suggesting a possible repulsive role for nociceptive afferences (TrkA). TrkA enriched dorsal root ganglia (DRG) explants showed chemorepulsion *in vitro* in presence of a *lyso*PtdGlc gradient. Furthermore, blocking antibodies for *lyso*PtdGlc used *in ovo*, showed a misprojection of TrkA axons in the primordial dorsal funiculus. Finally, a receptor screening proposed GPR55 as putative receptor for this extracellular cue. GPR55 *knockout* mice phenocopy the DRG axon misprojections induced by *lyso*PtdGlc blocking antibodies, confirming the role of this receptor-sensing glia released *lyso*PtdGlc in this system (Guy *et al.* 2015).

Axonal regeneration

In the early 20th century, pioneering studies from Ramón y Cajal showed that the mammalian CNS is unable to regenerate following a lesion (Ramón y Cajal 1914). Neuroscientists have since delved on the idea that understanding CNS development could be the key to hi-jack regenerative mechanisms following CNS injury. Interestingly, similar lesion experiments carried out on dorsal root ganglia axons (which belong to the PNS) resulted in robust regeneration of their peripheral branch and functional recovery following the lesion, whereas their central branch projecting into the CNS did not regenerate. Therefore, something either intrinsic or extrinsic to CNS neurons is responsible for their lack of regeneration (Fig. 5a). This fundamental question has sparked years of intensive research

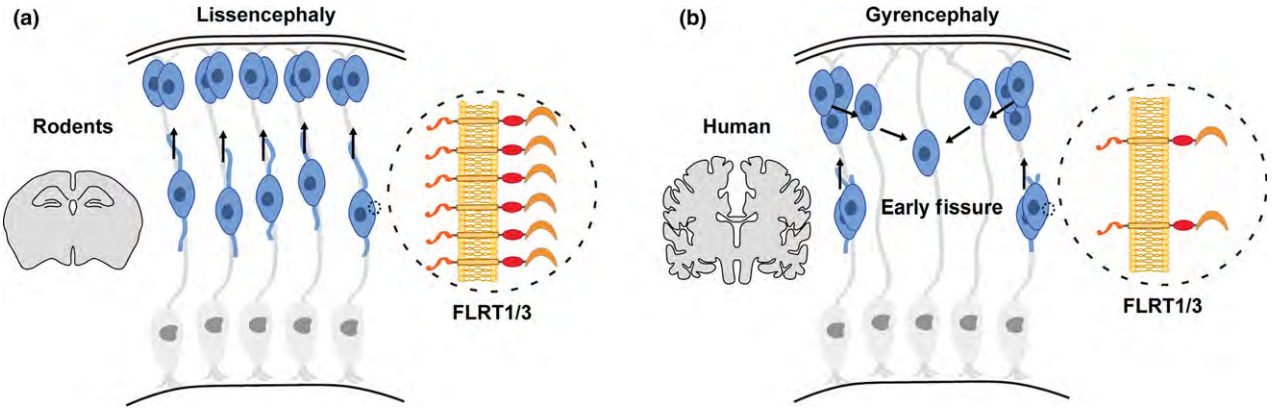

Fig. 4 Cortical folding relies on Fibronectin Leucine Rich-repeat Transmembranes (FLRTs) expression. Cortical folding appears to be dependent on the presence of the cell adhesion proteins FLRT1 and FLRT3 during cortical expansion, where (a) higher expression in migrating cortical progenitors is associated with parallel migration, resulting in a lissencephalic cortex. Conversely, (b) lower FLRT1 and 3 expression favors lower migration rates, and promotes lateral adhesion resulting in a gyrencephalic cortex.

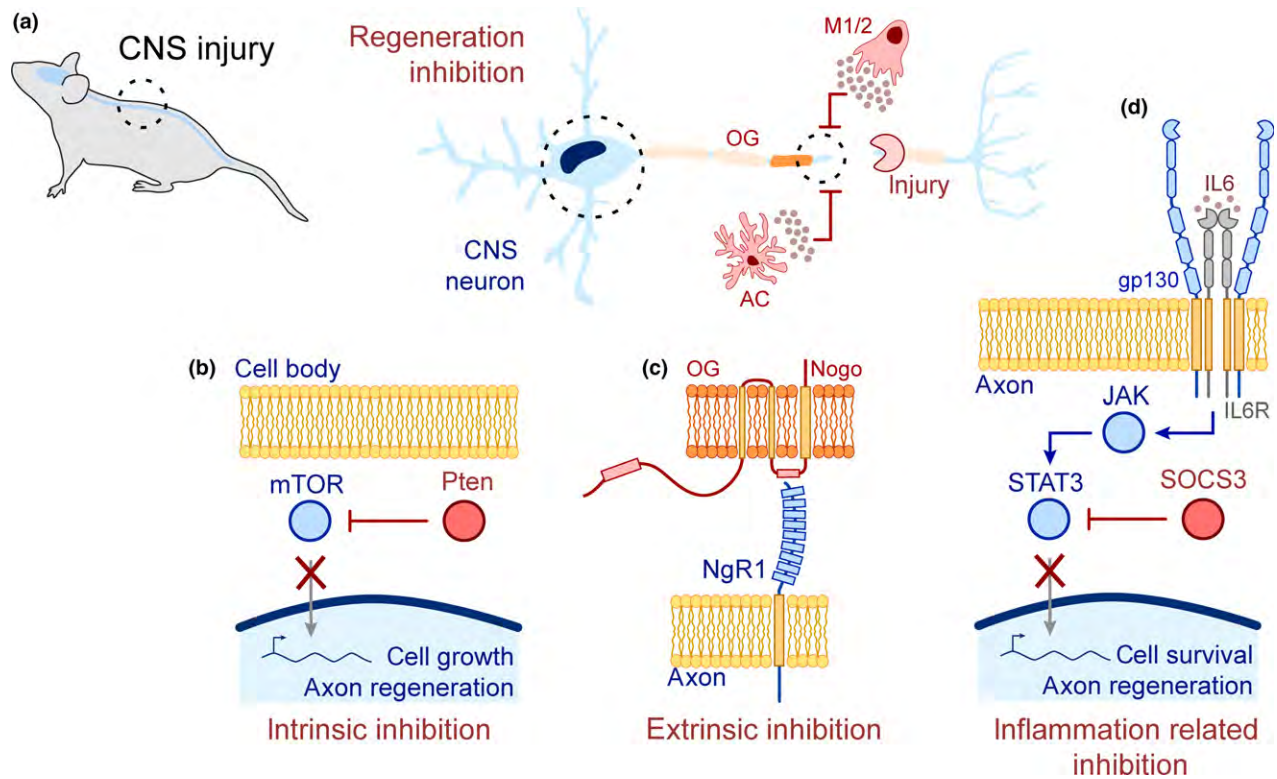

Fig. 5 Molecular mechanisms for CNS regeneration. (a) After CNS injury, extrinsic and intrinsic mechanisms impair axonal regeneration. These events occur both in the cell soma and the injure site and they are the main targets of strategies aiming at promoting regeneration. Most of the extrinsic inhibition comes from the recruitment of astrocytes and macrophages to the injury area and the "activation" of local oligodendrocytes. (b) In injured neurons, Pten blocks the mammalian target of rapamycin (mTOR) pathway that induces axon regeneration. The complete or conditional depletion of Pten in RGCs or corticospinal tract neurons, promotes the regeneration of their axons after injury. (c) Moreover oligodendrocytes at the lesion site, start to express inhibitory signalling molecules such as Nogo and myelin associated glycoproteins that will block axonal regeneration. The simultaneous depletion of Pten and Nogo, significantly promotes axonal regeneration. (d) Finally, The expression of cytokines by macrophages also promote axon outgrowth. Suppressor of cytokine signaling 3 (SOCS3) expression in lesioned axons blocks signal transducer and activator of transcription 3 (STAT3), a downstream effector of this cascade. Together with Pten, the depletion of SOCS3 also increases the regeneration rate of RGC axons.

to understand the molecular mechanisms activated after axotomy and to develop strategies for inducing axonal regeneration. Here, we will discuss some of the current approaches and challenges in regeneration of CNS and PNS axons.

Central nervous system regeneration

Visual system regeneration

Optic nerve (ON) transection or crush, have become a predominant models for studying CNS regeneration. The ON only contains axons which originate from RGC neurons in the retina. Directly following ON lesions, multiple inhibitory pathways are triggered. The activator protein 1 and the transcription factor subunit c-Jun (Fos-binding protein p39) both act in synergy to trigger cell death in RGCs following an experimental axotomy (Hüll and Bähr 1994). In addition, interplay between c-Jun and the activating transcription factor 2 dictates cell fate following ON crush. When both are up-regulated, they promote cell survival. However, reduction in activating transcription factor 2 expression induces apoptosis (Martin-Villalba *et al.* 1998). The activation of c-Jun is driven by calcium influx, since specific inhibition of calcium channels leads to reduction of c-Jun activity in ON crush models. Remarkably, the inhibition of calcium channels not only reduces acute axon neurodegeneration, but also improves axonal regeneration (Ribas *et al.* 2017). The RhoA/ROCK/LIMK pathway, which can be activated by a variety of cytokines and inflammatory mediators, is another critical inhibitory mechanism that mediates repulsive signals in the injured CNS. The knockdown of either Rho associated coiled-coil containing protein kinase 2 (ROCK2) or its downstream substrate LIM domain kinase 1 promotes neuronal regeneration following ON crush. However, only ROCK2 knockdown was found to be neuroprotective in RGCs following ON axotomy (Koch *et al.* 2014). ROCK2 down-regulation leads to reduced calpain and caspase3 activity and a concurrent increase in protein kinase B (Akt) activity (Koch *et al.* 2014). Pharmacological inhibition of RhoA/ROCK pathway through Y-27632 or Fasudil administration promotes neuronal regeneration in a dose-dependent manner, probably because of enhanced MAPK and Akt phosphorylation (Lingor *et al.* 2007; Lingor *et al.* 2008). Pharmacological modulation of this pathway, thus, could represent a therapeutic approach for CNS cell restoration.

Another inhibitory pathway exists in the surrounding environment of the lesion (Fig. 5b-d). The myelin inhibitory proteins: Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte-myelin glycoprotein suppress axonal growth in the optic nerve by acting through Nogo receptors where they act in an orchestrated manner with other co-receptors, such as p75 neurotrophin receptor and epidermal growth factor receptor (Domeniconi *et al.* 2002; Wang *et al.* 2002b; Wang *et al.* 2002c; Koprivica 2005). Notably, deletion of its downstream signaling pathway, through protein kinase C appears to restore axonal growth by blocking Rho activation (Sivasankaran *et al.* 2004). Furthermore, the over-expression of dominant negative Nogo receptors in RGCs promoted axonal regeneration (Fischer 2004).

Alternatively to extrinsic factors inhibiting axon regeneration, many groups have shown that the intrinsic mechanisms prevent CNS axon regeneration (He and Jin 2016). One critical pathway, put forward by the group of Zhigang He, was the phosphoinositide 3-kinase/mammalian target of rapamycin (mTOR) signaling pathway. Following ON crush, a dramatic decrease in phosphoinositide 3-kinase/mTOR activity is observed (Park *et al.* 2008). Indeed, following ON crush, mTOR activity is suppressed by the phosphatase and tensin homolog (PTEN) (Fig. 5b). Genetically deleting PTEN in RGCs, using an adeno-associated virus, induces robust and long-distance axon regeneration following ON crush (Park *et al.* 2008). Interestingly, PTEN deletion following ON crush only stimulates the regeneration of a subset of RGCs (Park *et al.* 2008). A large number of RGC types exists with distinct physiology and projection patterns (Sanes and Masland 2015; Martersteck *et al.* 2017). Therefore, it is not surprising that distinct RGCs types respond heterogeneously to injury. Further studies have shown that a specific subtype of RGCs, the α-RGCs, are able to survive following ON crush and express insulin-like growth factor receptor (IGF1) as well as osteopontin (OPN) (Duan *et al.* 2015). Reprogramming of RGCs after injury is accompanied by changes in mRNA expression profiles. The transcription factors that are expressed after injury appear to determine whether a specific sub-type of RGC will regrow. The Kruppel-like factors 4 and 9 (KLF4 and KLF9), for example, play a major role suppressing axon development (Qin *et al.* 2013; Apara *et al.* 2017). KLF4 interacts with Tyr705-phosphorylated signal transducer and activator of transcription 3 (STAT3) suppressing its activity and function as an intrinsic barrier for regeneration of damaged adult RGC axons (Qin *et al.* 2013). KLF9 functions as another intrinsic inhibitor for axon regeneration as shRNA mediated knockdown of KLF9 promote RGC survival and axon regeneration following optic nerve injury *in vivo* (Apara *et al.* 2017). This KLF9-mediated inhibition is via interaction of the upstream kinase c-Jun N-terminal kinase 3 (JNK3) (Apara *et al.* 2017). Recent findings indicate that micro RNAs 135a and 135b (miRNA135s) could regulate KLF4 expression during axon development. Intravitreal administration of miRNA135 induced axon regeneration following ON injury, in part by suppressing KLF4 expression in RGCs (van Battum *et al.* 2018). SOX11, on the other hand, plays a dual role. When overexpressed, it can stimulate axon growth of non-α-RGCs while it induces cell death of α-RGCs following ON crush (Norsworthy *et al.* 2017). In addition to intrinsic growth metabolism, neuroinflammation has been shown to be critical

for RGCs axonal regeneration (Smith *et al.* 2009). The simple intraocular injection of Zymosan (protein-carbohydrate complexes derived from yeast cell wall), which enhances macrophage infiltration in the injured ON, greatly stimulates the expression of GAP-43 in RGC axons, resulting in accelerated axonal regeneration (Leon *et al.* 2000).

During the past decades, major effort has been made toward the development of combinatorial therapeutic approaches, targeting two or more neuronal pathways. Over stimulating cell growth programs by deleting PTEN and suppressor of cytokine signaling 3 (SOCS3) promotes a well-sustained axon regeneration (Fig. 5d), by brake-releasing two independent pathways that converge into axon growth-related gene expression (Sun *et al.* 2011). In an alternative approach, the use of the pro-inflammatory Zymosan, in combination to PTEN inhibition and cAMP analogue administration promotes axonal regeneration, and allows the recovery of long distance axonal degeneration (Kurimoto *et al.* 2010). The critical step following regeneration and functional synapses formation is the restoration of the conductance and visual function following injury. Treatment with the voltage-gated potassium channel blocker 4-aminopyridine (4-AP) or its methyl derivative 4-AP-3-Me restores conduction and visual acuity following PTEN/SOCS3 co-deletion. Similar phenomena were observed when mice were treated with 4-AP following OPN overexpression in the presence of IGF1 and ciliary neurotrophic factor. This highlights the importance of combination therapy for axon regeneration and improving visual conduction (Bei *et al.* 2016).

Spinal cord regeneration

Another attractive model for studying CNS regeneration is that of spinal cord injury (SCI). In addition to its scientific interest, SCI has a dramatic clinical impact, with the world health organization approximating between 250 000 to 500 000 people suffer from SCI each year (Courtine and Sofroniew 2019). The Cortico spinal neurons (CSNs) located in the mammalian neocortex are the major output from the brain to the spinal cord (making up to 90% of projections), which mediate both motor and sensory functions (Wang *et al.* 2017). Indeed, corticospinal tract (CST) lesions, such as a bilateral pyramidotomy, lead to the complete loss of voluntary movement. Following a spinal cord lesion, extrinsic mechanisms such as growth inhibitors or glial scars, inhibit axonal regeneration (Gaudet and Fonken 2018). Several inhibitory signaling molecules have since been identified such as Nogo or myelin-associated glycoproteins (Caroni and Schwab 1988; McKeon *et al.* 1991; Afshari *et al.* 2009; Lang *et al.* 2015). Indeed silencing these inhibitory cues in mouse or rat models of spinal cord injury has shown some success (Schmandke *et al.* 2014). Another approach, led by Zhigang He's group, questioned whether the inability of CNS neurons to regenerate involved intrinsic factors. They identified that mTOR (mammalian target of rapamycin) activity and *de novo* protein synthesis are suppressed after CNS lesions (Park *et al.* 2008). Reactivation of the mTOR pathway by silencing of PTEN (phosphatase and tensin homolog) and TSC1 (tuberous sclerosis complex 1), leads to extensive CST axon regeneration (Park *et al.* 2008). Together, these findings proved that both intrinsic and extrinsic mechanisms were responsible for inhibiting CST axon regeneration after spinal cord injury. Accordingly, the combined genetic deletion of Nogo receptors and PTEN, led to a major increase in the regeneration and sprouting of lesioned CSNs (Geoffroy *et al.* 2015). However, there was little to no functional amelioration in lesioned animals.

The lack of functional rescue observed in double mutants of Nogo and PTEN led to the idea that a better understanding of the locomotor system was required. Indeed, very little was known about the localization, development, and function of the CSNs responsible for voluntary movement. Using retrograde viral tracing strategies, it was found that CSNs were localized in both the motor and somatosensory cortex. Two major nuclei were identified, the rostral forelimb area (RFA) and the caudal forelimb area (CFA) (Wang *et al.* 2017). To better understand the precise function of RFA and CFA CSNs in voluntary task, a food pellet retrieval task was used to tease apart which CSNs were responsible for specific motor movements. Using AAV:Cre-driven GCamp6 expression in CSNs, it was shown that RFA CSNs fired prior to grasping the food-pellet, whereas CFA CSNs fired prior to reaching as well as post-grasping the food pellet (Wang *et al.* 2017). These data provide evidence supporting a parallel organization of motor tasks responsible for specific behavior organized in a topographic manner.

While much work has focused on spinal cord lesions, the majority of patients suffer from partial lesions. However, partial spinal cord injuries still result in complete loss of motor function below the site of injury. This hints toward the idea that unlesioned axons are unable to properly function despite being spared from injury. By carrying out a staggered hemisection of the thoracic spinal cord on opposing sides, Chen *et al.* (2018) took advantage of a partial spinal cord injury model to carry out a small compound screening approach. They identified that an agonist of the potassium/chloride transporter (KCC2) resulted in increased weight bearing strength in mice following lesion (Chen *et al.* 2018). Because of the complexity of spinal circuits, they questioned whether KCC2 activity was required by multiple or distinct neuronal subsets (excitatory, inhibitory, motor). Interestingly, only overexpression of KCC2 in inhibitory neurons (Vgat:Cre) resulted in an improved weight-bearing strength in injured mice. Moreover inhibitory neurons below the staggered lesion were dispensable for this rescue, since overexpressing KCC2 only in inhibitory neurons between the lesions was sufficient to rescue the weight bearing strength. Overall, this identifies a crucial role for inhibitory interneurons in a closed-circuit to be critical in associating the

excitation to inhibition ratio required to regulate functional recovery following a lesion (Chen *et al.* 2018).

The translation of these findings to the treatment of spinal cord injury, won't be simple as the genetic manipulation of tumor suppressor genes may not be suitable for the clinic. Attractive treatment alternatives could consist of applying growth factors (which occur endogenously in the CNS). However, adult CNS neurons lose their sensitivity to growth factors such as brain-derived neurotrophic factor (Liu *et al.* 2017). Moreover adult CSNs treated with OPN can be sensitized to the IGF1 by reactivating the mTOR pathway (Liu *et al.* 2017).

Furthermore, the identification that spared axons following partial spinal cord injury could be re-synchronized to induce functional recovery opens many questions, one of which, is the importance of inhibitory synapses conserved amongst other species. Indeed, the complexity in human spinal cord circuitry may pose a major challenge toward this clinical implication.

For instance, how does our current understanding on excitatory/inhibitory ratios in the rodent spinal cord translate to the human spinal cord? This is a daunting question since inhibitory feedback loops in human spinal cord may be more complex and thus more challenging to re-stimulate. Furthermore, more research should focus on understanding the coordinated action between neurons and glial cells. Synaptic activity, axonal and dendritic growth and regeneration are fine-tuned by glial cells (Liu *et al.* 2017). There are a few studies investigating how glial scar-induced disruption may be overcome by improving the communication between neurons and glial cells. Of note, exosomes released by glial cells in the PNS have shown to promote robust axonal regeneration and survival (Lopez-Leal and Court 2016). A similar result was obtained from mesenchymal stem cells releasing exosomes following spinal cord injury (Li *et al.* 2018; Liu *et al.* 2019).

Peripheral nerve regeneration

Insults such as physical trauma, chemotherapy or metabolic disorders can lead to peripheral nerve damage (Scholz *et al.* 2009). As previously mentioned, PNS axons have retained considerable capacity to regenerate following injury and to form functional connections with their original targets (Bremer *et al.* 2017). This seems in part because of a cell-intrinsic growth-promoting response of PNS neurons and to a favorable environment for axonal regeneration (Bremer *et al.* 2017). However, many aspects of this process, including how regenerating axons navigate across the lesion site and select their original trajectory at branch choice points, are not well understood *in vivo*. Whilst many animal models have been used to study PNS regeneration, the zebrafish has been heavily studied because of its transparency (allowing for *in vivo* live imaging) as well as the ability for genetic manipulation. Adult and larval fish both have well-defined PNS circuits and stereotyped behaviors, facilitating cell biology studies underlying PNS axon regrowth and synapse re-establishment (He and Jin 2016; Rasmussen and Sagasti 2017).

In vertebrates, spinal motor nerve degeneration after transection occurs through morphological hallmarks characteristic of Wallerian degeneration (Fig. 6a), a stereotyped form of degeneration (Waller 1851). Live imaging on zebrafish showed that following nerve transection, degradation of the distal axon happens within 120–240 min (Rosenberg *et al.* 2012). Moreover it highlighted that individual axons within the transected nerves initiate fragmentation at different times independent of myelination and thickness of the axons. Once initiated, fragmentation occurs along the entire length of the axon within minutes. Recruitment of macrophages to the injury site starts between 60–120 min before nerve fragmentation, and with the onset of axonal fragmentation, macrophages enter the nerve and begin to phagocytose nerve debris. Experimental elimination of Schwann cells through genetic ablation does not change the recruitment and behavior of macrophages to the injury site suggesting that this process is independent on Schwann cells (Dutton *et al.* 2001; Rosenberg *et al.* 2012).

In zebrafish, 80% of regenerating axons retain the ability to select their original branch-specific trajectory in both ventral and dorsal nerve branches following complete nerve transection (Isaacman-Beck *et al.* 2015). After complete nerve transection, usually a single axon emerges from the proximal nerve stump to pioneer a regenerative path across the injury site. At later stages, multiple emerging axons join the pioneering axon and extend with about twice the speed of the pioneering axon across the injury gap. The synaptic low-density lipoprotein receptor-related protein 4 is critical for the regrowth of follower axons across the injury gap and toward their original targets (Gribble *et al.* 2018) (Fig. 6c). Live-cell imaging shows that Schwann cells provide directionality to axons, by crossing the injury site and navigating to their original trajectory. An interaction between Schwann cells and motor axons is triggered following motor nerve transection leading to highly coordinated changes in axonal and Schwann cell morphology during both degeneration and regeneration (Fig. 6b). For instance, once axons start to fragment, Schwann cell membranes, localized distal to the lesion site, undergo dramatic morphological changes returning to a more immature state (Rosenberg *et al.* 2014). Lrp4 promotes the morphological changes associated with Schwann cells re-differentiation after injury-induced de-differentiation. *In vivo* evidence suggests that low-density lipoprotein receptor-related protein 4 promotes peripheral nerve regeneration through a non-canonical, Agrin/MuSK independent signalling pathway that is critical for neuromuscular synapse development in mammals and zebrafish (Gribble *et al.* 2018). The importance of this process in promoting vertebrate nerve regeneration is also confirmed by

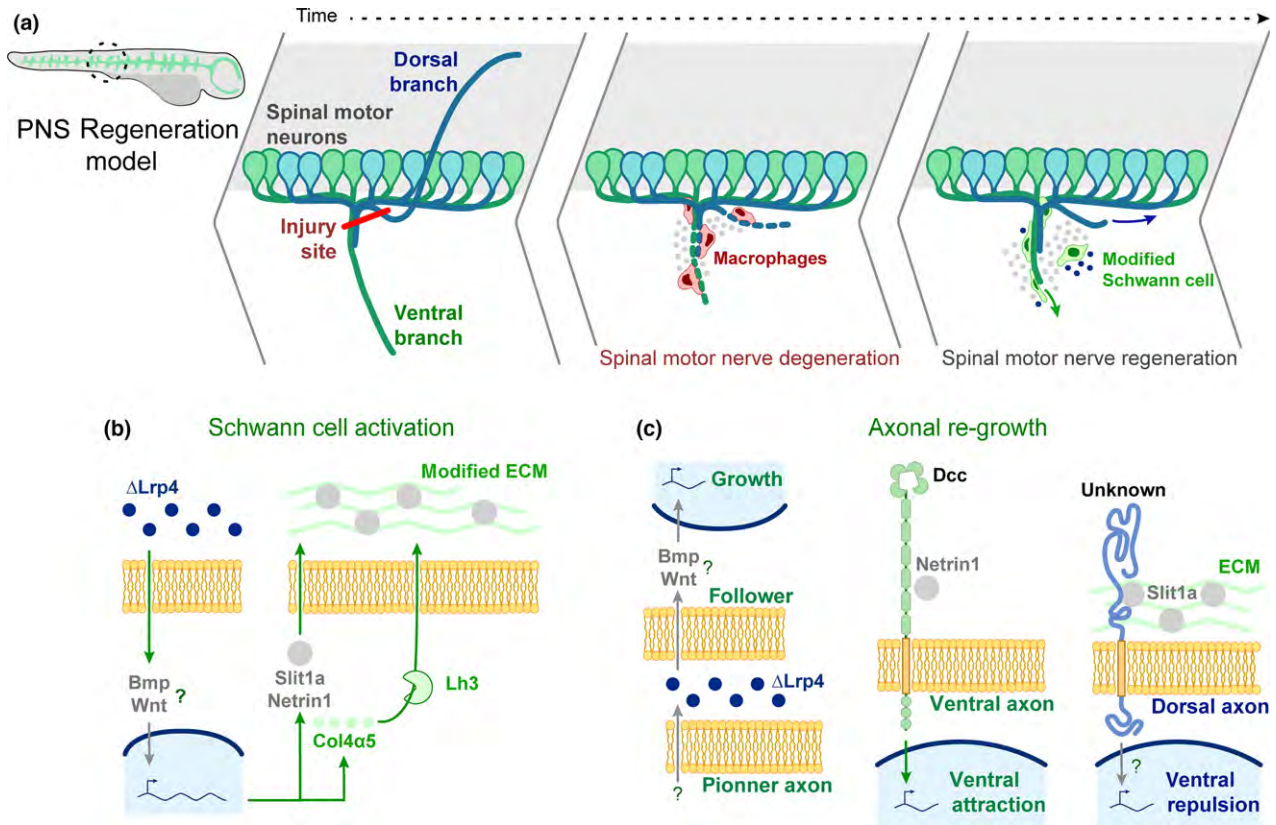

Fig. 6 PNS axon regeneration in zebrafish spinal motor nerves. (a) Zebrafish has extensively been used as PNS regeneration model. Its transparency allows live-imaging of axons and genetic manipulations remain simpler than in mammals. In this model, a transection of both, dorso-ventral spinal cord motor branches is performed. First, a Wallerian degeneration of the sectioned nerves occurs, dependent on macrophages activity. Then, spontaneous regeneration occurs, promoted by intrinsic and extrinsic signals. (b) After injury, 80% of the lesioned axons retain the ability to regenerate. This relies on Schwann cell activation that will ensure the proper pathfinding of the regenerating axons through different mechanisms. This activation occurs by exposure to ΔLrp4 and triggers the expression of axon guidance molecules (Netrin-1 and Slit1a) and the remodelling of the extracellular matrix (ECM). (c) There is evidence that nerve regrowth relies on the extension of a single pioneer axon that will be used as migration scaffold by follower axons. This process seems dependent on ΔLrp4 but no receptors have been identified yet. Axon guidance of dorsal or ventral projections differs. Netrin-1 and Dcc promotes the growth of ventral axons while Slit1a prevent dorsal axon from growing dorsally, through a yet unknown receptor.

the impairment of peripheral nerve regeneration by Topoisomerase I inhibitor, identified through a fin removal assay performed by Bremer and colleagues, which hypothesizes that Topoisomerase I promotes peripheral nerve regeneration by regulating gene transcription specifically in de-differentiated Schwann cells (Bremer *et al.* 2017).

In zebrafish mutants lacking Schwann cells, 50–80% of transected nerves show a failure in regenerating axons along their original trajectory through the ventral myotome compared with 20% in wild-type (Rosenberg *et al.* 2014). Netrin1 and its receptor DCC have been implicated in promoting the extent of axon regeneration (Fig. 6c): *in vivo Netrin1b* mRNA is expressed in Schwann cells before and after motor nerve transection, and *dcc* mRNA is detectable in motor neurons during initial axonal regrowth. In $dcc^{zm130198}$ mutants, characterized by a 90% reduction of *dcc* mRNA, 40% of regenerating motor axons extended not only along their original path but also along ectopic lateral trajectories. This suggests that DCC is required to guide regenerating ventral motor axons across the injury gap toward their original trajectory *in vivo* (Rosenberg *et al.* 2014).

Early after transection (7–11 h post transection), dorsal axons sprout growth cones that explore the environment with multi-directional extensions and retractions. In the following 2–4 h, only the growth cones extending along the correct dorsal path are stabilized and quickly extend, supporting the existence of extrinsic cues that drive the growth cones through the branch point (Isaacman-Beck *et al.* 2015). Among these cues, the collagen-modifying glycosyltransferase lysyl hydroxylase 3 (*lh3*), expressed by Schwann cells, has a crucial role in promoting target selectivity of regenerating dorsal, but not ventral nerve axons (Fig. 6b). For this

process, equally fundamental is Collagen4a5 (col4a5), the *lh3* substrate, which is over expressed in a small group of Schwann cells located ventral and ventrolaterally to the transection gap. Col4a5 destabilizes mistargeted axons, directing regenerating axons toward their original targets. Following the nerve transection there is an up-regulation of the canonical axon guidance repellent *slit1a* in cells expressing col4a5. Hypothetically, in response to injury, Schwann cells ventral to the transection site, secrete col4a5, which binds and accumulates Slit, thereby forming a repulsive barrier to direct dorsal axons onto their original dorsal path (Isaacman-Beck *et al.* 2015) (Fig. 6c).

Real-time imaging on live zebrafish has allowed deciphering some of the intrinsic and extrinsic mechanisms responsible for peripheral nerve regeneration, but the molecular mechanisms and the specific cellular interactions which are vital for axon regeneration are not completely understood. Furthermore, the identification of other regeneration-promoting molecules could allow the development of new neuronal repair strategies. Based on that premise a fin removal assay was developed that enabled to perform the first whole organism small molecule screen to identify pathways that promote vertebrate nerve regeneration (Bremer *et al.* 2017). The approach utilized the regeneration of the ring-like nerve of zebrafish larvae pectoral fin after removal as readout of axonal regrowth. 480 bioactive compounds with known biological targets were screened to identify molecular pathways promoting nerve regrowth. After excluding 134 compounds which affected larvae health, the remaining compounds were combined in 69 distinct pools and added each of these pool to larvae immediately following fin amputation to evaluate the re-formation of regenerating axons of a ring-like nerve network at the fin base that normally occurs in 24 hours. In larvae exposed to 15 pools regenerating axons failed to form the characteristic ring-like network. Next, each of the compounds was tested within a given pool individually. This failed to identify a singly effective compound in 20% of pools which reduced nerve regrowth in the first pass of the screen. Despite the fin removal assay is a powerful screening method to study nerve regeneration, the high false positive rate indicates the importance of a second method to confirm the results (Fig. 7).

Other strategies for CNS/PNS repair

Many strategies have shown incredible potential for regeneration of the CNS following an injury, but a major concern remains the significant death of neurons (Ling *et al.* 2015; Mckee and Daneshvar 2015). Moreover complex diseases such as stroke, amyloid-β plaque accumulation and inflammatory-mediated neurodegeneration lead to broad defects such as defective communication, glial scar formation and ultimately neuronal loss, which make it challenging to repair (Chauhan 2014; Albrecht *et al.* 2015). In such cases, the development of cell therapy has shown some promising results (Gates *et al.* 2000). Stem cell manipulation is a powerful tool to understand neurodevelopment and its integration into developing tissue can recapitulate neurogenesis. In vivo strategies based on stem cell replacement such as human and mice-derived embryonic stem cells (ESCs) for brain repair in models of neurological diseases, have made significant progress in pre-clinical trials (Barker *et al.* 2015; Péron *et al.* 2017). It is known that the lack of endogenous repair in the brain leads to a condition of life-long disease and disability after a neuronal damage. Thus, understanding how well the transplanted neurons are able to mature and integrate into damaged circuits is a challenging task (Fig. 7a).

Because of the complexity of the organization of the cerebral cortex in terms of highly specific topography and connectivity (Guillemot *et al.* 2006; Tiberi *et al.* 2012), the replacement of lost neurons is a daunting challenge. A notable initial attempt at regenerative cortical cell therapy showed that transplanting embryonic cortical tissue from transgenic mice to lesioned cortex in an adult brain could regenerate neurons and establish neuronal projections and synaptic connections (Wernig 2004; Gaillard *et al.* 2007). These findings have been corroborated by data from other studies which have shown that not only ESCs have intrinsic mechanisms of corticogenesis (Gaspard *et al.* 2008) but induced pluripotent stem cell-derived neurons also can regenerate functional cortical neurons (Falkner *et al.* 2016; Espuny-Camacho *et al.* 2018).

There are certain prerequisites for the ESCs to successfully integrate the malfunctioning adult cortex (Fig. 7b). Re-establishment of neuronal connectivity and function requires identity match between the damaged brain area and the transplanted material (Michelsen *et al.* 2015). Human embryonic stem cell-derived visual cortical neurons, once grafted into the lesioned adult murine cortex, are able to mature and integrate into the corresponding cortical layers, acquiring a visual-like identity and rewiring the circuit with appropriate inputs and outputs (Espuny-Camacho *et al.* 2018). Interestingly, Human embryonic stem-derived cells transplanted into motor cortical areas showed a reduced maturation and a lower capacity to send long-range projections, suggesting that the areal identity match represents an important factor for successful cortical transplantation.

Another key factor accompanying identify match (Fig. 7c), is the adaptation to the extrinsic *in vivo* environment to establish polarity, such as microenvironment generated by blood vessels (Javaherian and Kriegstein 2009) or composition of extracellular matrix (Fietz *et al.* 2012). Context-wise, junctional complexes block the incorporation of grafted cells at the apical surface (Espuny-Camacho *et al.* 2013). For this reason, a new grafting method called TETCaD (transplantation to epithelial tissue with calcium depletion) has been developed, using moderate concentrations of EGTA (ethylene glycol tetra-acetic acid) to chelate calcium,

INFORME DE LABORES 2019

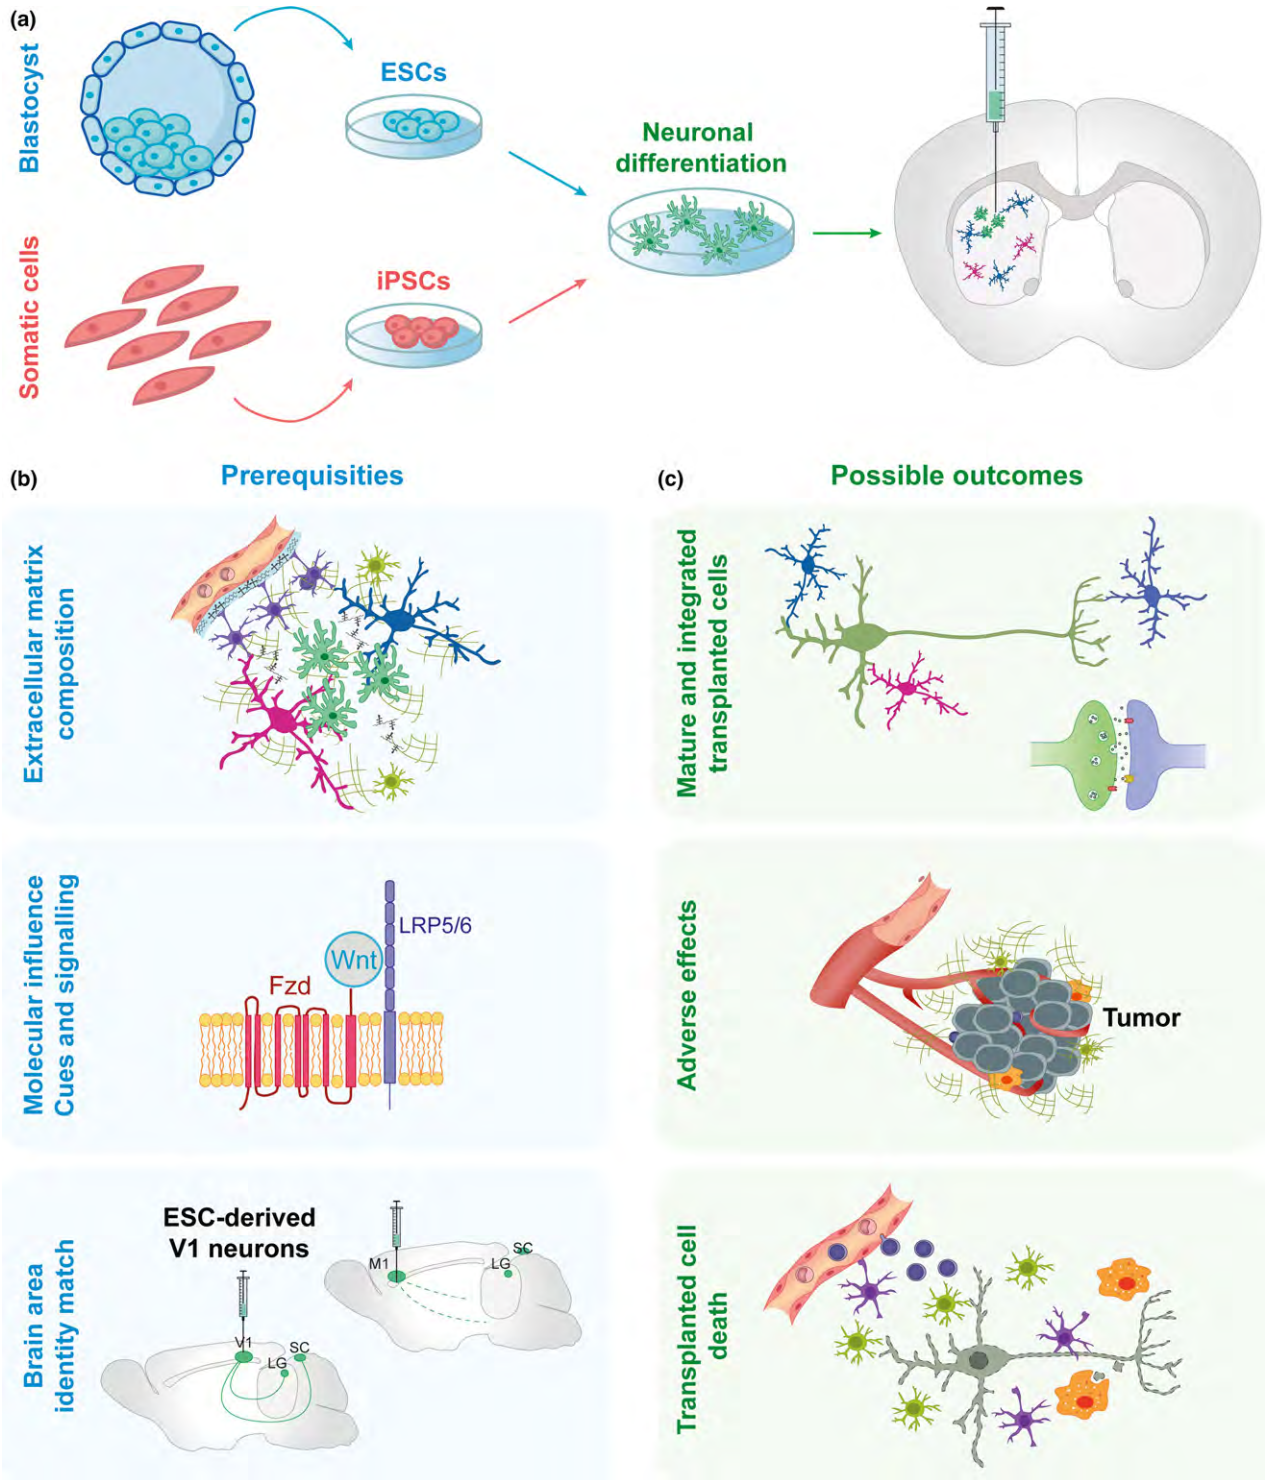

Fig. 7 Cell therapy. (a) Strategies based on stem cell replacement such as human- and mouse-derived embryonic stem cells (ESCs) and induced pluripotent stem cell (iPSC)-derived neurons. Grafting iPSC-derived neurons in brain circuits requires (b) adaptation to the extrinsic in vivo microenvironment or composition of extracellular matrix, lesion site-specific cues and signalling pathways, and identity match between the damaged brain area and the transplanted material. (c) Transplanted neurons could mature and integrate into damaged circuits; however, potential adverse effects as tumors or neuron death should be addressed before these strategies are transferred to the clinic.

increasing efficiency of transplantation and dissociating adherents junctions in the epithelial tissue (Nagashima *et al.* 2014). Lastly in the molecular level, lesion site-specific cues and signalling pathways such as the WNT signalling and NOTCH2NL genes have been implicated in human corticogenesis (Raitano *et al.* 2015; Fiddes *et al.* 2018; Suzuki *et al.* 2018). *In vitro* and *in vivo* use of induced pluripotent stem cells in animal models simulating human diseases such as stroke (Tornero *et al.* 2013), Alzheimer's disease (AD) (Espuny-Camacho *et al.* 2017) and multiple sclerosis (Theotokis *et al.* 2015), highlight the hallmarks of synaptic activity, connectivity and cortical neuronal maturation (Suzuki and Vanderhaeghen 2015). Specifically for AD, the significant expression of non- coding RNA sequences in grafted human neurons further opens up an entirely new avenue for investigating the involvement of non-coding RNAs in AD-induced neurodegeneration.

Altogether, establishing the molecular mechanisms regulating fate acquisition and plasticity after cell transplantation is of great importance in the light of preclinical studies. Determining which cues are involved in fate maintenance, area specificity and functional integration in the adult brain will be pivotal for successful outcomes in stem cell-based therapies. These signaling events may also play major roles in neurodegeneration so targeting pathways such as the Wnt pathway, may result in the establishment of novel therapeutic approaches. Nonetheless, potential adverse effects and host-transplant compatibility should be addressed before these approaches can be considered for clinical applications.

Low Dimensionality, High Robustness in Neural Population Dynamics

Román Rossi-Pool[1,*] and Ranulfo Romo[1,2,*]

Neuronal populations respond within a small number of relevant dimensions. New research by Trautmann et al. (2019) shows that spike sorting is not necessary to extract the important features of this low-dimensional population signal. Combined responses of multiple neurons (multiunit activity) only generate small changes in the extracted signals.

Neural population dynamics do condense to a few meaningful signals. Several thousands of single-neuron responses give rise to a small number of significant population dynamics ("*E pluribus pauca*"). Low dimensionality of neural data appears to be a general biological feature, observed in several experiments and animal models (Gao and Ganguli, 2015; Kobak et al., 2016; Rossi-Pool et al., 2017). Further, the dimension-reduced representation of the neural data across time constitutes a surface with smooth curvature (manifold). In recent years, different dimensionality reduction methods have been employed to infer the relevant latent population signals. Neural responses at a macroscopic level have helped neuroscientists to infer computational principles hidden in the heterogeneous activity of single neurons (Ames et al., 2014; Churchland et al., 2012; Kaufman et al., 2014; Rossi-Pool et al., 2019). This means that structures and invariant features of the data emerge by zooming out from single-neuron responses. However, what are the biological implications of the low dimensionality and smooth curvature of the population dynamics?

In general, population analyses employ a weighted sum of single-unit activity to compute the meaningful population signals from data. Therefore, to obtain each component of the population dynamics, different weights (importance) are given to each individual neuron of the network. Multiunit activity, recorded with a simple voltage threshold at each single channel, randomly combined activity from several neurons (Figure 1A). Notably, single neurons with analogous or different coding dynamics (high tuning correlation) are mixed spatially (see Figure S2 in Trautmann et al., 2019). Then, each multiunit response constitutes a random selection of single units that could be compelling for the same or different population components. Considering that the neural response is low dimensional, is it possible to obtain population dynamics employing multiunit instead of single-unit activity?

In this issue of *Neuron*, Trautmann et al. (2019) address this question, offering important new evidence of the robustness of population dynamics. The authors found that spike sorting is not necessary to accurately determine which population signals are most meaningful. To endorse this claim, they replicate results from three previous studies, originally spike sorted (Ames et al., 2014; Churchland et al., 2012; Kaufman et al., 2014) but now directly using the unsorted multiunit activity. Notably, they were able to extract population signals, employing threshold-crossing multiunit activity, with only minor differences with respect to the signals found in the previous studies. When dimensionality reduction methods are applied to random linear combinations of single-unit responses, they yield analogous neural trajectories. Equivalent hidden population responses emerged from both approaches (Figure 1A). Not only do these results have great implications for facilitating future population studies, they also provide new evidence of the robustness and stability of population signals. Moreover, multiunit responses include hash activity that cannot be sorted into isolated neurons. This unsortable activity could carry relevant signals that increase the statistical power of the population analysis.

In addition to the previously recorded neurons, the authors collected new neural data using silicon Neuropixels probes during a motor reaching task. Employing this new high-density recording technique (~20 μm site spacing), Trautmann et al. (2019) were able to sort hundreds of single neurons per trial. Again, the same population dynamics were obtained with the well-isolated single neurons. Importantly, their results suggest that more independent observations of the neural population are fundamental to compute the important aspect of the network. Contrary to that, redundancy given by high-density electrodes will not improve accuracy to infer the underlying neural signals. However, the authors used this new recording technique to provide significant additional evidence that nearby neurons do not share similar tuning properties. The results show that there are no spatially organized clusters of neurons with similar selectivity. This finding opens new questions that could be tackled with these high-density recordings. Is noise correlation higher between nearby neurons? Is there any relationship between distance, tuning, and noise correlation? These important questions could help to understand the underlying architecture of neural microcircuits.

As the authors assert across the manuscript, these results are restrained to population analysis. Crucial to this point, there are still many important questions to be addressed with single units. To evaluate individual cells' properties, like tuning to

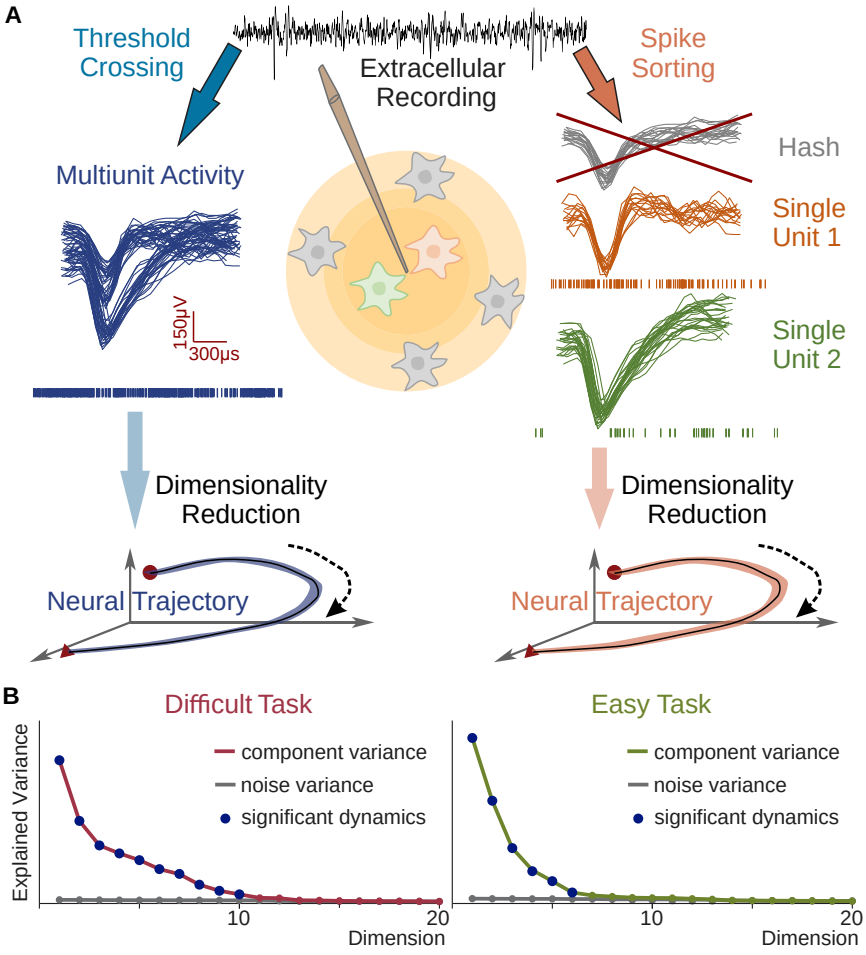

Figure 1. Single-Unit Versus Multiunit Activity in Low-Dimensional Neural Trajectories
(A) Single-unit activity obtained with spike sorting or multiunit activity obtained from threshold crossing gives rise to similar neural dynamics. Note that in the single-neuron approach, hash activity is discarded. (B) Easy and difficult tasks exhibit low dimensionality. Few significant dynamics explain most of the variance. A more difficult task displays more significant dynamics (above noise) than an easier task.

a stimulus parameter, spike sorting is still imperative. Studies based on single units are extremely important to understand the basic operations employed by neuronal circuits. Some of the most profound understandings of the neural mechanisms of working memory and decision making were obtained from studies of single-neuron activity across brain areas (Hernández et al., 2010). Furthermore, to our knowledge, there are no population-level studies analyzing neural features across areas.

To give a deeper interpretation of their results, the authors apply the theory of random projections (Ganguli and Sompolinsky, 2012). This theory is pertinent when a low-dimensional neural response is enclosed in a high-dimensional space. In this case, each single-neuron activity represents one axis of the high-dimension space. While the number of significant dimensions in a neural state is around ten, the number of recorded neurons could be on the order of thousands (Gao and Ganguli, 2015). Under these circumstances, recording small numbers of random linear combinations of single-neuron activity (multiunit activity) is enough to extract the meaningful population responses (Figure 1). Applying this theory, Trautmann et al. (2019) show that higher-dimensional neural data require a larger number of multiunit channels to properly estimate the population dynamics. Importantly, recent results suggest that dimensionality is associated with the complexity of the task (Rossi-Pool et al., 2017, 2019). When a task is too easy, the number of relevant dimensions decreases (Figure 1B). Note that to consider a neural dimension as significant, its explained variance should be higher than the noise variance associated with this component. Markedly, several tasks have shown that many significant dimensions and most of the network variance is captured by pure temporal latent signals (Kobak et al., 2016). These timing signals could be understood as a necessary substrate on which parameter coding responses can develop (Rossi-Pool et al., 2019).

Another important problem to be answered in future research is the relevance of the population-level responses. Do population responses reveal fundamental processes of brain circuits or do they only represent suitable pictures of their dynamics? Are the population responses, calculated with dimensional reduction approaches, still meaningful when the task is much more complex? Is it possible to establish an electrophysiological relationship between population signals and the oscillatory activity computed with local field potentials, which is considered to measure the level of synchronization of neural activity? These and other important questions are still open for future studies.

The work of Trautmann et al. (2019) leads the way to some other important, unresolved questions. Which are the biological reasons to have population neural responses with low dimensionality and high robustness? One possible hypothesis is that neurons from a downstream area could obtain the relevant neural information from upstream areas combining randomly single-unit activity. This population feature could help to facilitate communication across brain areas. Another complementary hypothesis is that low dimensionality gives stability and redundancy to the network. Once a complex task is learned, the neuronal population response could be prone to tolerate perturbation in its dynamic. However, under this stability, how do the networks learn a completely new task or variations of a previously acquired task? Is the dimensionality of the population higher when the subject is being trained

in a new task? New experiments, computational analyses, and theoretical biology developments are necessary to clear up these propositions.

To conclude, Trautmann et al. (2019) present a meticulous study showing how dimensionality reduction methods can be employed with multiunit instead of single-unit activity, and by doing so, they provide new evidence to the actual debate about the functional roles of dimensionality, robustness, stability, and redundancy of neural network dynamics.

Body temperature control is a critical brain function. In this issue of *Neuron*, Wang et al. identify a negative feedback circuit in mouse preoptic area of the hypothalamus that regulates body temperature to counter fever.

Body temperature regulation is a fundamental homeostatic function in mammals. The maintenance of a constant body core temperature (T_c) at approximately 37°C is controlled by a central nervous network in an orchestrated manner. The thermoregulation system also plays a key role in host defense against pathogens through elevation of T_c, a response called fever. How is this accomplished? As a concept, the thermoregulation system consists of three components: sensory afferents, the central integration center, and command outputs (Morrison and Nakamura, 2019). The thermoregulatory center in the brain receives information through sensory afferents from thermoreceptors in the skin to detect ambient temperature and from thermoreceptors in viscera, muscle, spinal cord, and brain to detect body temperature. The thermal information is integrated in the thermoregulatory center, and then the center provides commands to thermoeffectors to control heat production or heat loss (Morrison and Nakamura, 2019). Work in the past decade has greatly advanced our understanding of the role of the temperature-sensitive TRP (transient receptor potential) family of cation channels in cutaneous thermosensation, particularly heat sensation (Dhaka et al., 2006). However, the molecular and cellular mechanisms underlying body temperature regulation in the brain remain largely unknown.

In mammals, the preoptic area (POA), located in the rostral pole of the hypothalamus, is thought to function as the thermoregulatory center in which a variety of thermal information, including ambient and body temperature, is integrated for the maintenance of temperature homeostasis (Morrison and Nakamura, 2019) (Figure 1). In their classic work in 1938, Magoun and colleagues precisely defined the thermosensitive area in the POA (Magoun et al., 1938). Later, single-unit studies in 1960s to 1980s showed that about 30% of POA neurons are warm-sensitive, 10%

During discrimination between two sequential vibrotactile stimulus patterns, the primate dorsal premotor cortex (DPC) neurons exhibit a complex repertoire of coding dynamics associated with the working memory, comparison, and decision components of this task. In addition, these neurons and neurons with no coding responses show complex strong fluctuations in their firing rate associated with the temporal sequence of task events. Here, to make sense of this temporal complexity, we extracted the temporal signals that were latent in the population. We found a strong link between the individual and population response, suggesting a common neural substrate. Notably, in contrast to coding dynamics, these time-dependent responses were unaffected during error trials. However, in a nondemanding task in which monkeys did not require discrimination for reward, these time-dependent signals were largely reduced and changed. These results suggest that temporal dynamics in DPC reflect the underlying cognitive processes of this task.

behaving monkeys | dorsal premotor cortex | temporal signals | context-dependent signals | ramping activity

Our ability to anticipate the occurrence of future events is crucial when performing many cognitively demanding behaviors. For example, the benefits of anticipating the arrival of sensory inputs can be decisive in our perceptual behavior (1–3). In this way, neural circuits engaged in cognitive processes of this type would profit from employing temporal signals. Thus, the timing information contained in those signals may then constitute a mechanism to anticipate future task events. In fact, during experiments it is common to find neurons that display noteworthy temporal dependencies in their firing rate (4–9). In particular, a large proportion of the individual neurons from the frontal lobe cortices exhibit intricate time-dependent responses that mesh in myriad ways with stimulus identity and decision outcomes during behavioral tasks (4, 10–12). However, individual neurons must be reflecting a more widespread response across the network; temporal signals that represent anticipation of task events and stimulus identity must be coded at the population level. Recently, these neuronal population signals from the frontal lobe cortex were studied employing methods that reduced the dimensionality of network dynamics (11, 13). These methodological approaches facilitated the recognition of latent population responses during cognitive tasks (14–17). Notably, large differences between the population variance related to purely temporal signals and task parameter coding were observed (11, 13). Markedly, even if the tasks examined were completely different and employed two types of animal models, the temporal signals always captured more than 65% of the total variance. These results indicate that temporal signals occupy a central role during the execution of any behavioral task.

Here, to further investigate the temporal responses in single units and neuronal population, we employed the network activity recorded in dorsal premotor cortex (DPC) during a temporal pattern discrimination task (TPDT) (18, 19). Monkeys were trained to report whether the temporal patterns of two vibrotactile stimuli (P1 and P2) of equal mean frequency were the same or different (Fig. 1*A* and *SI Appendix*) by pressing one of two push-buttons (pbs). In two prior works, we studied the coding capacity of DPC single neurons (18) and population responses (19). In the first work, we showed that DPC neurons coded the stimulus patterns as broader categories and signaled them during the working memory, comparison, and decision periods of the TPDT. Furthermore, neurons exhibited mixed selectivity (20) and an extreme heterogeneity in their coding dynamics (21, 22). In our second work, we showed that this heterogeneous population activity can be condensed into two major coding components: one that persistently represented in working memory both the first stimulus identity and the postponed informed choice, and another that transiently coded the initial sensory information and the result of the comparison between the two stimuli. These dynamics, hidden in the neuronal coding heterogeneity, emerged in the DPC population response.

An important hypothesis is that the temporal signals should adjust to different cognitive contexts. Here, we tested this conjecture employing single-unit and population methodological approaches. First, focusing on the cognitively demanding TPDT, we compared the variance related to coding against time-dependent variance, using both single DPC neurons and population average. In the two cases, the results were analogous: the proportion of variance related with timing is much higher than that associated with task parameter coding. This means that temporal dynamics is responsible for the

Significance

When trained monkeys discriminate between two sequential vibrotactile stimulus patterns, neurons in the dorsal premotor cortex (DPC) code current and remembered inputs and the commands expressing the decision report. Additionally, responses of these neurons and neurons with no coding responses also reflect the timing of the task sequence. What is the cognitive relevance of these time-dependent signals? We show that time-dependent signals reflected the temporal sequence of the task during both hits and error trials but diminished or disappeared during a nondemanding cognitive task that did not require discrimination for reward. Also, strong links were detected between neuronal population and individual neurons' time-dependent signals. These time-dependent responses may function as the substrate network dynamics on which task coding components emerge.

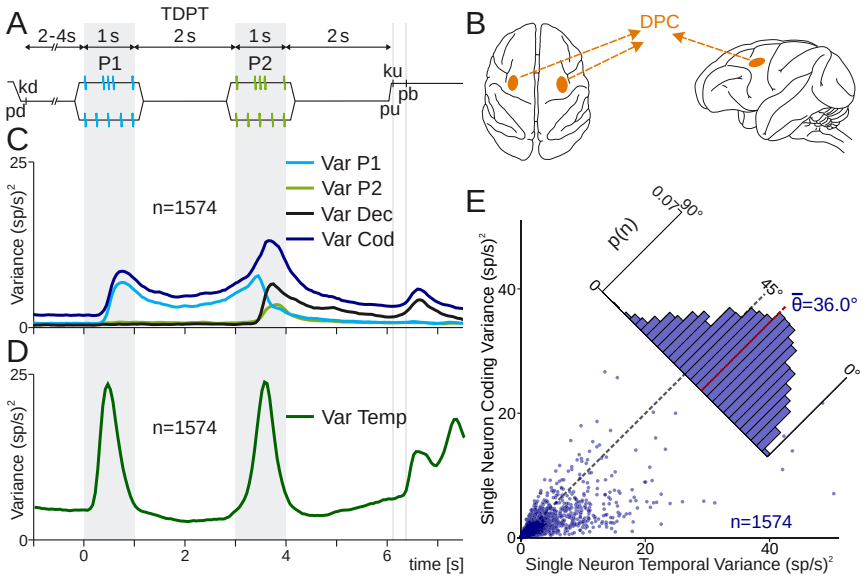

Fig. 1. Temporal pattern discrimination task (TPDT), single DPC neuron, and population variances. (*A*) Trial sequence of events. The mechanical probe is lowered (pd), indenting the glabrous skin of one fingertip of the right restrained hand; the monkey places its free hand on an immovable key (kd). After a variable prestimulus period (uniformly distributed from 2 to 4 s), the probe vibrates, generating one of two possible stimulus patterns [P1, either grouped (G) or extended (E); 1 s duration; mean frequency of 5 Hz]; after a first delay (2-s length, from 1 to 3 s) between P1 and P2, the second stimulus is delivered, again either of the two possible patterns (P2, either G or E; 1-s duration; mean frequency of 5 Hz); after a second fixed delay (2-s length, from 4 to 6 s) between P2 and pu, the monkey releases the key (ku) and presses the push-button (pb) to indicate whether P1 and P2 were the same or different (P2 ≠ P1). (*B*) Top (*Left*) and lateral (*Right*) views of the brain. Dark orange spots mark the location of the dorsal premotor cortex (DPC). Single DPC neurons were recorded from both hemispheres, while trained monkeys performed the TPDT. (*C*) Population instantaneous coding variance (Var_{COD}, blue, *SI Appendix*, Eq. **S1**), P1 variance (Var_{P1}, cyan trace), P2 variance (Var_{P2}, light green trace), and decision variance (Var_{DEC}, black trace). (*D*) Population instantaneous temporal variance (Var_{Temp}, green trace). (*E*) Single-neuron temporal variance (*x* axis, *SI Appendix*) is plotted against single-neuron coding variance (*y* axis, *SI Appendix*). Each dot corresponds to one neuron (n = 1,574). Diagonal line (45°) indicates equality between both measures. *Inset* histogram show angular distributions for the population (<θ> = 36.0°). In general, $SNVar^{i}_{Temp}$ is higher than $SNVar^{i}_{Cod}$.

large proportion of DPC firing rate fluctuations during the TPDT. In addition, we identified several DPC neurons with pure temporal responses. These responses also proved to be heterogeneous. Furthermore, we focused on the pure temporal signals that emerged from the DPC population. Most of the population variance was captured by these pure temporal components. These signals were engaged during relevant periods of the task: they reflected stimulus arrival and button presses, and had ramping activity during delays.

To further address our hypothesis, we investigated the role of these temporal signals in two different cognitive contexts. First, when the monkeys performed the TPDT and after during a nondemanding variation of the task [light control task (LCT)]. During this control task, no parameter encoding was found in single neurons and population dynamics. Notable, the time-dependent signals observed in the TPDT reduced their intensity or completely vanished during this nondemanding task. Additionally, the temporal variance was diminished in single-unit responses and in their population average. Several temporal neurons reflected this decline in their temporal responses. These results show that pure temporal responses were bound to the cognitive processes of the TPDT. Second, we focused on the relevance of the temporal responses during error trials. Noteworthy, temporal variance remained unaffected in both single neurons and population average during the animals' hit and error responses. These findings support the idea that the temporal-dependent signals code the temporal sequence of this task. Collectively, our results indicate that time-dependent signals observed in both levels, single units and population dynamics, could be interpreted as a necessary substrate on which the coding responses can develop to reach a decision during the TPDT.

Results

Previously, we identified and classified single neurons associated with relevant task parameter coding during the TPDT (ref. 18 and *SI Appendix*, Fig. S1 *A–L*). DPC neurons (Fig. 1*B*) exhibited a high heterogeneity among their responses during the TPDT. Additionally, several single units coded more than one task parameter throughout the task. This is illustrated in *SI Appendix*, Fig. S1, where we display 12 DPC neurons that coded different task parameters (P1, decision and class identity). Most of these neurons showed mixed selectivity in their coding responses (18, 20). We then condensed these heterogeneous single-unit responses into two major population signals that built an elegant and compact solution for the task, consistent with the monkeys' psychophysical performance (19).

Here, to measure the response's variability associated with task parameters coding, we calculated the population instantaneous coding variance during the TPDT (Var_{COD}, *SI Appendix*; Fig. 1*C*, blue trace). This metric quantified the firing rate fluctuations among classes and neurons at each time point. Clearly, time bins in which more neurons code task parameters usually give rise to higher instantaneous coding variance. Additionally, we calculated the population variance associated with each task parameter: P1 (Var_{P1}, *SI Appendix*; Fig. 1*C*, cyan trace), P2 (Var_{P2}, *SI Appendix*; Fig. 1*C*, light green trace), and decision period (Var_{Dec}, *SI Appendix*; Fig. 1*C*, black trace). In a previous work (18), we quantified the coding dynamic as the percentage of cells that coded each task parameter. Notably, those coding dynamics closely resembled the specific task parameter variances observed here. This means that there was a close relationship between the number of neurons coding a task parameter and the population coding variance associated with it. Notice that before the arrival of P1 (prestimulus period), there is no task parameter to be coded. Thus, one could expect that the population variance associated with each task parameter should be zero. Nevertheless, all of the traces shown in Fig. 1*C* exhibit a positive value before P1. This nonzero instantaneous variance observed during the prestimulus period could be interpreted as an estimate of the basal variances associated with residual fluctuations. When each type of variance is higher than its basal value, these larger fluctuations must be associated with task parameter coding.

Population and Single-Unit Temporal Variance During the TPDT. We wondered how much population variance could be associated with temporal dynamics during the TPDT. To quantify this, we calculated the population instantaneous temporal variance with respect to its mean response (Var_{Temp}, *SI Appendix*; Fig. 1*D*). At each time bin, Var_{Temp} quantifies the quadratic square sum among the neuron's responses of the difference between their mean firing rates for each time bin [$r^{i}(t)$] and mean firing rates across the whole task

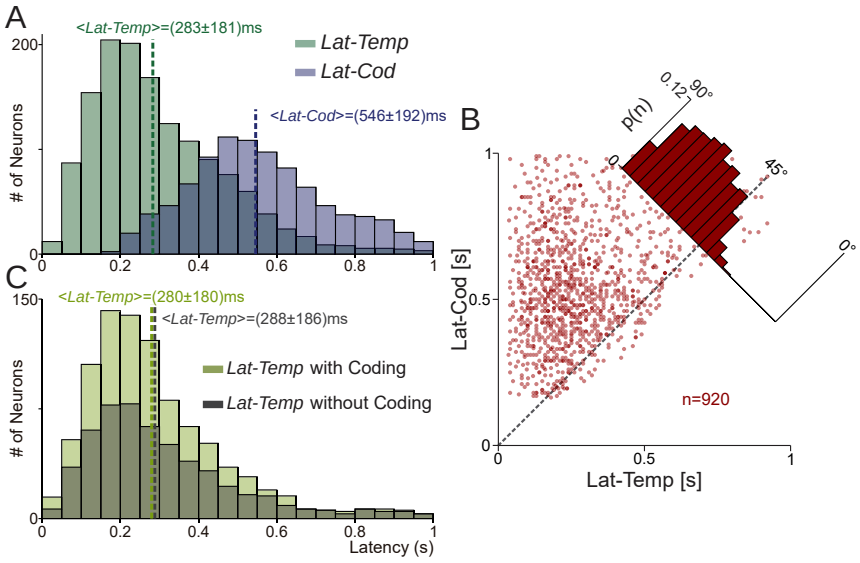

Fig. 2. Temporal and coding latency variances. (*A*) Latency distribution for neurons with temporal (green; n = 1,436) or coding (blue; n = 946) variance statistically different from their basal values during P1. In general, pure temporal signal ($<Lat_{Temp}>$ = 283 ± 181 ms) appeared before coding signals ($<Lat_{Cod}>$ = 546 ± 192 ms). (*B*) Neurons with significant latencies of temporal and coding variances (n = 920). Lat_{Temp} (x axis) is plotted against Lat_{Cod} (y axis). Each dot corresponds to one neuron. Single-neuron latencies were higher for coding than for temporal variances. (*C*) Latency distributions of temporal variance for neurons with significant Lat_{Temp} and Lat_{Cod} (n = 920; light green) and for neurons with only significant Lat_{Temp} (n = 516; dark green). Latency distributions are statistically the same in both groups ($<Lat_{Temp}>$ = 280 ± 180 ms vs. $<Lat_{Temp}>$ = 288 ± 186 ms). Response temporal latencies were very much alike for neurons with significant temporal and coding responses and for neurons with only significant temporal signals.

(^{i}, from −1 to 7.5 s). Whenever the mean population activity departs from its mean value, the temporal variance will increase. Remarkably, the instantaneous temporal population variance was much higher than the coding variance at any time bin (Fig. 1*C* vs. Fig. 1*D*). The same effect was observed using the temporal population fluctuation $Fluc_{Temp}$ computed with respect to the mean basal firing rate (*SI Appendix*, Fig. S2*A* and Eq. **S6**). Hence, most of the population variance in firing rate over the extent of a trial corresponded to variability across the sequential events of the task rather than across classes. Even though $Fluc_{Temp}$ was highest at stimulus arrival, it exhibited large values during both working memory (from 1 to 3 s) and postponed decision (from 4 to 6 s) delay periods. Additionally, Var_{Temp} and $Fluc_{Temp}$ displayed high values after pb presses.

To further study temporal variance, we focused on single-neuron responses. For each unit, we compared the variance associated with parameter coding ($SNVar^i_{COD}$) with the temporal variance ($SNVar^i_{Temp}$) during the whole task period (from −1 to 7.5 s). On one hand, $SNVar^i_{COD}$ measures the variance of the firing rate among classes from each individual cell (*SI Appendix*, Eq. **S7**). On the other hand, $SNVar^i_{Temp}$ computes the average temporal variance for each neuron across the whole task (*SI Appendix*, Eq. **S8**). Note, in these single-neuron metrics (Fig. 1*E*), we averaged across time bins for each unit, whereas in Fig. 1*D* we averaged across neurons for each time bin. Each point in Fig. 1*E* represents one neuron response, and the position in the plot was defined by $SNVar^i_{Temp}$ (x axis) and $SNVar^i_{COD}$ (y axis). In concordance with the results observed in Fig. 1*D*, individual neurons displayed higher values of $SNVar^i_{Temp}$ than $SNVar^i_{COD}$. Hence, the mean value of the angular distributions was $<\theta>$ = 36.0° (Fig. 1*E*, red dotted line), which means that most of the neurons were closer to the temporal than the coding axis. Analogous results were found computing the single-neuron temporal fluctuation ($SNFluc^i_{Temp}$, *SI Appendix*, Eq. **S9**) with respect to their mean basal firing rate (from −1 to 0 s, *SI Appendix*, Fig. S2*B*). Looking at the distribution shown in Fig. 1*E* and *SI Appendix*, Fig. S2*B*, we can see that there were no neurons with coding variance only. Thus, it is unlikely to find cells with significant task parameter coding and where the firing rate curves cancel out when averaged over trials of different classes.

Temporal Versus Coding Latencies. We wondered whether the pure temporal responses increased earlier than the task parameter coding variances. For each neuron, we quantified the time bin at which the temporal and the coding variance increased significantly with respect to its basal value during P1 (from 0 to 1 s). These time bins defined two different latencies: Lat_{Temp} and Lat_{Cod}. Fig. 2*A* shows the latency distributions for Lat_{Temp} and Lat_{Cod}. During P1, more neurons displayed a significant increase in the temporal variance (n = 1,436; 91.2%) than in the coding response variance (n = 946; 60.1%). Importantly, the temporal signals emerged before than the coding signals (Fig. 2*A*, $<Lat_{Temp}>$ = 283 ± 181 ms vs. $<Lat_{Cod}>$ = 546 ± 192 ms). Thus, pure temporal responses could act as a precursor for task parameter coding. Previously, similar response and coding latencies were found using a completely different approach (18). In addition, most of the neurons with significant Lat_{Cod} exhibit significant Lat_{Temp} (n = 920). For each of these neurons, we plotted Lat_{Temp} (Fig. 2*B*, x axis) against Lat_{Cod} (y axis). In general, the single-neuron temporal responses appeared before the coding signals. This was further documented by dividing the temporal latency (n = 1,436) during P1 into two groups: one with significant coding latency (n = 920) and another without coding (n = 516). Notably, we show that Lat_{Temp} distributions were statistically the same for these two groups of neurons (Fig. 2*C*). This means that the temporal signals from single neurons emerged independently of whether the neurons significantly encoded task parameters.

Temporal Responses of Single DPC Neurons. We employed $SNVar^i_{Temp}$ and $SNFluc^i_{Temp}$ to identify neurons with strong temporal signals. Fig. 3 and *SI Appendix*, Fig. S3 illustrate typical temporal activity of single DPC neurons. Clearly, all of these neurons' responses are not essentially related with task parameter coding. Most of these neurons do not code any task parameters during the task. These neurons exhibit response dynamics that vary over time, but not in a manner that encodes task variables. Furthermore, DPC neurons exhibited a large repertoire of neuronal responses associated with pure temporal dynamics. Some of these neurons were involved in stimulus arrival with positive (Fig. 3*F* and *SI Appendix*, Fig. S3 *B*, *D*, and *F*–*H*), negative (Fig. 3*E* and *SI Appendix*, Fig. S3 *C* and *I*), or mixed (Fig. 3*C* and *SI Appendix*, Fig. S3*A*) responses. Another group of neurons was associated with ramping activity during the delay periods (Fig. 3 *A*, *B*, and *D* and *SI Appendix*, Fig. S3 *A*, *F*, *G*, and *I*). Finally, another overlapping group of neurons was related to temporal responses after pb (Fig. 3 *A*, *D*, and *F* and *SI Appendix*, Fig. S3 *A*, *C*–*E*, and *G*–*I*). Interestingly, there were neurons that only respond during pb,

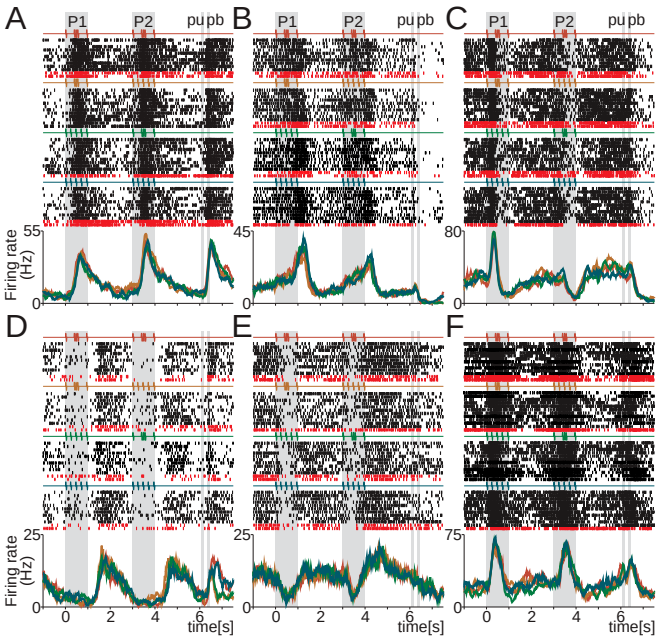

Fig. 3. Single DPC neurons with notable temporal activity during the TPDT. (*A–F*) Raster plots of six temporal exemplary neurons sorted according to the four possible classes. Each row of ticks is one trial, and each tick is an action potential. Trials were randomly delivered and were sorted by class afterward (only 10 out of 20 trials per class are shown). Correct and incorrect trials are indicated by black and dark red ticks, respectively. Traces below the raster plots are average per-class firing rates [peristimulus time histograms (PSTHs)] for each temporal neuron. Each color refers to one of the four possible classes: G-G (red); G-E (orange); E-G (green); and E-E (blue). Neurons exhibit pure temporal dynamics without coding any task parameter.

independently of the decision outcome (*SI Appendix*, Fig. S3*E*). Therefore, even for temporal signals, the complexity and diversity of responses was broad. To handle this temporal heterogeneity, we applied dimensional reduction methods of the population activity to reveal temporal latent signals.

Population Principal Components Exhibit Temporal Signals. Such dimensional reduction was done using a condensed population-level representation of the data, based on the state space of neural responses. The state of the DPC population was represented by a point in a n-dimensional (n = 1,574) space of firing rate responses. Each dimension, at each time point, corresponded to the firing rate of one neuron. The dynamics of the network was described by combining 1,574 firing rates mostly recorded separately (15, 19, 23–25). As neurons' activity evolves over time, the point moves through the space, forming a trajectory that represents the response of the population.

We first employed principal-component analysis (PCA) to identify a lower dimensional subspace underlying the DPC network dynamics (26). The covariance matrix used for PCA was quantified from the whole task (*SI Appendix*, Eq. **S10**). Even if PCA could be used to reduce the dimensionality of the dynamics, the new subspace was deficient in highlighting temporal signals or task parameter dynamics (*SI Appendix*, Fig. S4). Overall, PCA gave a much more complex picture of the population dynamics, dominated by strong temporal signals mixed with parameter coding responses. The first five PCs were ordered by the amount of explained total variance (ETV) (*SI Appendix*, Eq. **S15**). For each PC, we displayed the population activity projections sorted by classes. In general, PCs exhibited strong temporal signals that dominate the population dynamics. Notice that the fifth PC displayed a ramping temporal activity during the first (from 1 to 3 s) and second (from 4 to 6 s) delay periods (*SI Appendix*, Fig. S4). Even though PCA was a fully unsupervised approach, it was possible to recognize almost pure temporal responses such as the fifth PC.

Population Temporal Dynamics. Then, to focus on the task timing signals from the population activity, we applied demixed PCA (dPCA) (13). Employing dPCA, we were able to extract a low-dimensional subspace more sensitive to the pure temporal responses. Contrary to other approaches, dPCA split the population variability associated with different task parameters employing marginalized matrices. Here, we center our analysis on decomposing the population temporal responses. In a previous study (19), we studied the population components associated with coding task parameters. Fig. 4*A* displayed the first five temporal dPCs that captured most of the variance during the task. To calculate the temporal dPCs, we applied a temporal marginalization of the population activity. Then, we averaged the responses of all of the trials without considering class identity. The temporal dPCs were optimized to maximize (*SI Appendix*, Eq. **S13**) the ETV (*SI Appendix*). Due to this optimization, the population activity of the four classes overlapped when they were projected onto this axis (Fig. 4*A*). We selected class E-G (c3, green trace) to be on top of the other four traces.

The first temporal dPC displayed an intense response during P1 and P2 periods (Fig. 4*A*). This component captured 23.9% ETV and represented the most relevant demixed signal. We remark that there was no component with higher variance associated with task parameter coding. This means that the sensory stimulation gave rise to strong temporal dynamics that underlay the coding of the stimulus pattern. Notably, second temporal dPC (Fig. 4*A*) exhibited a strong temporal response immediately after the pb press. This signal contrasted highly with the first dPC: It was less involved in stimulus presentation and more engaged with a population dynamic after the animals reported their decisions. Although this component was related with the last period of the trial, it explained 13.5% of the total variance. This signal was presumably linked with the strong decision signal that emerged after pb (ref. 18 and Fig. 1*C*). By construction, this second temporal dPC was orthogonal to the first dPC. This means that the sensory temporal signal (first dPC) was independent of the signal after pb presses (second dPC). The third temporal dPC projections showed a mixed dynamic with sensory and persistent responses (Fig. 4*A*, 9.5% ETV). It exhibited a stepped change during P1 followed by persistence during the first delay; after that, it showed another stepped response during P2, again followed by persistence during the second delay between P2 and pu. Remarkably, the neural projections onto the fourth temporal dPC presented a temporal pacemaker during both delays (Fig. 4*A*). This component, which explained 8.25% ETV, begins in each stimulus period with a negative value and reaches peak values during P1, P2, and pb. We notice the resemblance between this component and the fifth PC shown in *SI Appendix*, Fig. S4. We hypothesize that this pacemaker component could act as an internal time estimator that allows the network to predict the arrival of relevant events during this cognitively demanding task. Last, the fifth temporal dPC showed a ramping temporal activity during the first delay, and with markedly smaller one during the second delay (5.84% ETV).

Task Dimensionality and Temporal Signals. Subsequently, we studied the dimensionality of the population across the TPDT. We wonder: How many dimensions or components were necessary to explain the network dynamics? Moreover, how many of these relevant dimensions were pure temporal signals? To estimate quantitatively the dimensionality, we used both dPCA and PCA. We constructed a noise population covariance matrix that only included single-trial variability (X_{noise}; *SI Appendix*, Eq. **S16**). Using this noise

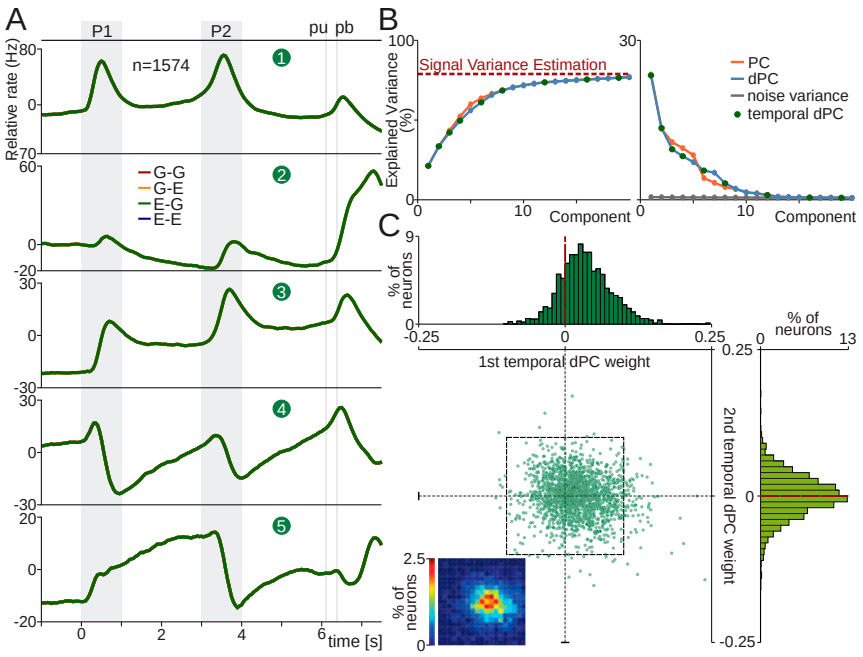

Fig. 4. DPC population temporal signals during the TPDT. (*A*) dPCA was applied to the temporal marginalized covariance matrix obtained from the TPDT. Population activity, sorted by classes, was projected onto the temporal dPCs. Temporal dPCs were ordered according to their explained total variance (ETV). First five temporal dPCs: first ETV, 23.9%; second ETV, 13.5%; third ETV, 9.5%; fourth ETV, 8.25%; fifth ETV, 5.84%. (*B*) Cumulative sum of explained signal-plus-noise variance (*Left*, ESNV). The dashed red line shows an estimate of the fraction of task-related variance. ESNV per component (*Right*). The red traces correspond to PCs; the blue traces are for dPCs. The gray trace represents the percentage of noise variance explained by the dPCs. The green points indicate which dPCs are temporal. (*C*) Central graph: For each neuron, we use its first and second temporal-dPC weights to plot its location on the plane. Heat-map *Inset* (*Bottom Left*) shows the joint weight distribution (20 × 20 grid, 0.01 bin side length, corresponds to black dashed square; color scale goes from 0 to 2.5%). First temporal-dPC weight distribution tends to positive values: $\mu = 0.028$; $\sigma = 0.035$ (*Top*). Second temporal-dPC weights are equally distributed for positive and negative values: $\mu = 0.0001$; $\sigma = 0.029$ (*Right*).

covariance matrix, we estimated the fraction of the "signal-plus-noise" variance that was related to noise. The percentage of variance that was related with signal and not with noise ($1 - Var_{Noise}$) determined the red dashed line in Fig. 4*B*. In Fig. 4*B*, *Left*, we compared the cumulative explained variance for PCs and dPCs. Using both techniques, we obtained analogous results: Few components are necessary to reach the signal variance estimation. In addition, the dimensionality of the population responses estimated with dPCA was equivalent to the one calculated with PCA. Consistently, in Fig. 4*B*, *Right*, we showed that there were only few dPCs that captured higher explained signal-plus-noise variance (ESNV) than noise variance (*SI Appendix*). This means that the inherent population fluctuations (noise) projected onto the dPCs captured significantly less variance, but only compared with the first few components. Keep in mind that there were 1,574 possible dimensions. However, few components are enough to explain the relevant dimensions of the network. We calculated that around 12 dPCs are at least 50% above inherent noise variance. This number estimates the dimensionality of the population responses during the TPDT. In a previous study, this approach was applied to estimate the dimensionality of the dynamic in a frequency discrimination task (11).

Most notably, 7 out of 12 relevant dimensions are pure temporal signals (green dots in Fig. 4*B*). Then, a large proportion of the dimensions of the network are only related to time. Even more, the first four dimensions, which captured 55.15% ETV (48.1% of ESNV), are temporal signals. These results are strong evidence that temporal signals are a relevant part of the network response and that they might act as a substrate for coding dynamics.

A Common Anatomical Substrate for Temporal Signals. We speculated on whether there were separate categories of neurons involved in different temporal components. To explore this possibility, we plotted for each neuron their first and second temporal-dPC weights (Fig. 4*C*). We did not identify evidence for separate clusters of neurons. Even if we showed individual neurons with responses that resembled each of these two components (*SI Appendix*, Fig. S3 *G* and *F* for first dPC, and *SI Appendix*, Fig. S3*E* for second dPC), this was not the general trend. Analogous results were observed when we plotted the weights of other temporal dPCs. Thus, although these temporal signals can be read out independently, they were built from the same anatomical substrate. Analogous results were found in previous studies for other types of components and tasks (11, 13, 19, 27).

Additionally, we calculated the distribution of the weights given by this dPCs for each of the 1,574 neurons. Note that the weight distribution for the first temporal dPC (Fig. 4*C*, *Top*) exhibited a bias to positive values ($\mu = 0.028$; $\sigma = 0.035$). This means that the sensory temporal signals were in general positive (excitatory). Although it was possible to identify negative (inhibitory) temporal sensory neurons (Fig. 3*E* and *SI Appendix*, Fig. S3 *C* and *I*), they were not as abundant as the positive sensory neurons (Fig. 3*F* and *SI Appendix*, Fig. S3 *B*, *D*, and *F*–*H*). However, the weights given by the second temporal dPCs (Fig. 4*C*, *Right*) were equally distributed for both positive and negative values. These results agree with previous studies that found that coding components behave like zero-centered Gaussians distributions (11, 13, 19). Similar distributions were found for higher-order temporal dPCs. Thus, except for the first dPC, the other components exhibited zero-centered weight distributions. Furthermore, the unimodal weight distributions also suggested that there was not a clear division between single neurons that might have participated in temporal signals from those neurons that did not.

Population and Single-Unit Temporal Variances During the LCT. To further quantify whether the DPC temporal signals depended on the animal's task performance, many of the neurons ($n = 462$) were also tested in a control variant of the TPDT. In each trial, the monkeys received identical stimuli as in the TPDT, but the correct answer was indicated by a continual visual cue (Fig. 5*A*). We refer to this task as LCT.

As before, we calculated the population instantaneous coding variance during the LCT (Var_{COD}, *SI Appendix*; Fig. 5*B*). Analogously, we calculated the population variance associated with each task parameter: P1 (Var_{P1}; Fig. 5*B*), P2 (Var_{P2}), and decision (Var_{Dec}). Under the LCT, the population coding variance was no longer related to the identity of the stimulus pattern or the decision report (Fig. 5*B*). Accordingly, the population coding variance stayed constant and equal to its basal value during the whole task. These results agree with the coding dynamics of individual

Downloaded at instituto de Biotecnologia/UNAM on October 20, 2020

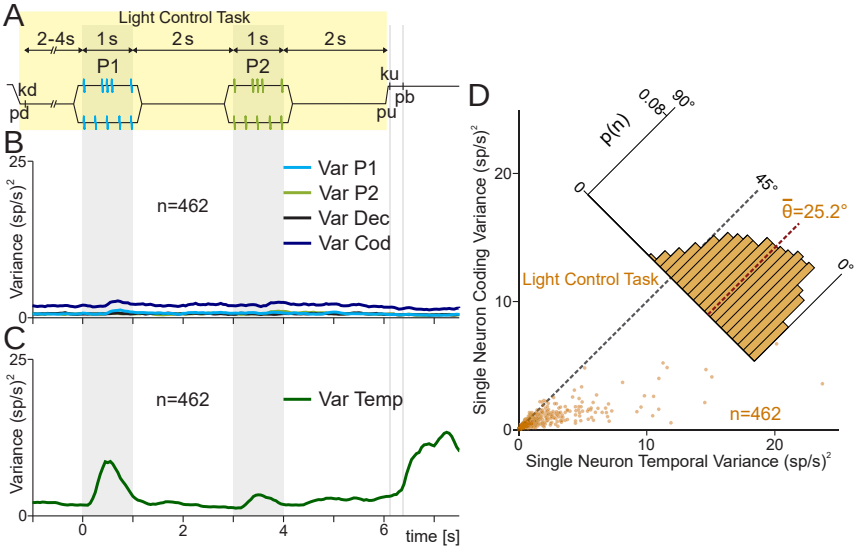

Fig. 5. Single DPC neuron and population variances during the LTC. (*A*) During LCT, events proceeded exactly as in Fig. 1*A*, except that when the probe touched the skin, the correct pb was illuminated. The light was turned off after pu, triggering the pb press. Thus, stimuli and movements were identical to the TPDT, but were cued by visual stimuli. Performance in the LCT was 100% across classes. (*B*) LCT population instantaneous variances: Var_{COD} (blue, *SI Appendix*); Var_{P1} (cyan trace), Var_{P2} (light green trace), and Var_{DEC} (black trace). Note the marked differences with Fig. 1. (*C*) LCT population instantaneous temporal variance (Var_{Temp}, green trace). (*D*) Single-neuron temporal variance during LCT (*x* axis, *SI Appendix*) is compared against single-neuron coding variance during LCT (*y* axis). Each dot corresponds to one neuron ($n = 462$). *Inset* histogram show angular distributions for the population ($\langle\theta\rangle = 25.2°$). During the LCT, $SNVar^i_{Temp}$ is much higher than $SNVar^i_{Cod}$.

neurons observed before (18). Even though stimuli and final movements were the same as in the TPDT, no coding variance modulation was observed. Thus, the population coding variance increased above its basal state only when the task demanded it.

Again, we wonder how much population variance could be associated with temporal dynamics. We remark that although coding variance was not modulated, the firing rate of the neurons evolved during the LCT. To further show this, we quantified the population instantaneous temporal variance (Var_{Temp}, *SI Appendix*, Fig. 5*C*) during the LCT. In contrast to coding variances, Var_{Temp} evolved during the LCT. Thus, fluctuations in firing rate are only involved in timing of the task events. However, the values Var_{Temp} are not as high as during the TPDT (compare Fig. 5*C* with Fig. 1*D*). Thus, we could speculate that part of the temporal signals were still present during LCT, but other temporal dynamics diminished or disappeared. In addition, we compared the variance associated with coding ($SNVar^i_{COD}$) and temporal ($SNVar^i_{Temp}$) for each neuron during the LCT. Each dot in Fig. 5*D* represents one neuron during LCT ($SNVar^i_{Temp}$, *x* axis; $SNVar^i_{COD}$, *y* axis). In concordance, neurons displayed much higher temporal than coding responses. Coding variance remained at small values for all 462 neurons and the angular distribution was biased to small angles ($\langle\theta\rangle = 25.2°$; Fig. 5*D*).

Temporal Responses of Single Neurons in the TPDT vs. the LCT. Do the responses of single neurons undergo their own decrease in temporal variability during LCT? To quantify this, we chose neurons with high temporal variance during the TPDT that were also tested in the LCT. In Fig. 6 and *SI Appendix*, Fig. S5, we show typical DPC temporal activity under both task conditions. In concordance with the differences in Var_{Temp} between Figs. 1*D* and 5*C*, most of the temporal responses declined or vanished during LCT. Notably, even the sensory temporal signal during the stimulus arrival are diminished noticeably during the LCT (Fig. 6 and *SI Appendix*, Fig. S5 *A–C*). All ramping activity observed during the TPDT ceased (Fig. 6 *A* and *C* and *SI Appendix*, Fig. S5 *A–E*). Some of the temporal signals after pb presses remained during both task

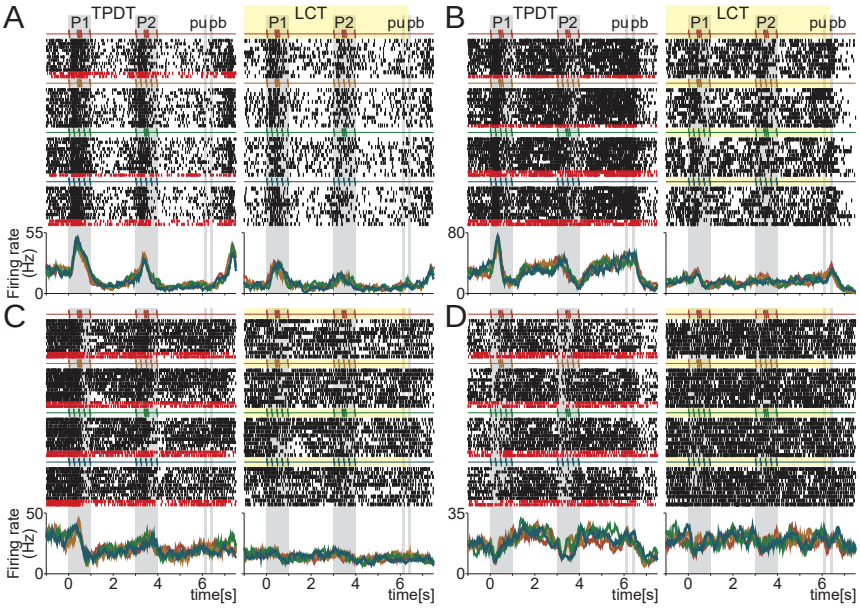

Fig. 6. Single DPC neurons with notable temporal activity compared between TPDT and LCT. (*A–D*) Raster plots of four temporal exemplary neurons tested in both conditions: TPDT (*Left*) and LCT (*Right*). Responses are sorted according to the four possible combinations of G and E stimulus patterns delivered during P1 and P2. Correct and incorrect (only in TPDT) trials are indicated by black and dark red ticks, respectively. Traces below the raster plots are average per-class firing rates (PSTHs) for each neuron and condition. Each color refers to one of the four possible stimulus combinations of G and E; the resulting four classes are c1 (G-G, red), c2 (G-E, orange), c3 (E-G, green), and c4 (E-E, blue). Note that these neurons are different from those shown in other figures.

conditions (*SI Appendix*, Fig. S5 *D–F*). In summary, during the LCT, the temporal signals of individual neurons diminished or ceased, while the coding responses disappeared (18).

Population PCs During the LCT. To investigate whether population temporal signals depended on the cognitive context, we implemented the same population analysis to a subgroup of neurons (n = 462) recorded during TPDT and LCT. First, we applied PCA to the population response under each condition (*SI Appendix*, Fig. S6). We displayed the first five PCs during the TPDT for this subpopulation. We remark that although the number of neurons decreased from 1,574 to 462 (29.3%), the dynamics remained approximately the same (compare *SI Appendix*, Fig. S4 with *SI Appendix*, Fig. S6*A*). This suggests that network dynamics was robust and stable under changes in the number of neurons.

Next, we computed the PCs for the same group of neurons under the LCT (*SI Appendix*, Fig. S6*B*). Although the PCs did not show task-related coding, they exhibited prominent temporal responses. Moreover, all of the components appeared to be associated with the stimulus arrivals or the pb presses. Notably, the PCs' dynamics during delay periods are much weaker than in TPDT. Furthermore, the ramping temporal activity was no longer present under LCT.

Single-Neuron Temporal Variance Compared Between the TPDT and LCT. Based on the results shown in the previous three sections, we speculated that single neurons may diminish their temporal variance under a nondemanding cognitive task (LCT). To test this hypothesis, we compared $SNVar^{i}_{Temp}$ under both task variants. Each point in Fig. 7*A* was determined by the two values: the TPDT $SNVar^{i}_{Temp}$ (x axis) and the LCT $SNVar^{i}_{Temp}$ (y axis). In concordance, cells presented much higher temporal variance under the demanding task (TPDT) than the nondemanding task (LTC). Additionally, the distribution (Fig. 7*A*) was biased to small angles (<θ> = 27.5°). Similar results were found comparing $SNFluc^{i}_{Temp}$ for each task condition (*SI Appendix*, Fig. S7*A*). This is further evidence that several temporal signals were recruited only when the task was demanding enough.

Task Dimensionality and Temporal Signals During the LCT. We applied dPCA to obtain the temporal components optimized for the LCT population. Then, we estimated the dimensionality of the responses during LCT. In Fig. 7*B*, *Top*, we displayed the cumulative sum of total variance captured by the dPCs. We computed the fraction of the total population variance associated with the signal variance (red dashed line). Consistently, few components were enough to reach the estimated signal variance. Additionally, the first six components are pure temporal dPCs. In Fig. 7*B*, *Bottom*, we estimated ESNV from each LCT component and its fraction associated with noise (gray trace). Notably, only six temporal components were significantly above the noise variance estimate. This means that the dimensionality of the network dynamic diminished from 12 dPCs during the TPDT to 6 dPCs during the LCT. Similar results were found using the same neurons (n = 462) to calculate the dimensionality of the network under both task conditions (*SI Appendix*, Fig. S6 *C* and *D*). This dimensionality reduction was due to two factors: the lack of coding dynamics and the decline of temporal signals during LCT.

In Fig. 7*C*, we show the temporal dPCs optimized for the LCT activity. Comparing the temporal dPC from TPDT and LCT, the persistent activity and the ramping responses of Figs. 4*A* and 7*D* were no longer present in Fig. 7*C*. This means that temporal signals are not equivalent in LCT and TPDT, except for those related to stimuli or pb presses. Nevertheless, the intensity of the

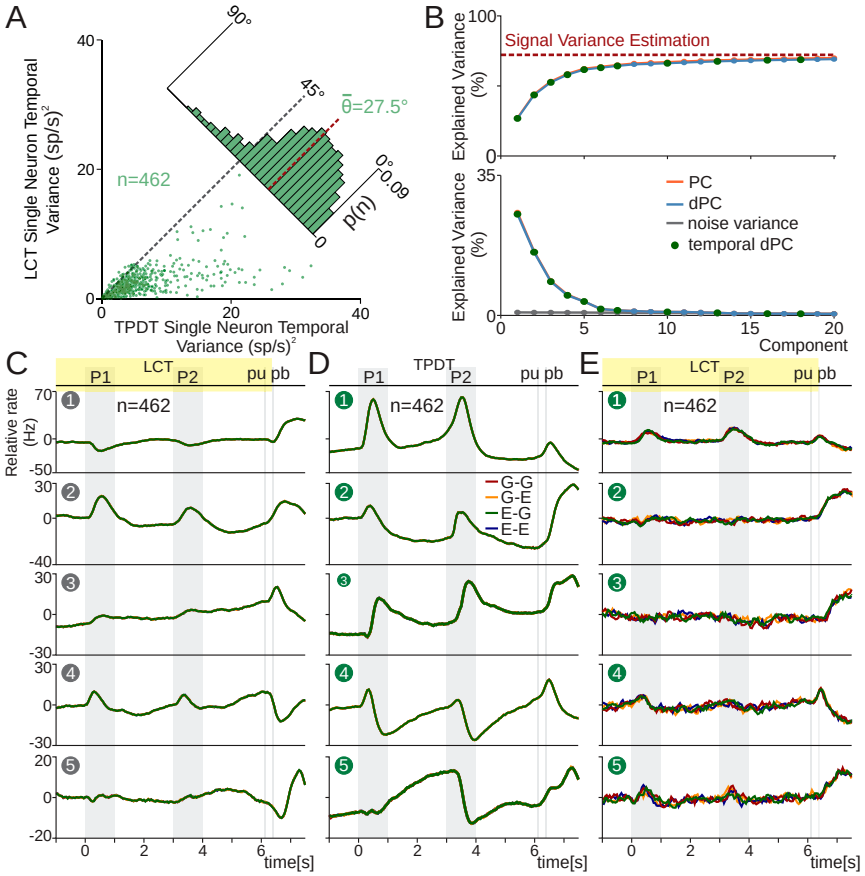

Fig. 7. DPC population temporal signals during the LCT. In this figure, we restricted our analysis to the neurons that were recorded during both TPDT and LCT (n = 462). (*A*) $SNVar^{i}_{Temp}$ in TPDT (x axis, *SI Appendix*) is compared with $SNVar^{i}_{Temp}$ in LCT (y axis). Each dot corresponds to one neuron tested in both conditions (n = 462). *Inset* histogram show angular distributions for the population (<θ> = 27.5°). $SNVar^{i}_{Temp}$ is much higher in TPDT than LCT. (*B*) Cumulative sum of the explained signal-plus-noise variance (ESNV) of the PCs and dPCs during LCT (*Top*). The dashed red line shows an estimate of the fraction of task-related variance. (*Bottom*) ESNV of PCs (red) or dPCs (blue). The gray trace represents the percentage of noise variance explained by each dPCs. The green points indicate the temporal dPC. (*C–E*) Population activity, sorted by class identity, was projected onto each dPC. Components were ordered by their explained total variance (ETV). The same y scale was used among projections to facilitate comparison. (*C*) First five temporal dPCs optimized for the LCT. First ETV, 30.5%; second ETV, 19.5%; third ETV, 10.6%; fourth ETV, 6.4%; fifth ETV, 4.3%. (*D*) dPCA was applied to the temporal marginalized covariance matrix obtained from the whole TPDT (n = 462). These signals are similar to those in Fig. 4*A*. First ETV, 25.1%; second ETV, 14.8%; third ETV, 10.3%; fourth ETV, 9.1%; fifth ETV, 6.4%. (*E*) LCT activity was projected into exactly the same axes than in *D*. Since dPCs were optimized for TPDT population activity, projections of LCT activity showed more fluctuations.

Downloaded at Instituto de Biotecnología/UNAM on October 20, 2020

sensory component clearly diminished during the LCT. The most plausible explanation is that as task parameter coding was not necessary during LCT, the temporal responses that supported this coding ceased or disappeared. Note that the first temporal dPC explained 30.5% of the total variance and was mainly associated with the signal after pb presses. Furthermore, the second dPC was involved with stimulus arrival and pb signal (19.5% ETV). Moreover, the absence of coding during LCT, except for the timing of the task events, entailed similar results when we used dPC or PC projections (compare Fig. 7*C* vs. *SI Appendix*, Fig. S6*B*).

Context-Dependent Temporal Signals. To examine the differences between TPDT and LCT temporal signals, we benefited from the 462 neurons recorded in both task conditions. We calculated the temporal dPCs, now restricted to only those neurons during TPDT. The results were presented in Fig. 7*D*. Again, as with PCA, the temporal dPCs of this subgroup of neurons (n = 462) matched those of the full population (Fig. 4*A*). Then, the number of neurons was reduced from 1,574 to 462, and the temporal components remained unaltered. On the other hand, when we used the TPDT temporal dPCs to project the LCT population activity, we observed a pronounced disappearance of most of the temporal signals (Fig. 7*E*). Thus, the same temporal axes were used to project the TPDT (Fig. 7*D*) and LCT (Fig. 7*E*) population activities. This analysis allowed us to compare between task conditions, the temporal signals that remained or disappeared within the components. Consistent with our previous result, the persistent and ramping responses calculated during the TPDT (Fig. 7*D*) were no longer present in LCT projections (Fig. 7*E*). However, the temporal responses observed after pb during TPDT, remained unaltered across all LCT projections. This is evidence that pb temporal signals are unconnected to those during the delays. All of these results agree with what was observed across the exemplary neurons (Fig. 6 and *SI Appendix*, Fig. S5). Collectively, our population findings suggest a close relationship between the temporal dynamics and task execution. These results are strong evidence that some temporal signals were only recruited when parameter coding was needed to solve the TPDT.

Population and Single-Neuron Temporal Variances During Hit and Error Trials. We wanted to determine to what degree the pure temporal signals in the DPC population predicted the monkeys' performance. We investigated whether the evoked temporal variance was somehow different between correct (hit) vs. incorrect (error) trials during the TPDT. For this, we computed (Var_{Temp}) during hit and error trials (Fig. 8*A*). We restricted this analysis to a subgroup of neurons with at least three error trials in each of the four classes (n = 547). Note that during LCT there were no error trials to analyze; the performance was consistently 100%; this reflects that this guided task was not cognitively demanding, which was part of the intended design.

Notably, Fig. 8*A* shows that Var_{Temp} evolved together during hit and error trials (the same conclusion was obtained employing $Fluc_{Temp}$; *SI Appendix*, Fig. S7*B*). In other words, at each time point, the quadratic distance between the population mean and the basal firing rate during hit and error trials was approximately the same. This means that it is impossible to use Var_{Temp} or $Fluc_{Temp}$ to predict the animals' choice. This result gave us a first suggestion that temporal responses were the same for error and correct choices. We then evaluated the error effect in temporal variance of single neurons. This was made by measuring the $SNVar^{i}_{Temp}$ for each cell during hit and error trials. Similar as we have done previously, on Fig. 8*B* we compared on the same plot the $SNVar^{i}_{Temp}$ associated with hit (x axis) and error (y axis) trials for each single neuron (n = 547). We found that $SNVar^{i}_{Temp}$ evoked by the two types of trials were statistically identical (Fig. 8*B*; $\langle\theta\rangle = 46.9 \pm 10.1°$). The same effect was observed when $SNFluc^{i}_{Temp}$ is compared in hit vs. error trials (*SI Appendix*, Fig. S7*C*). This means that it would also be impossible to differentiate between hit and error trials, based on the temporal variance of single DPC neurons.

Population Temporal Signals During Hit and Error Trials. Finally, we investigated the relationship between the population temporal signals and monkeys' behavior. For this purpose, we studied the differences between hit and error trials on the temporal dPCs. We constructed single-trial activity matrices by pseudorandomly selecting trials from all neurons. Then, we plotted the average and SD of repeated projections (1,000) of single-trial activity onto the temporal axis used in Fig. 4*A*. For error trials, we randomly chose one error trial per iteration for each neuron in each class. Since all neurons (n = 1,574) had at least one error trial per class, we employed the full population for this analysis. The average (solid lines) and SD (shading) of single-hit trial projections are shown in Fig. 8*C*. Note the similarity between the traces in Figs. 4*A* and 8*C*. In addition, the single-trial projection onto each temporal dPC produced small values of SD throughout the task.

Even if it is possible to think that an error in the temporal signal could contribute to an error report, this is not in agreement with our

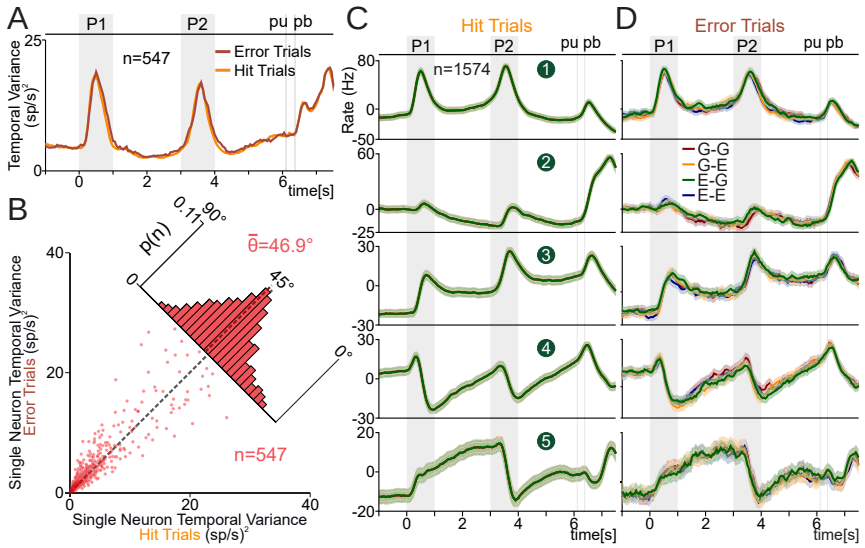

Fig. 8. DPC temporal signals during hit vs. error trials. (*A* and *B*) We restricted our analysis to the neurons (n = 547) with at least three error trials for each class. (*A*) Var_{Temp} (*SI Appendix*) for hit (red) and error (orange) trials. (*B*) $SNVar^{i}_{Temp}$ during hit trials (x axis) is compared against $SNVar^{i}_{Temp}$ during error trials (y axis). Each dot corresponds to one neuron (n = 547). *Inset* histogram show angular distributions ($\langle\theta\rangle = 46.9°$). $SNVar^{i}_{Temp}$ are statistically the same in hit and error trials. (*C*) Temporal dPCs, calculated with hit trials, were used to repeatedly project the population activity of single hit trials. First five temporal dPCs were ordered according to their ETV. Traces show the average (solid line) and SD (shading) for 1,000 hit trial projections. (*D*) The same temporal dPCs as for *C* (calculated with hit trails) were used to project the population activity in single-error trials. The solid lines and shadings were constructed in the same manner, but with error trial population activities.

Downloaded at Instituto de Biotecnología/UNAM on October 20, 2020

results. Clearly, there was a high correspondence between the temporal signals in error (Fig. 8*D*) and hit (Fig. 8*C*) trials. In general, our findings suggest that errors were not associated with the temporal signals. This finding is complemented by previous studies that have shown strong evidence that error trials were associated with task parameter miscoding (18, 28). We remark the notable differences between the temporal signals found in error trials (Fig. 8*D*) with the LCT temporal components (Fig. 7*C*). On one hand, a nondemanding task led to a decline in temporal responses (Fig. 7*C*). On the other hand, during error trials, the temporal signals remained unchanged (Fig. 8*D*).

Discussion

Previously, we showed that DPC codes the relevant task parameters of the TPDT. Here, we found that although a large percentage of DPC neurons were involved in coding dynamics, the variance related to coding task parameters was small in comparison with the size of temporal variance over time. We observed this by using both single-unit and population-averaged approaches. In both cases, the time-dependent responses showed higher variance than task parameter coding.

Contrary to the neuronal responses recorded in the active task (TPDT), during the control task (LCT), DPC neurons did not code task parameters. Furthermore, the only task-related responses that remained during LCT were some pure temporal fluctuations, but their variance were reduced in comparison with the TPDT. Again, this observation was corroborated using both single-unit and population-averaged approaches. Nevertheless, focusing on the error trials, the total amount of temporal variance was similar to hit trials. Then, fluctuations in firing rate related to time were not affected during the animals' errors. Thus, it is not possible to predict an error employing neither single neurons nor population temporal variance.

To extend our analyses to the neuronal population level, we employed dimensionality reduction methods (15, 23–25, 29). We found that the population dynamics were robust and stable despite the high variability in the single neuron's responses. Consistently, a recent study has shown that population responses are unaffected using multiunit threshold crossing activity instead of sorted individual neurons (30). Although PCA served to reduce the dimensionality of the data, most of the components did not reveal a useful representation of the data (13, 14). Consequently, we used dPCA to focalize on the temporal signals of the network responses (13). Thus, we split the whole DPC responses into a more tractable problem. Notable, although temporal dPCs are not linked to task parameter coding, their high explained variance suggested that they constituted a crucial element of task execution. Importantly, these temporal population signals were unaffected during error trials. However, previous studies have shown that coding signals noticeably changed during animals' errors (18, 19, 28). Combining both results, we hypothesize that errors emerge as task parameter miscoding, but not due to the pure temporal signals. This is further supported by the fact that LCT temporal population signals significantly decreased their intensities or disappeared. These results agree with the decreased in variance measured in single units during the LCT. Thus, a big proportion of the temporal signals appeared only when the animals performed the TPDT. The population signals that remained during LCT were only associated with the stimulus arrival and pb responses. To further understand the role of temporal signals during nondemanding tasks, future studies could employ passive tasks (31–34). Under this condition, stimuli remain the same, but animals are not required to push a button to receive reward. Since there was no decision report and no overt attention is necessary in this context, temporal signals in DPC could cease entirely. In support of this conjecture, other studies have shown that coding dynamics vanish completely in frontal cortices during the passive condition (31, 34).

Several studies have shown that neural activity was often sensitive to the temporal task sequence. In particular, a significant proportion of frontal lobe cortex neurons respond to the amount of time elapsed during the delay period between two events. Cells with these types of responses are generally called ramping neurons (4, 10). Note that it was not necessary for the subject to estimate the duration of the delay period to provide an appropriate answer. If they appear, as they do, it should be because they offer some advantage or alternatively, due to some constraint upon the network dynamics. Here, we showed that these ramping responses are commonly found in DPC neurons during both delays (from 1 to 3 s and from 4 to 6 s). Furthermore, we observed that peacemaker-shaped signals prominently emerged from the population response during the TPDT. Notably, they disappeared during the nondemanding task. This suggests that ramping signals were only generated during the active task. Since the network did not code task parameter during the LCT, it did not need to infer the arrival of the task events. Based on those results, we speculate that as the pacemaker component was no longer necessary, it vanished. Future studies could examine the relevance of this ramping activity during task designs in which each trial consists of delay periods of different durations (6, 35–37). Under duration uncertainty, peacemaker signals could adapt, or become useless to predict the stimulus arrival.

We would like to emphasize that a large proportion of the TPDT network dimensions were only associated with time events. In addition, there was a large disparity between the variance captured by population temporal signals vs. the variance associated with task parameters coding. Furthermore, most of the significant TPDT components were only associated with the temporal sequences of task events: 7 out of 12 relevant dimensions were pure temporal signals. However, during the LCT the dimensionality was even smaller than in the TPDT, and all significant components were associated with the temporal signals. These results are in concordance with a recent theoretical work (38) that showed that network's dimensionality increases from a simple task to a more complex one. Altogether, this is further evidence that time-dependent signals emerging in relation to different stages in the task constitute an essential element of the network dynamics during cognitive tasks.

A functional distinction between task coding components and time-dependent variations in firing rates has been proposed previously (11, 39). These studies suggested that functional separation appears at the population level, but not at the single neuron's responses. Our results indicate that temporal readouts arose from diffuse combinations of the single neuron's responses. The distributions of the weights given to each neuron indicate that they share a common anatomical substrate: the distributions were unimodal and Gaussian-like. Despite this, it was still possible to identify single neurons with temporal dynamics that resembled the population dynamics. This means that although these temporal signals emerge at the population level, there are usually stereotypical neuron responses that mimic these temporal responses. However, we were not able to separate them into different categories or give them labels; neuronal response exists in a continuum. This agrees with the notion that the functional separation does not emerge at the single-neuron level (13, 27).

Another important question regarding time-dependent signals is how they are generated. One possibility is that they are generated by a mechanism independent of the task parameter coding dynamics; a sort of master clock that could allow timing across a variety of contexts (40). However, we are inclined to think that our results point in the direction of a different mechanism that has been already proposed: Neuronal populations can inherently produce temporal signals relevant to the task being performed (41). Many networks models have been put forth to address this issue: Recurrent networks could supply a robust and flexible dynamics to encode the passage of time (42–44).

In previous studies, it was suggested that pure time-dependent signals could adapt much faster than task coding components (5, 10, 11). In other words, temporal signals during delays could readapt in blocks of trials with different durations. This mechanism

Downloaded at Instituto de Biotecnología/UNAM on October 20, 2020

could increase the flexibility for coding dynamics to solve the same task under different durations (45–47). Although in our experiment we could not test this hypothesis, it is an important question to address in future experiments.

To conclude, we propose that the temporal signals in DPC (or in any other brain areas) could be interpreted as a substrate necessary to supply a framework on which the task parameter coding dynamics can be computed during sequential events required to reach a decision report. Whether these signals are gradually constructed, beginning in sensory areas or whether they arise abruptly in the frontal lobe cortex remain open questions. This yields at least two possibilities: there exist specific brain areas that construct temporal signals such as the ones extracted here, which are broadcast to other regions, or, rather, the capacity to estimate time through these signals is embedded in the circuits across the brain. Further work is needed to answer these possibilities.

Materials and Methods

Monkeys were trained to report whether the temporal structure of two vibrotactile stimuli of equal frequency was the same or different (*SI Appendix*). Neuronal recordings were obtained in DPC while the monkeys performed the TPDT. Methods for single-unit and population analysis are provided in *SI Appendix*. Animals were handled in accordance with standards of the National Institutes of Health and Society for Neuroscience. All protocols were approved by the Institutional Animal Care and Use Committee of the Instituto de Fisiología Celular, Universidad Nacional Autónoma de México.

ABSTRACT **Experimentally relocating mitochondrial genes to the nucleus for functional expression (allotopic expression) is a challenging process. The high hydrophobicity of mitochondria-encoded proteins seems to be one of the main factors preventing this allotopic expression. We focused on subunit II of cytochrome *c* oxidase (Cox2) to study which modifications may enable or improve its allotopic expression in yeast. Cox2 can be imported from the cytosol into mitochondria in the presence of the W56R substitution, which decreases the protein hydrophobicity and allows partial respiratory rescue of a *cox2*-null strain. We show that the inclusion of a positive charge is more favorable than substitutions that only decrease the hydrophobicity. We also searched for other determinants enabling allotopic expression in yeast by examining the *COX2* gene in organisms where it was transferred to the nucleus during evolution. We found that naturally occurring variations at within-membrane residues in the legume *Glycine max* Cox2 could enable yeast *COX2* allotopic expression. We also evidence that directing high doses of allotopically synthesized Cox2 to mitochondria seems to be counterproductive because the subunit aggregates at the mitochondrial surface. Our findings are relevant to the design of allotopic expression strategies and contribute to the understanding of gene retention in organellar genomes.**

INTRODUCTION

Most mitochondrial proteins are encoded in the nuclear genome, translated by cytosolic ribosomes, and directed to mitochondria. However, migration of mitochondrial genes to the nucleus occurs widely in nature (Adams and Palmer, 2003; Burger *et al.*, 2003; Timmis *et al.*, 2004). These relocalized nucleotide sequences acquire more complex regulation and tend to exhibit lower mutation rates (Martin and Herrmann, 1998). Mitochondrial genomes mainly encode subunits of oxidative phosphorylation (OXPHOS) complexes. In general, these proteins are embedded in membranes and are highly hydrophobic, a feature that is considered to be one of the main driving forces for the retention of a genome in mitochondria (Johnston and Williams, 2016).

Experimentally relocating mitochondrial genes to the nucleus holds promise for the development of treatments of mitochondrial diseases (De Grey, 2000; DiMauro *et al.*, 2006; Kyriakouli *et al.*, 2008). A mutation in the mitochondrial genome, yielding a defective protein, could be overcome in principle by the import of a nucleus-encoded functional version of the protein. Multiple efforts have been undertaken to express mitochondria-encoded genes allotopically using yeast or mammalian model systems, but conflicting and inconsistent results call for careful interpretation of results and warrant further experimental testing (Oca-Cossio *et al.*, 2003; Perales-Clemente *et al.*, 2011).

The *COX2* gene, encoding subunit 2 (Cox2) of cytochrome *c* oxidase (C*c*O), provides an example of natural migration of a mitochondrial gene to the nucleus. This gene is generally mitochondria-encoded, but in a few organisms it is found in the nuclear

genome (Adams *et al.*, 1999; Pérez-Martínez *et al.*, 2001; Szafranski, 2017). For example, *COX2* was transferred to the nucleus in some members of the legume lineage, resulting in mitochondrial and nuclear versions of *COX2*. The representative species of this lineage encode Cox2 in the nuclear DNA, in the mitochondrial DNA, or in both genomes, depending on which copy was activated and/or inactivated (Adams *et al.*, 1999; Daley *et al.*, 2002a,b). Also, the *COX2* gene has been relocalized experimentally to the yeast nucleus (Supekova *et al.*, 2010), and subsequent studies have provided supporting genetic and biochemical evidence for successful allotopic expression (Cruz-Torres *et al.*, 2012; Elliott *et al.*, 2012; Rubalcava-Gracia *et al.*, 2018). The substitution of a tryptophan for an arginine in position 56 ($Cox2^{W56R}$), within the first transmembrane segment (TMS) of allotopically produced Cox2, decreases its hydrophobicity and allows the partial respiratory rescue of a *cox2*-null yeast strain, with an estimated ~60% recovery of CcO levels as compared with the wild-type strain (Cruz-Torres *et al.*, 2012). This partial complementation can be attributed solely to diminished import, since a mitochondrial *COX2* gene producing the W56R variant cannot be distinguished from wild-type (Rubalcava-Gracia *et al.*, 2018). The decrease in hydrophobicity of the first TMS in Cox2 also occurred during the natural relocation of the *COX2* gene to the nucleus in legumes (Daley *et al.*, 2002b). Other necessary modifications for successful allotopic expression include recoding the mitochondrial gene to the nuclear genetic code and fusing a sequence encoding a mitochondrial targeting sequence (MTS) to the open reading frame. Given that the W56R substitution was found in a random mutagenesis screen of 20,000 alleles (Supekova *et al.*, 2010), it is likely that this is the only permissible change that enables import from the cytosol to the mitochondria and at the same time maintains CcO functionality. This underscores the power of such an approach to uncover mutations allowing the allotopic production of other mitochondria-encoded proteins.

Here, we further explored the W56 position in Cox2 by testing whether other residues with similar properties to arginine could confer allotopic expression. We also tested whether naturally occurring changes in the legume *Glycine max* Cox2 enable yeast Cox2 to be imported from the cytosol into mitochondria and assembled into a functional CcO. Finally, we evidenced that dosage of the cytosol-synthesized Cox2 precursor is critical for the outcome of allotopic expression.

RESULTS

Other substitutions at residue 56 enable the allotopic expression of *COX2*

First, we tested whether other changes at position 56, besides the tryptophan-to-arginine substitution (Supekova *et al.*, 2010) (W56R), can restore the respiratory growth of a *cox2*-null strain expressing an allotopic version of *COX2*. We substituted W56 for two residues sharing at least one physicochemical property with arginine: lysine (W56K), which also has a positive charge, and glutamine (W56Q), which has the closest hydrophobicity score to arginine (Calado-Botelho *et al.*, 2011). Upon introduction of the allotopic constructs encoding $Cox2^{W56K}$ or $Cox2^{W56Q}$ into a *cox2*-null strain, we observed a restoration of respiratory growth. Respiratory growth of the strain with the W56K substitution was comparable to that of the strain carrying the W56R substitution, while the recovery of respiratory competence by $Cox2^{W56Q}$ was significantly less (Figure 1A). Hence, the growth behavior of yeast carrying these constructs was $Cox2^{W56R} = Cox2^{W56K} > Cox2^{W56Q}$. As a negative control, we included a strain expressing an allotopic wild-type *COX2* gene (producing the $Cox2^{WT}$ subunit). As expected, neither this construct producing $Cox2^{WT}$, nor the empty plasmid, was able to restore respiratory growth in the *cox2*-null strain (Figure 1A).

Previous work evidenced that most of the allotopically synthesized $Cox2^{W56R}$ protein accumulates as an unprocessed precursor (i.e., still carrying its MTS) detected in the mitochondrial fraction (Supekova *et al.*, 2010; Cruz-Torres *et al.*, 2012; Rubalcava-Gracia *et al.*, 2018). We thus performed cellular fractionations to test the cytosolic versus mitochondrial distribution of $Cox2^{WT}$, $Cox2^{W56K}$, and $Cox2^{W56Q}$. Most of the Cox2 precursors were found associated with mitochondria (Figure 1B), indicating that, similarly to $Cox2^{W56R}$, the limiting step occurs before their processing into mature forms in the mitochondrial matrix. Our results show that other residues at position 56 allow allotopic expression of *COX2* and that the inclusion of a positive charge in the first TMS (W56K) is favorable over a substitution that only diminishes hydrophobicity (W56Q).

Mutations that allow the nuclear expression of *COX2* in legumes also confer allotopic expression in yeast

Next, we sought to identify other changes in Cox2 that might enable its allotopic expression in the yeast system. We reasoned that in organisms that naturally encode *COX2* in the nucleus, the protein

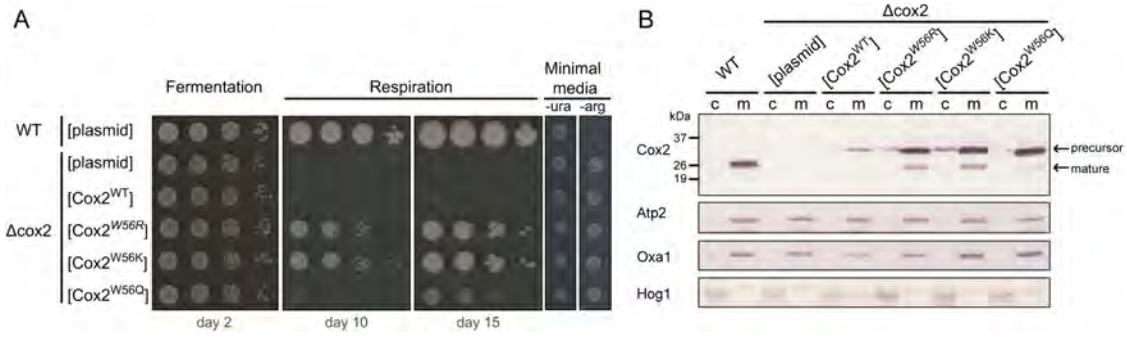

FIGURE 1: Substituting residues of properties similar to those of arginine in position 56 of allotopic Cox2 restores cellular respiration to a *cox2*-null strain. (A) Tenfold serial dilutions of yeast liquid cultures from strains transformed with the indicated constructs or with an empty vector (plasmid) were plated on fermentable (glucose), respiratory (ethanol + glycerol), and minimal, selective media (-ura or -arg, for verifying the presence of the transforming plasmid or the mitochondrial genome, respectively). (B) Immunoblots decorated with an anti-Cox2 antibody of cytosolic (c; 100-µg) and mitochondrial (m; 50-µg) fractions of the indicated yeast strains. The Cox2 precursor and mature forms of Cox2 are indicated. Antibodies anti-Atp2 and anti-Oxa1 were used to immunodetect the corresponding mitochondrial markers and anti-Hog1 was used for the cytosolic marker. Squared brackets indicate Cox2 variants expressed from plasmids. All the Cox2 variants contain an MTS from Oxa1.

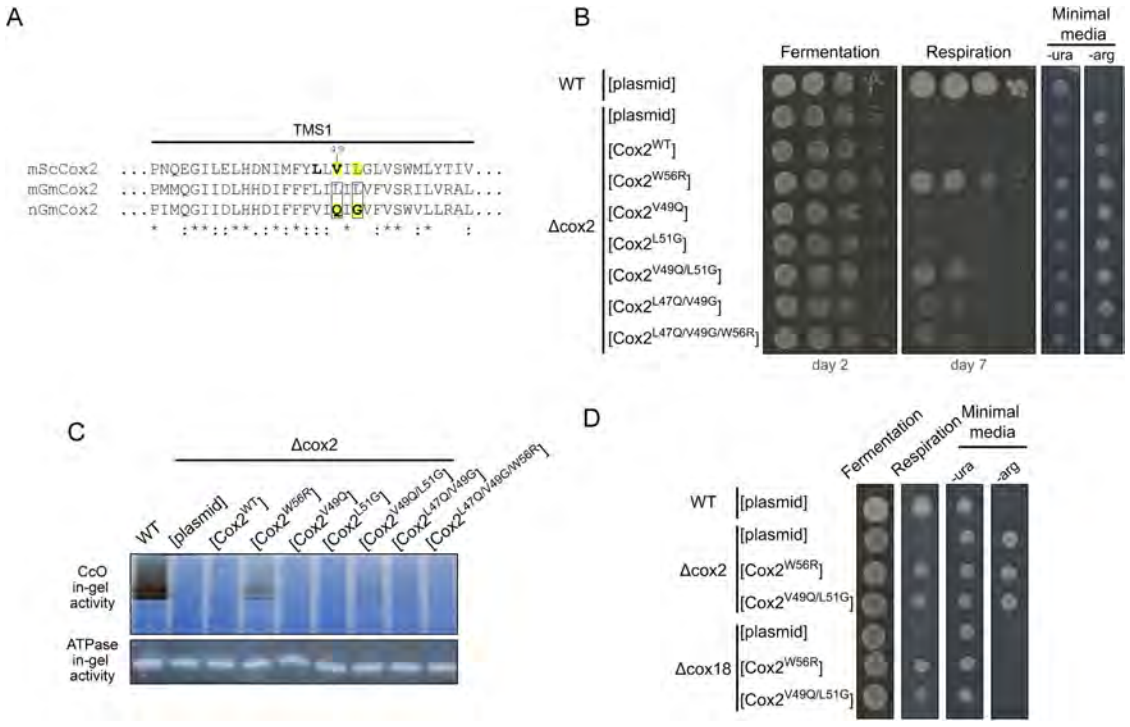

FIGURE 2: Mutations that allow the nuclear expression of *COX2* in legumes also confer allotopic expression in yeast. (A) Sequence alignments of the first transmembrane segment (TMS1) from the yeast Cox2 (mScCox2) and the mitochondrial and nuclear Cox2 versions of *Glycine max*, mGmCox2 and nGmCox2, respectively. An asterisk (*) indicates positions that have a single, fully conserved residue. A colon (:) indicates conservation between groups of strongly similar properties (scoring >0.5 in the Gonnet PAM 250 matrix). A period (.) indicates conservation between groups of weakly similar properties (scoring ≤0.5 in the Gonnet PAM 250 matrix). Key residues that are critical for import of the legume Cox2 from the cytosol are boxed (see text). Two yeast Cox2 constructs were designed based on this alignment: $Cox2^{V49Q/L51G}$ and $Cox2^{L47Q/V49G}$. (B) Tenfold serial dilutions of yeast cultures from the indicated strains were spotted on fermentable (glucose), respiratory (ethanol + glycerol), and minimal, selective media (-ura or -arg). (C) In-gel activity staining of complex IV and of complex V as a loading control. Isolated mitochondria (250 µg) from the indicated strains were solubilized with lauryl maltoside and resolved by BN-PAGE. (D) Strains (WT, Δ*cox2*, and Δ*cox18*) were plated on fermentable (glucose), respiratory (lactate), and minimal, selective media (-ura or -arg). Squared brackets indicate Cox2 variants expressed from plasmids. All the Cox2 variants contain an MTS from Oxa1.

sequence must carry determinants for import into the mitochondria and subsequent assembly into a functional holoenzyme. For example, the legume *Glycine max* expresses the *COX2* gene from both nuclear and mitochondrial genomes (Adams *et al.*, 1999). Previous research showed that a two-residue substitution within the first TMS of Cox2 is necessary and sufficient for the mitochondrial version of Cox2 to be imported into isolated mitochondria. Accordingly, the nucleus-encoded Cox2 protein could no longer be imported into the organelle when the residues (Q and G) at these two positions were modified to the ones (L and L) present in the mitochondria-encoded Cox2 (Daley *et al.*, 2002b; Figure 2A). The conclusion from this study is that this two-residue substitution was determinant in facilitating the import of Cox2 from the cytosol to the mitochondria.

To test whether this two-residue substitution could confer allotopic expression in the yeast system, we sought to reproduce the legume *COX2* mutations in the *COX2* sequence from yeast. We generated an alignment of the two legume Cox2 subunits with the one from yeast and identified that the key residues conferring import of the legume Cox2 correspond to a valine and a leucine at positions 49 and 51 in the yeast sequence (Figure 2A). We therefore engineered the mutations corresponding to the single and double substitutions V49Q and L51G in yeast *COX2*. We observed that only the $Cox2^{V49Q/L51G}$ variant was able to restore respiratory growth in a *cox2*-null strain, while the $Cox2^{V49Q}$ and $Cox2^{L51G}$ variants could not (Figure 2B), demonstrating that both changes are required for successful allotopic expression of *COX2*. However, the respiratory growth of the $Cox2^{V49Q/L51G}$ strain was less than that of the $Cox2^{W56R}$ strain. To test whether the overall decrease in hydrophobicity within the first TMS of Cox2 is sufficient for restoring respiratory growth, we substituted other aliphatic residues at other positions, resulting in the construct $Cox2^{L47Q/V49G}$. To explore any additive effect, a triple *COX2* mutant corresponding to W56R combined with a double substitution (L47Q/V49G/W56R) was also generated. All these constructs could restore the respiratory growth of a *cox2*-null strain, although to a lesser extent than the construct producing $Cox2^{V49Q/L51G}$. We also could not observe any additive effect in the strain producing the $Cox2^{V49Q/L51G/W56R}$ variant. Using *in-gel* activity staining, we verified that CcO activity correlated with the observation that the $Cox2^{W56R}$ variant exhibits increased respiratory growth compared with that in the variants containing two-residue substitutions (Figure 2C). In contrast, another OXPHOS complex, ATPase, exhibited comparable activity for all strains.

Next, we questioned whether $Cox2^{V49Q/L51G}$ follows the same biogenesis pathway as that of allotopically produced $Cox2^{W56R}$. In contrast to orthodox Cox2, synthesized in mitochondria, allotopically

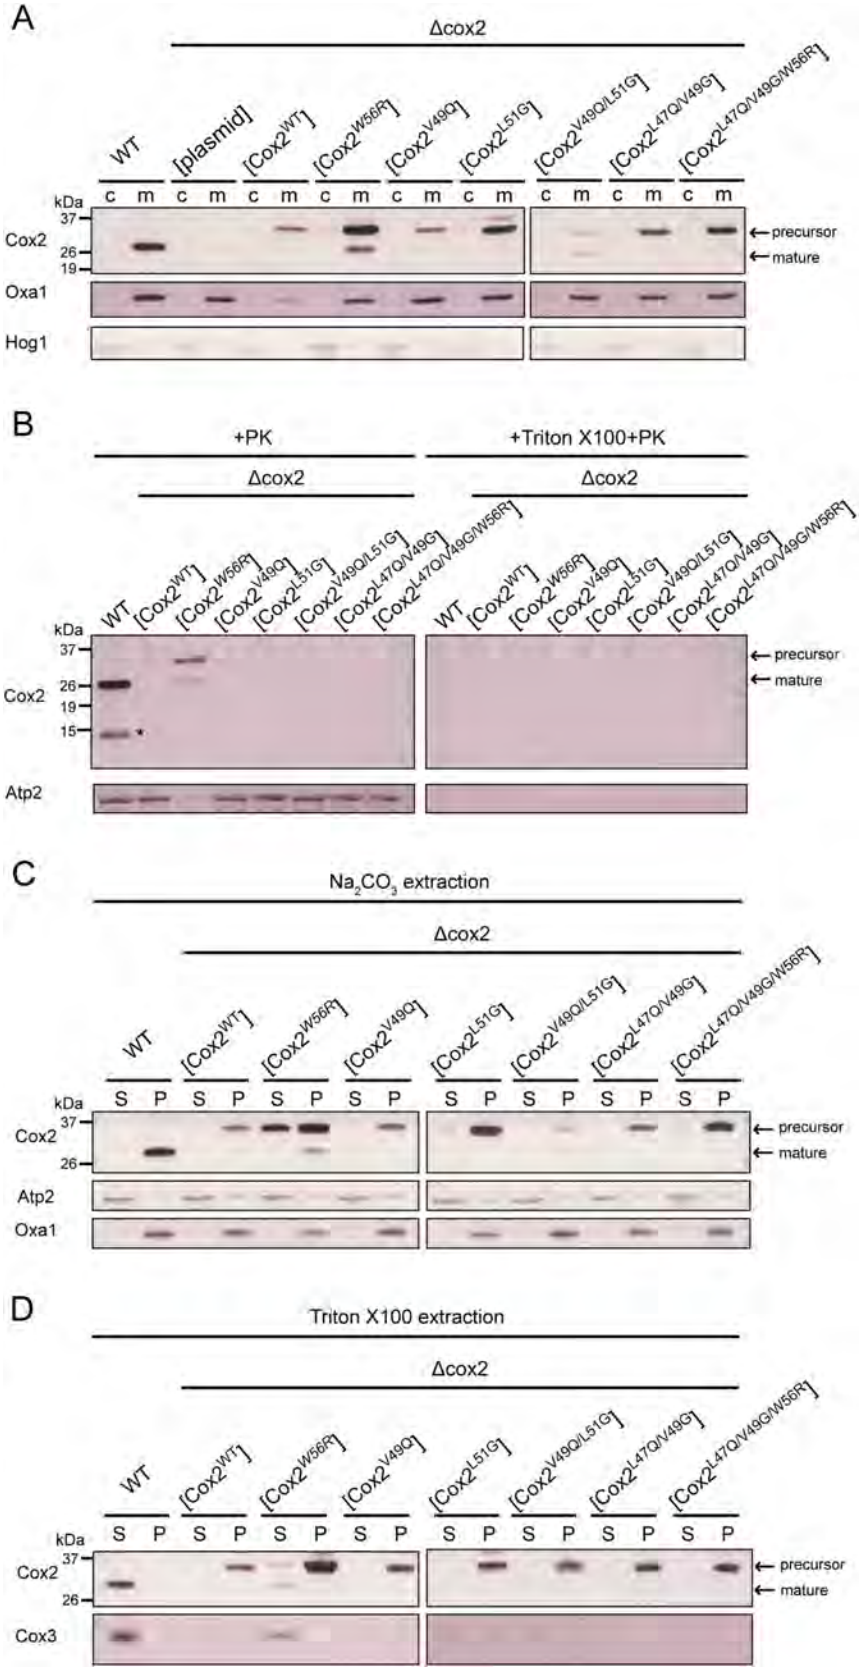

FIGURE 3: The allotopically synthesized proteins face the limiting step by aggregating at the mitochondrial periphery. (A) Immunoblots decorated with anti-Cox2 of cytosolic (c; 100-μg) and mitochondrial (m; 50-μg) fractions. Arrows indicate the precursor and mature forms of Cox2. The mitochondrial markers Oxa1 and the cytosolic marker Hog1 were decorated with their corresponding antibodies. (B) Isolated mitochondria (50 μg) were treated with proteinase K (PK) to degrade proteins external to the outer membrane. Parallel samples were preincubated with Triton X-100 to dissolve the membranes and to make all mitochondrial proteins accessible to protease degradation. The asterisk indicates partial degradation of Cox2, possibly due to imperfect mitochondrial preparation. (C) Carbonate extraction separating the membrane extrinsic proteins in the supernatant (S) from the integral membrane proteins in the pellet (P) from yeast expressing the indicated constructs. Atp2 was used as a soluble protein marker and Oxa1 as an integral membrane protein marker. (D) Triton X-100 extraction separating the detergent-solubilized proteins in the supernatant (S) from the (detergent-resistant) aggregated proteins in the pellet (P) from yeast expressing the indicated constructs. Cox3 was used as a solubilized membrane protein marker. Squared brackets indicate Cox2 variants expressed from plasmids. All the Cox2 variants contain an MTS from Oxa1.

synthesized $Cox2^{W56R}$ does not require the Cox18 translocase for the correct insertion of its second TMS into the inner membrane (Elliott *et al.*, 2012), and it was postulated to be released laterally into this membrane directly from the TIM23 complex (Rubalcava-Gracia *et al.*, 2018). We observed that, similarly to the $Cox2^{W56R}$ strain, the $Cox2^{V49Q/L51G}$ variant is able to restore respiration when expressed in a *cox18*-null (Figure 2D), indicating that the Cox18 translocase is completely dispensable. This suggests that the second TMS of $Cox2^{V49Q/L51G}$ is released laterally into the inner mitochondrial membrane by the TIM23 translocator.

We observed that while the mature forms of Cox2 were protected from degradation upon incubation of mitochondria-enriched fractions with proteinase K (PK), a result indicative of mitochondrial localization, the Cox2 precursors were mostly degraded by the protease (Figure 3, A and B). These results may be interpreted in two ways: either the precursors are associated with the external face of the outer mitochondrial membrane or they are retained while in transit through the TOM and TIM23 complexes with their C-termini still exposed to the cytosol (note that our anti-Cox2 antibody recognizes the C-terminus of Cox2). To distinguish between these two possibilities, we performed carbonate and Triton X-100 extractions of the mitochondrial fractions. We found that the precursors are mostly resistant to both carbonate (Figure 3C) and detergent treatments (Figure 3D). As expected, mature Cox2 proteins resist carbonate extraction but are solubilized into the supernatant upon Triton extraction (Figure 3, C and D). These observations suggest that most Cox2 precursors aggregate at the external mitochondrial surface, thus preventing their import.

Taken together, our data show that substitutions at a position different from that of W56

enable the successful allotopic expression of *COX* and that a major limiting step for importing allotopic Cox2 into mitochondria is its aggregation.

Lowering the dose of allotopic *COX2* expression enhances Cox2 import and assembly in CcO

While the use of a multicopy plasmid for allotopic expression of *COX2* to ensure successful complementation seemed justified a priori (Supekova *et al.*, 2010), we wondered whether reducing the allotopic expression of *COX2* would decrease the rescue of the respiratory defect proportionally. For this purpose, we opted to test allotopic expression under a condition where the same *COX2* construct carried in the multicopy plasmid was used as a single copy. To achieve this, we integrated the *COX2*-expressing construct (under the same phosphoglycerate kinase promoter and terminator present in the multicopy plasmid) in the nuclear genome. Surprisingly, we observed a notable increase in respiratory growth in the strains expressing the nuclear-integrated constructs producing $Cox2^{W56R}$ and $Cox2^{V49Q/L51G}$ in comparison with the strains producing the same Cox2 variants from a multicopy plasmid (Figure 4A). Growth of the yeast containing the single-copy $COX2^{W56R}$ construct was even comparable to that of a wild-type strain, and the strain containing the single-copy $COX2^{V49Q/L51G}$ exhibited more robust respiratory growth than the one with the high-copy $COX2^{W56R}$. The strain producing $Cox2^{WT}$ did not display any growth in respiratory medium, even at low doses. Immunodetection of Cox2 in mitochondria-enriched fractions of these strains showed that, at low dosage, $Cox2^{W56R}$ and $Cox2^{V49Q/L51G}$ only accumulated in their mature forms at levels similar to those of the WT strain (Figure 4B). As previously observed, at high dosage, $Cox2^{W56R}$ and $Cox2^{V49Q/L51G}$ were mainly observed as precursors, with only a fraction converted to the

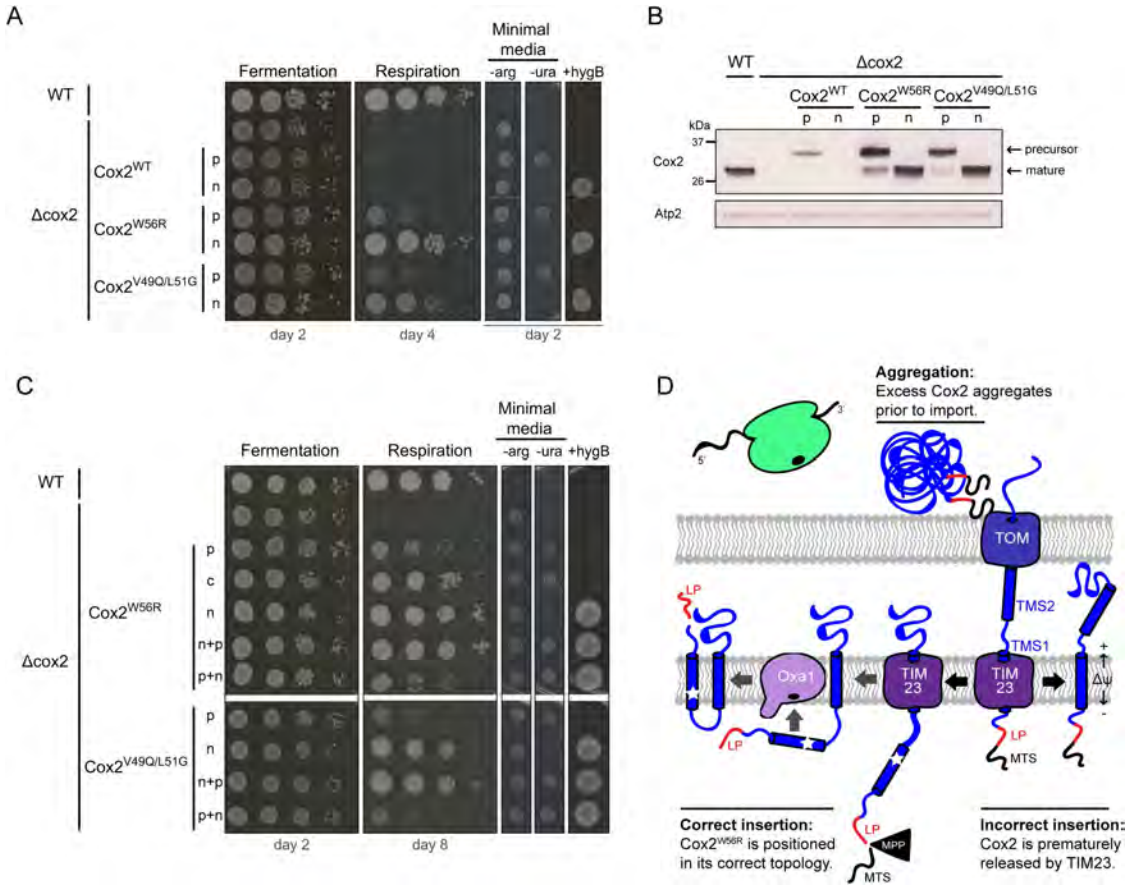

FIGURE 4: Lowering the expression of allotopic *COX2* in a *cox2*-null strain improves rescue of the respiratory growth. (A) Tenfold serial dilutions of yeast cultures from the indicated strains were plated on fermentable (glucose), respiratory (ethanol + glycerol), and minimal, selective media (-arg or -ura) and in the presence of hygromycin B (+hygB). The letter p represents expression from a multicopy plasmid, and the letter n represents expression from a single copy inserted in the nuclear genome. (B) Cox2 steady-state levels in isolated mitochondria (50 µg) from the indicated strains. Arrows indicate the precursor and mature forms of Cox2. The letters p and n indicate expression levels as in A. (C) Tenfold serial dilutions of yeast cultures from the indicated strains were plated on fermentable (glucose); respiratory (ethanol + glycerol), and minimal, selective media (-arg or -ura) and in the presence of hygromycin B (+hygB). The letter c represents expression from a centromeric plasmid. The order of the letters indicates the order in which *COX2*-expressing constructs were introduced into yeast cells. All the Cox2 variants contain an MTS from Oxa1. (D) Biogenesis model of allotopically synthesized Cox2. On the left, insertion of Cox2 results in its correct topology. On the right, the high hydrophobicity of the first TMS leads the cytosol-synthesized Cox2 to aggregate at the mitochondrial periphery or to be prematurely released by TIM23 into an incorrect topology. TOM: translocase of the outer membrane, TIM: translocase of the inner membrane, MPP: mitochondrial processing peptidase, LP: leader peptide, MTS: mitochondrial targeting sequence, TMS: transmembrane segment.

mature form. In line with the absence of respiratory growth of the strains carrying the *COX2*^{WT} construct, the Cox2^{WT} protein was observed only as a precursor and, at low dosage, its steady-state level was probably extremely low, as we could not detect it under our experimental conditions (Figure 4B). We observed the same behavior, that is, enhanced respiratory growth, lower accumulation of precursors, and higher levels of mature forms of Cox2, when the same constructs were expressed in few copies from a centromeric plasmid (Figure 4C and unpublished data). To test the importance of high versus low doses of Cox2 for the rescue of respiratory growth, we increased the dosage by producing the high-copy Cox2 variants (p) in a strain already encoding a single-copy Cox2 in the nuclear genome (n). We observed that this strain (n+p) grew in respiratory medium to levels similar to those of the strain expressing Cox2 encoded only in the nucleus (Figure 4C) and verified the presence of the precursors by immunoblotting (unpublished data). Unexpectedly, these increased levels of expression did not show the same growth defect of the high-copy Cox2 strain. However, when we inverted the order of production of allotopic Cox2 variants in the cells by integrating Cox2 into the nuclear genome in a strain already encoding a high-copy Cox2 (p+n), we observed that this strain showed the same level of respiratory growth as the strain expressing a high-copy Cox2 from a plasmid (Figure 4C).

The aforementioned results suggest that, although overexpression of allotopic *COX2* constructs is able to restore respiration to *cox2*-null strains, directing high doses of these proteins to mitochondria at the same time is counterproductive. Because the limiting step resides in the import of allotopic Cox2, low-dose expression seems to have a better outcome in terms of aggregation propensity and recovery of the respiratory growth.

DISCUSSION

The experimental relocation of mitochondrial genes to the nucleus has paved the way for the development of therapies intended to treat syndromes caused by mutations in the mitochondrial genome (González-Halphen *et al.*, 2004; Taylor and Turnbull, 2005; Kyriakouli *et al.*, 2008; Calvo and Mootha, 2010; Gorman *et al.*, 2016). Ongoing research has unveiled several constraining factors that limit allotopic expression (Claros *et al.*, 1995; Oca-Cossio *et al.*, 2003; Figueroa-Martínez *et al.*, 2011; Björkholm *et al.*, 2017). Because most proteins encoded in the mitogenome are integral to the membrane, the high hydrophobicity and the number of TMSs in these proteins seem to be major limiting factors for their import when synthesized in the cytosol (Claros *et al.*, 1995; Johnston and Williams, 2016). In this work we also found that aggregation propensity, which is directly correlated with high hydrophobicity (Chiti *et al.*, 2003; Dobson, 2004), contributes to the efficiency of importability before assembly of allotopic Cox2 into cytochrome *c* oxidase. Average hydrophobicities for the first TMSs of the different Cox2 variants used in this work are shown in Table 1.

First, we turned our attention to the Cox2 subunit to examine the importance of the residues enabling its allotopic production. Previous work demonstrated that substituting a tryptophan for an arginine decreases the hydrophobicity of the first TMS of Cox2 by adding a positive charge (Supekova *et al.*, 2010). In this study, substitution of a lysine or glutamine in the same position also allowed recovery of the respiratory growth, but residues containing a positive charge (arginine and lysine) yield better rescue than a residue decreasing the hydrophobicity (glutamine). It is possible that Cox2^{W56Q} is poorly inserted into the mitochondrial inner membrane, because the key determinant for importability is the presence of a positive charge (R^+ or K^+) and not reduction of the hydrophobicity

Cox2 variant	TMS1	H

Average hydrophobicity for the first transmembrane segment of each Cox2 variant used in this work. The "biological scale" was experimentally obtained and provides a hydrophobicity value for each residue present in the TMS of a model yeast mitochondrial protein (Calado-Botelho *et al.*, 2011). Cox2 variants are ordered by decreasing hydrophobicity (increasing hydrophilicity). Residue substitutions are underlined.

TABLE 1: Average hydrophobicity of the Cox2 variants.

(Q) at this position (von Heijne, 1992; Andersson and von Heijne, 1994) (see Table 1). This view is supported by the fact that while a similar number of Cox2 variant precursors accumulate in the mitochondria, the mature form of Cox2^{W56Q} is significantly less abundant than those of Cox2^{W56R} and Cox2^{W56K} (Figure 1B). This indicates that Cox2^{W56Q} is probably limited in its insertion in the inner membrane because it is more prone to aggregation. That mature Cox2^{W56K} and Cox2 ^{W56R} accumulate at the same level reinforces the view that a positive charge at this position is the key determinant of Cox2 importation into mitochondria when it originates from the cytosol.

Here, we designed allotopic Cox2 variants in yeast based on naturally evolving alterations in legumes. Notably, we observed that the double substitution reported as key for nuclear expression of Cox2 in *Glycine max* also allowed the allotopically expressed yeast *COX2* to restore respiration to a *cox2*-null mutant. Similarly to what was observed in in vitro import assays in legumes (Daley *et al.*, 2002b), each single-substitution V49Q or L51G was insufficient to restore respiration. In line with the cytosol-synthesized Cox2 biogenesis model (Daley *et al.*, 2002a; Jiménez-Suárez *et al.*, 2012; Rubalcava-Gracia *et al.*, 2018), the first TMS (TMS1) of Cox2 is transferred to the matrix through the TIM23 translocase, while the second TMS is laterally released into the inner membrane by TIM23 (Figure 4D). As a final step, TMS1 is inserted from the matrix in the inner membrane by Oxa1, positioning Cox2 in its correct topology (Figure 4D). We assume that in the presence of either substitution (V49Q or L51G), the proteins aggregate at the mitochondrial periphery before import because they are too hydrophobic (Figure 4D and Table 1). Accordingly, only the double substitution, which diminishes the overall hydrophobicity of the TMS1 of Cox2, allows its correct insertion into the inner membrane.

It should be mentioned that the legume Cox2 substitutions (V49Q/L51G) are less efficient in conferring respiratory growth than the W56R that was identified through random mutagenesis (Supekova *et al.*, 2010). Indeed, the W56R substitution meets Goldilocks conditions: besides maintaining CcO activity intact (Rubalcava-Gracia *et al.*, 2018), it balances the need to diminish the hydrophobicity of Cox2 TMS1, but at the same time, it maintains the ability of TMS1 to be recognized as a transmembrane domain by the inner membrane translocator Oxa1. Notably, in the mitochondrial Cox2 sequence from *Glycine max*, the residue corresponding

to position 56 contains an arginine, indicating that a positive charge in the first TMS of Cox2 is permissible, at least in some organisms. Production of low levels of $Cox2^{V49Q/L51G}$ results in the accumulation of mature Cox2 at a level similar to that of $Cox2^{W56R}$, suggesting that insertion in the inner membrane occurs to the same extent for both Cox2 variants (Figure 4B). However, the fact that the rescue with $Cox2^{V49Q/L51G}$ is significantly less efficient indicates that the V49Q/L51G modifications impact the biogenesis of Cox2 or the activity of the yeast enzyme. Furthermore, we observed that the combination of W56R substitution with the V49Q and L51G changes did not further improve respiratory growth, and resulted in lower C*c*O activity, as observed in Figure 2C. We assume that, despite the fact that these mutations enable respiratory growth, they may also affect C*c*O activity. Another possibility is that the hydrophobicity of the first TMS of the $Cox2^{L47Q/V49G/W56R}$ subunit is lowered to such an extent (Table 1) that it is not promptly recognized as a transmembrane domain and is therefore only partially routed for insertion into the inner membrane by the Oxa1 translocator.

Our experiments indicate that allotopically expressed proteins face a limiting step by aggregating before their import into mitochondria. When we lowered the *COX2* expression levels by integrating the *COX2* gene into the nuclear genome, we observed a notable increase in the rescue of the *cox2*-null strain, which correlated with lower levels of precursor and corresponding enhanced levels of mature Cox2. It is conceivable that excess cytosol-synthesized Cox2 aggregates at the mitochondrial surface, limiting the import of allotopic Cox2 (Figure 4D). These aggregates do not affect the import of other mitochondria-targeted proteins, as the precursors of Oxa1 and Atp2 were not observed to accumulate in our mitochondrial preparations (Figures 1B, 3A, and 4B). We noted that aggregation can also be avoided if large doses of Cox2 are produced in a strain already synthesizing small doses of allotopic Cox2. We explain this observation by the importing competence of *cox2*-null mitochondria. If large doses of the precursors of Cox2 are directly produced in a *cox2*-null mutant, most precursors aggregate and only a fraction assemble into C*c*O, resulting in difficulties in restoring respiration and in building up the electrochemical gradient required for further protein import. At small doses, aggregation of Cox2 is prevented and its assembly into C*c*O is enhanced, giving rise to an optimal transmembrane gradient that facilitates further import of cytosolic proteins. These results suggest that expression levels of the allotopic gene (from a centromeric plasmid or a high-copy plasmid) define the levels of importability versus aggregation of Cox2. It is also conceivable that cytosolic chaperones and other aggregation-response proteins might play a role in preventing the aggregation of Cox2 precursors.

Aggregation propensity is directly related to hydrophobicity and has been an underinvestigated factor in the study of allotopic expression. Highly hydrophobic proteins imported from the cytosol must avoid aggregating at the mitochondrial periphery to cross both mitochondrial membranes. All reports of allotopic expression in either yeast or cell cultures use high-level expression plasmids to ensure a high accumulation of the desired protein products inside the mitochondria (Guy *et al.*, 2002; Manfredi *et al.*, 2002; Ojaimi *et al.*, 2002; Bokori-Brown and Holt, 2006; Bonnet *et al.*, 2008; Figueroa-Martínez *et al.*, 2011; Cwerman-Thibault *et al.*, 2015; Boominathan *et al.*, 2016). Here, we found that a high level of the allotopically expressed Cox2 protein may be detrimental to the mitochondrial import system.

In summary, we provide a proof of principle that mimicking the modifications found in an organism that naturally transferred its mitochondrial gene to the nucleus can result in successful allotopic expression. This strategy includes expressing a gene with adequate mutations in a low copy number to ensure that moderate protein quantities are produced for mitochondrial import. Our results underscore that dosage, a previously unexplored important parameter, may be critical for allotopic expression in mammals, especially in human cell lines. The relevance of our finding is high, since allotopic expression still represents a promising strategy for developing treatments for patients with mitochondrial diseases. Our data also stress the relevance of studying organisms that naturally and atypically encode hydrophobic mitochondrial OXPHOS proteins in the nuclear genome.

MATERIALS AND METHODS

Strains, gene constructs, and culture conditions

The *Saccharomyces cerevisiae* strains used in this study were derived from the D273-10B parental strain. We used NB40-36A as the wild-type strain *(MATα, arg8::hisG, leu2-3, 112, lys2, ura3-52,* [rho+]), EHW154 as the Δ*cox2* strain (*MATa, arg8::hisG, his3-ΔHindIII, leu2-3, 112, lys2, ura3-52,* [rho+] *cox2-208::ARG8m*), and CAB116 as the Δ*cox18* strain (*MATa*, *arg8::hisG, his3-ΔHindIII, leu2-3,112, lys2, ura3-53, cox18Δ::KanMX4* [rho+]). Cells were grown on YPD as fermentable medium (1% yeast extract, 2% bactopeptone, and 2% dextrose) or YPEG as nonfermentable medium (1% yeast extract, 2% bactopeptone, 3% ethanol, and 3% vol/vol glycerol). Minimal medium was SD or SGal (0.17% yeast nitrogen base [without amino acids and $(NH_4)_2SO_4$], 0.5% $(NH_4)_2SO_4$, 2% glucose or galactose supplemented with specific amino acids and nucleotides). All strains were grown at 30°C in liquid (with shaking) or solid medium (containing 1.75% agar). We calculated duplication times by measuring the absorbance of cultures with an initial $O.D._{600}$ of 0.01 every 2 h in a Bioscreen C spectrophotometer (Growth Curves, USA). Dilution series were performed by diluting 10-fold a culture of 0.5 $O.D._{600}$ and plating 3 µl on Petri dishes with the indicated medium.

The yeast allotopic $COX2^{W56R}$ gene was recoded for expression from the nucleus and a sequence encoding the MTS of Oxa1 was added at the 5′ end, as previously described (Supekova *et al.*, 2010). The construct was chemically synthesized (GeneScript, Piscataway, NJ) and cloned at the *Not*I site in the pFL61 vector, which contains a phosphoglycerate kinase (*PGK*) promoter and terminator (Minet *et al.*, 1992).

Additional *COX2* mutations (WT, W56K, W56Q, V49Q, L51G, V49Q/L51G, L47Q/V49G, L47Q/V49G/W56R) were constructed using the pFL61 plasmid containing the $COX2^{W56R}$ insert via site-directed mutagenesis, according to the manufacturer's instructions (QuikChange II site-directed mutagenesis kit, Agilent Technologies). The presence of the site-directed mutations was confirmed by DNA sequencing. For the expression of the constructs from centromeric plasmids, the fragments containing the *COX2* constructs flanked by the *PGK* promoter and terminator were cloned from pFL61 into pRS306H upon digestion with *Hin*dIII and *Sma*I restriction enzymes. Nuclear localization was achieved by integration transformation at the *URA3* nuclear locus using the pRS306H plasmid and hygromycin B resistance as a selection (Taxis and Knop, 2006).

Yeast cells were transformed in the presence of lithium acetate and salmon sperm DNA as described (Gietz and Schiestl, 2007). At least 12 transformed individual colonies were grown in Petri dishes containing fresh SD medium and then were replica-plated into YPEG to ensure that the selected colonies had respiratory growth similar to the rest of the transformants.

Isolation of yeast mitochondria

Mitochondria were isolated from 100–200 ml of liquid SGal cultures as previously reported (Herrmann *et al.*, 1994). Briefly, cells were harvested at logarithmic growth phase ($O.D._{600}$ 0.8–1.0), washed with H_2O at 4500 rpm in a Beckman Coulter JA-25.5 rotor (2500 × *g*) for 5 min, resuspended in TD buffer (100 mM Tris, 10 mM dithiothreitol), and centrifuged at 4500 rpm (2500 × *g*) for 5 min. The cells were resuspended in 10 ml of zymoliase buffer (1.2 mM sorbitol, 20 mM KH_2PO_4 [pH 7.4], 3–5 mg zymoliase/g of wet weight), incubated for 1 h in a shaker at 30°C, and centrifuged at 4500 rpm (2500 × *g*) for 5 min at 4°C. The pellet was resuspended in 1 ml of Dounce buffer (0.6 M sorbitol, 10 mM Tris [pH 7.4], 1 mM EDTA, 0.2% bovine serum albumin, 1 mM phenylmethylsulfonyl fluoride [PMSF]) using a homogenizer and pestle (30 strokes). Samples were transferred to 1.5-ml tubes and centrifuged at 4500 rpm in a microcentrifuge (2000 × *g*) for 5 min at 4°C. The supernatants were transferred to new tubes and centrifuged at 12,000 rpm (13,500 × *g*) for 10 min at 4°C. The supernatant (cytosolic fraction) was collected in new tubes and the pellet (mitochondrial fraction) was resuspended in 100 µl of SH buffer (0.6 M sorbitol, 20 mM HEPES, pH 7.4). Protein concentration was determined by a modified Lowry method (Markwell *et al.*, 1978). Mitochondria and cytosolic fractions were frozen and stored at –70°C until use.

Proteinase K protection assays

For protease treatment of mitochondria, 50 µg of mitochondria was gently resuspended in 100 µl of SH buffer and incubated at 20°C for 30 min in the presence of 100 µg/ml Proteinase K; parallel reactions were made in the presence of 1% Triton X-100. PMSF was added to all suspensions (at 4 mM final concentration), which were then incubated on ice for 10 min and centrifuged at 14,000 rpm (18,400 × *g*) for 10 min. Most of the supernatant in each tube was discarded; the pellet was resuspended with 4 µl of 6× loading buffer (375 mM Tris-HCl [pH 6.8], 6% SDS, 48% glycerol, 9% β-mercaptoethanol) + 4 mM PMSF and incubated for 1 min in boiling water before being loaded onto 12% SDS-tricine-PAGE gels.

Sodium carbonate and Triton X-100 extractions

Integral membrane proteins were separated from peripheral or soluble proteins by carbonate extraction. Aggregated proteins were separated from membrane proteins by Triton X-100 extraction. Briefly, 50 µg of mitochondria was incubated with 100 µl of cold 0.1 M Na_2CO_3 (pH 11.0) or with 9.4 µl of 1% Triton X-100 (2 mg Triton X-100/mg protein) for 30 min on ice. The samples were centrifuged at 90,000 × *g* in a TLA 55 rotor for 30 min at 4°C. Supernatants and pellets were incubated with 500 µl of 12.5% TCA for 15 min on ice, followed by centrifugation for 15 min at 14,000 rpm (18,400 × *g*) at 4°C. Samples were washed by adding 500 µl of cold 100% acetone, centrifuged for 10 min at 14,000 rpm (18,400 × *g*) at 4°C, and dried for ~10 min at room temperature. The dried pellets were resuspended in 15 µl of 1× loading buffer and incubated for 1 min in boiling water before loading onto 12% SDS-tricine-PAGE gels.

Gel electrophoresis and in-gel enzymatic activities

Denaturing gel electrophoresis was carried out via SDS-tricine-polyacrylamide gels with 12% acrylamide (Schagger, 1994a). Sample preparation and blue native polyacrylamide gel electrophoresis (BN-PAGE) were carried out as described (Schagger, 1994b). Briefly, mitochondria were washed twice in 250 mM sorbitol, 50 mM Bis-Tris (pH 7.0), and centrifuged at 12,000 rpm (13,500 × *g*) for 10 min at 4°C. The pellet was resuspended in sample buffer (750 mM aminocaproic acid, 50 mM Bis-Tris, pH 7.0) and solubilized with 2 g of lauryl maltoside per g of protein for 30 min with gentle stirring and centrifuged at 13,200 rpm (16,400 × *g*) at 4°C for 12 min. The supernatants were loaded on 5–15% polyacrylamide gradient gels. The stacking gel contained 4% (wt/vol) polyacrylamide. In-gel activities were carried out following established procedures for C*c*O activity (Wittig *et al.*, 2007; Wittig and Schägger, 2007) and ATPase activity (Zerbetto *et al.*, 1997; Wittig and Schägger, 2005). Gels were stained with Coomassie solution (50% ethanol, 10% acetic acid, 0.1% Coomassie Brilliant Blue G) or otherwise transferred and then subjected to immunodetection.

Immunodetection

From SDS-tricine-PAGE, proteins were electrotransferred onto a nitrocellulose Trans-Blot membrane (Bio-Rad) for immunodetection. Membranes were washed, blocked, and independently incubated for 4 h with the following antibodies: anti-Cox2 antibody at a 1:9000 dilution (Invitrogen; Molecular Probes), anti-Oxa1 antibody at a 1:1000 dilution, anti-Hog1 antibody at a 1:2000 dilution (Santa Cruz Biotechnology), and anti-Atp2 antibody at a 1:50,000 dilution. Alkaline phosphatase-conjugated IgGs (1:15,000 for 2 h) were used as secondary antibodies. Insoluble black–purple precipitates were formed upon addition of nitro-blue tetrazolium chloride and 5-bromo-4-chloro-3′-indolyl phosphate *p*-toluidine salt. Images of the immunodecorated polypeptide bands were captured in an HP Scanjet G4050. For immunodetection on previously probed membranes using a different primary antibody, membranes were stripped by incubation for 45 min at 50°C in the presence of 2% SDS, 62.5 mM Tris-HCl, pH 6.8, and 100 mM β-mercaptoethanol.

In silico protein sequence analysis

A TMS1 of 24 residues was considered for the yeast Cox2. The hydrophobicity calculations were performed using the "biological" hydrophobicity scale (Calado-Botelho *et al.*, 2011).

ACKNOWLEDGMENTS

We are grateful to Miriam Vázquez-Acevedo and Nallely Cabrera (Universidad Nacional Autónoma de México [UNAM]) for their expert technical assistance in making some of the constructs used in the present study. We thank Thomas D. Fox (Cornell University) for the gift of most of the strains used in this project, Soledad Funes (UNAM) for the kind gift of the Hog1 antibody and the Δ*cox18* strain, and Johannes M. Herrmann (Technische Universität Kaiserslautern) for the kind gift of the Oxa1 antibody. We also acknowledge Soledad Funes and Juan Miranda Ríos for insightful comments throughout this project. This work was partially supported by Grants 239219 and 279125 from the Consejo Nacional de Ciencia y Tecnología (CONACyT, Mexico) and IN 208917 from the Dirección General de Asuntos del Personal Académico (DGAPA-UNAM, Mexico) to D.G.-H. CONACyT also supported the graduate studies of D.R.-G. with a fellowship. The two summer research stays of P.P.H. in Mexico (2015 and 2016) and the posdoctoral fellowship of J.G.-R. were supported by DGAPA-UNAM. This article partially fulfills the requirements of D.R.-G. for a PhD from the Biomedical Sciences PhD program (Programa de Doctorado en Ciencias Biomédicas, Universidad Nacional Autónoma de México).

Abstract

Swine influenza is a worldwide disease, which causes damage to the respiratory system of pigs. The H1N1 and H3N2 subtypes circulate mainly in the swine population of Mexico. There is evidence that new subtypes of influenza virus have evolved genetically and have been rearranged with human viruses and from other species; therefore, the aim of our study was to identify and characterize the genetic changes that have been generated in the different subtypes of the swine influenza virus in Mexican pigs. By sequencing and analyzing phylogenetically the eight segments that form the virus genome, the following subtypes were identified: H1N1, H3N2, H1N2 and H5N2; of which, a H1N1 subtype had a high genetic relationship with the human influenza virus. In addition, a H1N2 subtype related to the porcine H1N2 virus reported in the United States was identified, as well as, two other viruses of avian origin from the H5N2 subtype. Particularly for the H5N2 subtype, this is the first time that its presence has been reported in Mexican pigs. The analysis of these sequences demonstrates that in the swine population of Mexico, circulate viruses that have suffered punctual-specific mutations and rearrangements of their proteins with different subtypes, which have successfully adapted to the Mexican swine population.

1 | INTRODUCTION

Swine influenza is a worldwide disease that causes damage to the respiratory system of pigs (Bouvier & Palese, 2008). Influenza viruses belong to the Orthomixoviridae family and have a genome composed of eight segments of ssRNA (–), where each one encodes for one or two proteins (Flint & Racaniello, 2001; King, Adams, Carstens, & Lefkowitz, 2012). The evolution of these viruses occurs through antigenic drift (Drift), characterized by the selection of new strains that contain amino acid changes in hemagglutinin (HA) and neuraminidase (NA) proteins; these changes are responsible for seasonal influenza infections (Carrat & Flahault, 2007; Treanor, 2004). In addition, these viruses can also have genetic rearrangements (Shift) associated with the emergence of pandemic viruses; these occur when a host cell is infected by more than one different virus subtype and the viral genomic segments are rearranged, generating a new combination (Boni, 2008; Webster, Laver, Air, & Schild, 1982; Zambon, 1999). Some accumulated and continuous mutations in the HA protein of the influenza virus have generated new antigenic strains that cause annual epidemics (Liao, Lee, Ko, & Hsiung, 2008). Pigs can naturally or experimentally be infected with viruses of avian or human origin because in the epithelial cells of the trachea, they express avian and

human type receptors (Ito et al., 1998; Scholtissek, Bürger, Bachmann, & Hannoun, 1983), which is why they are considered as mixing containers (Castrucci et al., 1993; Christoph Scholtissek, 1995). Currently, three subtypes of influenza viruses circulate mainly in pigs around the world: H1N1, H3N2 and H1N2 (Chambers, Hinshaw, Kawaoka, Easterday, & Webster, 1991). In the Mexican swine population, it has been reported the circulation of the H1N1 and H3N2 subtypes (Avalos, Sanchez, & Trujillo, 2011; López-Robles, Montalvo-Corral, Caire-Juvera, Ayora-Talavera, & Hernández, 2012); however, there are several studies showing the circulation of new subtypes of influenza virus, which have evolved genetically and have been rearranged with human viruses and from other species (Aguirre et al., 2014; Escalera-Zamudio et al., 2012; Nelson, Culhane et al., 2015; Nelson, Schaefer, Gava, Cantão, & Ciacci-zanella, 2015). On the other hand, there is evidence of the transmission of influenza viruses between different species (bird, pig, equine and human), as well as, rearrangements with different subtypes (H9N2, H4N6, H2N3, H3N8, H3N1, H5N2) in distinct parts of the world (Karasin, Brown, Carman, & Olsen, 2000; Lee et al., 2009; Ma et al., 2007; Peiris et al., 2001; Shin et al., 2006; Tu et al., 2009). These events highlight the requirement for a greater epidemiological surveillance, emphasizing the interest of isolating and characterizing the influenza viruses that circulate currently in the Mexican swine population.

2 | MATERIALS AND METHODS

2.1 | Samples

The research was carried out using 486 pig lung tissue samples from different production units located in twelve states of Mexico (Jalisco, State of Mexico, Guanajuato, Sonora, Michoacan, Puebla, Morelos, Yucatan, Queretaro, Hidalgo, Veracruz and Nuevo Leon) (Figure 1). The criterion for obtaining the samples was to use pigs that presented suggestive signology to infection with influenza virus.

The samples were remitted and processed in the Biosafety Laboratory Level 3 of the Medicine and Zootechnics Swine Department (DMZC) from the Veterinary Medicine and Zootechnics Faculty (FMVZ), National Autonomous University of Mexico (UNAM).

2.2 | RNA extraction

A total of 0.5 gr from each lung tissue was powdered in liquid nitrogen and homogenized in extraction buffer in order to obtain the RNA. RNA extraction was performed with the column technique using the QIAamp Viral RNA mini kit (QIAGEN, Germany) commercial kit, following the manufacturer's specifications. The purified nucleic acid was resuspended in 60 µl of elution buffer and stored at -70°C.

2.3 | qRT-PCR for the M gene

In order to confirm the presence of influenza virus A in the lung samples, a Real Time Reverse Transcription and Polymerase Chain Reaction (qRT-PCR) assay was performed using the FIND-IT INFLUENZA® (Biotecmol, México) commercial kit, directed to the identification of the matrix gene (M) and under the following conditions: 42°C for 30 min for reverse transcription, 95°C for 10 min for initial denaturation, 40 cycles at 95°C for 15 s for denaturation, 60°C for 45 s for annealing and 72°C for 5 min for extension.

2.4 | Sequencing of the Influenzavirus genome

The positive lung samples to the presence of influenza viruses were subjected to RT-PCR for the amplification of the eight gene segments of the virus, using the PathAmp™ FluA Reagents kit (Life Technologies, Carlsbad, CA) and a GeneAmp 9700 end point thermocycler (Applied Biosystems, CA). The RT-PCR products were visualized by electrophoresis in a 0.8% agarose gel.

Once the amplifications were obtained, the eight viral segments were sequenced using an Ion Torrent Genome Machine (PGM) System, following the manufacturer's specifications. Briefly, 100 ng of DNA input was used to prepare a library using the Ion Xpress™ Plus Fragment Library Kit (Life Technologies) by physical fragmentation of genome segments with the Bioruptor® Sonication System, in order to generate fragments of approximately 200 base pairs (bp). DNA fragments were linked to Ion-compatible adapters and amplified using the Ion PGM™Hi-Q™ OT2 Kit (Life Technologies) on an Ion OneTouch™ 2 System. The sequencing reaction was carried out using an Ion 314 Chip v2 and the Ion PGM™ Hi-Q™ Sequencing kit (Life Technologies). The obtained readings were subjected to quality filtering using the FastQC plug-in, and all of them were aligned with a Q-score ≥ 20 and assembled with the AssemblerSPAdes v 5.4.0 program. The average genomic coverage depth of the Ion Torrent PGM was up to 300-fold.

2.5 | Phylogenetic analysis

The obtained sequences were compared with those reported in the GenBank, selecting those with an identity percentage higher than 95%, using BLAST (Basic Local Alignment Search Tool) from the NCBI (National Center for Biotechnology) ("Nucleotide BLAST 2017: Search nucleotide databases using a nucleotide query"). The phylogenetic analysis was performed independently for each genomic segment with the MEGA 7.0.26 software the evolutionary history was inferred using the Maximum Likelihood method based on the General Time Reversible (GTR) model and discrete Gamma distribution with invariant sites was used (Kumar, Stecher, & Tamura, 2016; Nei & Kumar, 2000). The trees were edited with the FIGTREE v1.4.3 program ("FigTree 2017: Molecular evolution, Phylogenetics and Epidemiology").

2.6 | Viral isolation

For viral isolation, sterile 200 µl of lung suspension were inoculated into the allantoic cavity of ALPES1® embryos of 9–11 days, free of specific pathogens (SPF) and incubated at 37°C. The allantoic fluid

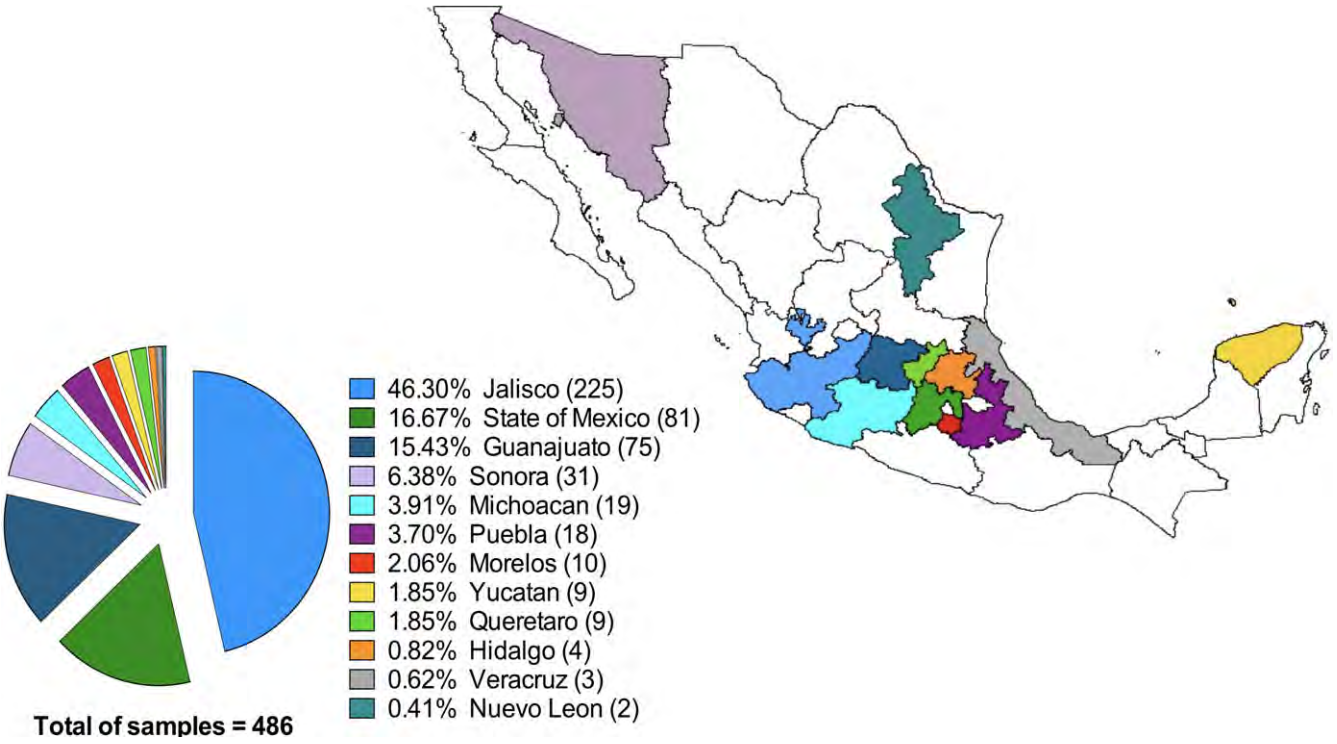

FIGURE 1 Percentage and number of samples per state. Different colors in the map represent the sampled states; whereas the graph shows the percentage and number of samples obtained for each state [Colour figure can be viewed at wileyonlinelibrary.com]

was collected at 24, 48 and 72 hr after inoculation and centrifuged at 423 *g* for 5 min (World Organisation for Animal Health, 2015). The viruses were titrated by hemagglutination (Ramírez, Carreón, & Mercado, 1996).

3 | RESULTS

Of 486 pig pulmonary samples, 10 (0.48%) were positive for influenza virus and 476 (99.52%) negative to the presence of this virus. From the positive samples, the complete genome of 8 influenza viruses was sequenced; three samples corresponded to the H1N1 subtype from the states of Guanajuato (2) and Jalisco (1), and two corresponded to the H3N2 subtype from the states of Jalisco and Hidalgo. An isolated H1N2 sequence was also obtained in the state of Guanajuato, while two H5N2 sequences came from Guanajuato and the State of Mexico (Table 1).

3.1 | Phylogenetic analysis of HA and NA genes

Regarding the evolutionary structure of the inferred topologies of the HA gene, the analysis of the sequences indicated that the HA protein of the GtoDMZC01(H1N2) virus was found in a clade with porcine and human H1N2 influenza viruses, reported in the United States in the period 2005-2010; whereas the HA of the GtoDMZC02(H5N2) and EdoMexDMZC03(H5N2) viruses, were found in a clade of avian influenza H5N2 viruses isolated in Mexico during 1994 and 1995. The HA of the GtoDMZC04(H1N1) virus was found in a clade of H1N1 human influenza viruses, isolated in the United States in 2013 and with one from Mexico isolated in 2014. On the other hand, there is homology between the HAs of JalDMZC05(H1N1) and GtoDMZC09(H1N1) viruses, which were found in a clade of porcine H1N1 influenza viruses isolated in Mexico in the period 2012-2014. The HA of the HgoDMZC11(H3N2) virus was found in a clade of Mexican H3N2 swine influenza viruses isolated in 2012 and 2013. The HA of the JalDMZC12(H3N2) virus was found in a clade with porcine influenza viruses from Canada and the United States, isolated during 2005 and 2006 (Figure 2).

Regarding the evolutionary structure of the inferred topologies from the NA gene, the analysis of the sequences indicated that the NA proteins of the GtoDMZC01(H1N2) and HgoDMZC11(H3N2) viruses were found in a clade with the Mexican H3N2 swine influenza viruses isolated in 2012 and 2013; while the NA of the GtoDMZC02(H5N2) and EdoMexDMZC03(H5N2) viruses were found in a clade of avian influenza H5N2 viruses isolated in Mexico during 1994 and 1995, and with the influenza viruses isolated in the United States in 1994 and 1995. The NA of the GtoDMZC04(H1N1) virus was found in a clade with H1N1 human influenza viruses isolated in the United States during 2013 and 2014. The analysis of the sequences indicated that the NA protein of the JalDMZC05(H1N1) and GtoDMZC09(H1N1) viruses were found in a clade of porcine H1N1 influenza viruses isolated in Mexico in the period of 2012–2014. The NA of the JalDMZC12(H3N2) virus was found in a clade with porcine influenza viruses from Canada and the United States, isolated during 2005 and 2006 (Figure 3).

[a]International classification for each virus. [b]Abbreviations used for each virus. [c]Genbank accession numbers for each virus. [d]by the qRT-PCR assay. [e]Identification used in the construction of inferred phylogenetic trees.

Regarding the origin identification of the eight genetic segments of the influenza viruses isolated in Mexico, it is clear that the eight segments that form the GtoDMZC01(H1N2) virus have a porcine origin; the genes of the PB1, PA, NP and NS proteins correspond to the H1N1 subtype, the NA to the H3N2 subtype and the proteins PB2, HA and M to the H1N2 subtype. In the case of the GtoDMZC02(H5N2) and EdoMexDMZC03(H5N2) viruses, their eight segments have an avian origin and correspond to the H5N2 subtype. On the other hand, the eight segments of the GtoDMZC04(H1N1) virus have a human origin and correspond to the H1N1 subtype; whereas, the eight segments of the JalDMZC05 (H1N1) virus have a porcine origin and also correspond to the H1N1 subtype. The eight segments of the GtoDMZC09(H1N1) virus have a porcine origin and the PB2, PB1, PA, HA, NP, NA and M proteins correspond to the H1N1 subtype; however, NS belongs to the H3N2 subtype. The eight segments of the HgoDMZC11

(H3N2) virus have a porcine origin; the PB1, NP, M and NS proteins correspond to the H1N1 subtype and the PB2, PA, HA and NA proteins to the H3N2 subtype. Finally, the eight segments of the JalDMZC12(H3N2) virus have a porcine origin and correspond to the H3N2 subtype (Table 2).

4 | DISCUSSION

In our study, the central region of Mexico is where the largest number of sequences was obtained; therefore, it could be the region where the largest number of rearrangements occur with viruses of

Notes. The Mexican isolates are located in the left side column and the segments of each protein are represented by a color chart depending on the subtype to which they belong: H1N1 (blue), H3N2 (pink), H1N2 (gray) and H5N2 (orange).
The letters that are inside the coloring boxes indicate the species to which they correspond: swine (S), chicken (C) and human (H).

different subtypes, due to production conditions where different species interact in the same habitat (INEGI, 2007).

In our analysis, we identified that in the GtoDMZC01(H1N2), GtoDMZC09(H1N1) and HgoDMZC11(H3N2) viruses, there are rearrangements between different subtypes. On the other hand, the inter-species barrier crossing was appreciated in the following viruses: GtoDMZC02(H5N2) and EdoMexDMZC03(H5N2), which were transferred intact from chicken to pig; and in GtoDMZC04 (H1N1) which was transferred intact from human to pig. Only two viruses were found without change JalDMZC05(H1N1) and JalDMZC12(H3N2). Several phylogenetic analyzes suggest that the transmission between species has occurred from birds to pigs (Karasin et al., 2000; Lee et al., 2009; Peiris et al., 2001), horses to pigs (Tu et al., 2009), and from humans to pigs (Nelson, Gramer, Vincent, & Holmes, 2012; Nelson et al., 2014).

There are several studies that have reported the transmission of influenza viruses between humans and pigs, suggesting that these viruses have circulated without being detected (Cappuccio et al., 2011; Nelson, Culhane et al., 2015; Nelson, Schaefer et al., 2015). In our study, we identified one subtype of viruses of human origin in Mexican pigs and although there are surveillance data regarding influenza viruses in the human population of this country ("Dirección General de Epidemiología, 2017", "FluNet, 2017"). Although, it has been reported that the H1N1 and H3N2 subtypes are officially circulating in the Mexican swine population, until 2012, a seroprevalence of 80.26% was reported for the first time in Mexico for the H1N2 subtype (Lara-Puente, 2012); whereas in other study, the serological evidence for the H1N2 subtype was shown since 2010 (Gaitán-Peredo, 2016). In addition, a virus was isolated in the central region of Mexico, where the genetic characterization and phylogenetic analysis determined that it corresponded to an H1N2 influenza virus, and that the segments came from humans and pigs, besides reporting a 26.74% seroprevalence towards the same subtype (Sánchez-Betancourt, Cervantes-Torres, Saavedra-Montañez, & Segura-Velázquez, 2017). In our study, an H1N2 influenza virus was phylogenetically analyzed, showing that all of its segments have a porcine origin; however, it is rearranged with the H1N1 and H3N2 subtypes.

In 2008, two H5N2 viruses were reported in Korea and were isolated from pigs. The sequencing and phylogenetic analysis of the proteins determined that the Sw/Korea/C12/08 isolate corresponds to a fully avian virus from wild birds (Lee et al., 2009), similar to the H5N2 viruses reported in our study, where all their proteins correspond to an avian virus. However, in our analysis, the H5N2 subtypes were located in a clade of influenza viruses that originated from production birds (chicken) that were isolated and characterized in Mexico during 1994 and 1995. This coincided with several low-pathogenicity outbreaks of influenza viruses in 1994, which mutated into a high pathogenicity H5N2 strain during 1995 ("Servicio Nacional de Sanidad, Inocuidad y Calidad Agroalimentaria, 2017").

In Mexico there is an evident scenario for the transmission of chicken virus to pigs, due to the existence of mixed production systems, where two different species (chicken and pigs) share physical spaces (INEGI, 2007). However, the participation of dogs in the dissemination and the interspecies transmission of influenza viruses should not be ruled out (Giese et al., 2008; Song et al., 2013). In China during 2009, an H5N2 influenza virus was isolated from a dog that showed respiratory signs (Guang-jian, Zong-shuai, Yan-li, Shi-jin, & Zhi-jing, 2012). Later on, the transmission of this virus from dog to dog was confirmed (Song et al., 2013). Afterwards, infective manifestations of this H5N2 virus were observed in cats and chickens (Hai-xia et al., 2014).

Our results show that in Mexico, there are viruses with gene rearrangements and viruses that have crossed the inter-species barrier; for this reason, it is important to continue characterizing the A-type influenza viruses circulating in animal populations, in order to identify the new variants, particularly those closely associated with humans to avoid potential zoonotic threats.

Based on the phylogenetic analysis, we conclude that within the Mexican swine population, there are circulating viruses that have undergone punctual mutations and protein rearrangements with different subtypes. On the other hand, we also determined that some segments of human influenza viruses have been rearranged with swine influenza viruses, and these have been detected in Mexican pigs (see figures S1–S6).

ACKNOWLEDGEMENTS

In Brief

RNA binding promotes CTCF-dependent chromatin loops. Saldaña-Meyer et al. show that mutation of the RNA-binding regions in CTCF (ZF1 and ZF10) disrupts gene expression, chromatin binding, and the formation of chromatin loops.

Highlights

- Transcriptional inhibition disrupts CTCF binding to chromatin
- RNA-binding regions (RBRs) in CTCF are found within ZF1 and ZF10
- Gene expression and chromatin binding are disrupted by RBR mutants
- Chromatin loops are markedly decreased in ZF1Δ and ZF10Δ mutant rescues

SUMMARY

The function of the CCCTC-binding factor (CTCF) in the organization of the genome has become an important area of investigation, but the mechanisms by which CTCF dynamically contributes to genome organization are not clear. We previously discovered that CTCF binds to large numbers of endogenous RNAs, promoting its self-association. In this regard, we now report two independent features that disrupt CTCF association with chromatin: inhibition of transcription and disruption of CTCF-RNA interactions through mutations of 2 of its 11 zinc fingers that are not required for CTCF binding to its cognate DNA site: zinc finger 1 (ZF1) or zinc finger 10 (ZF10). These mutations alter gene expression profiles as CTCF mutants lose their ability to form chromatin loops and thus the ability to insulate chromatin domains and to mediate CTCF long-range genomic interactions. Our results point to the importance of CTCF-mediated RNA interactions as a structural component of genome organization.

INTRODUCTION

Spatial and temporal control of gene expression is crucial for the development of multicellular organisms. Improper gene expression leads to developmental abnormalities and diseases such as cancer. In addition to the "linear" genetic information, the three-dimensional (3D) spatial organization of the eukaryotic genome within the nucleus contributes to genome function (Bonev and Cavalli, 2016; Merkenschlager and Nora, 2016).

The 3D genome is hierarchically organized: from nuclear compartments, to large insulated chromatin domains, to short-range *cis*-interactions. These chromatin domains are designated throughout the literature as topological associated domains (TADs), topologically constrained domains, physical domains, insulated neighborhoods, contact domains, or loop domains depending on their characteristics, size, and the algorithms used to identify them (Lieberman-Aiden et al., 2009; Dixon et al., 2012; Dowen et al., 2014; Nora et al., 2017; Rao et al., 2017). To avoid confusion, we simply call them chromatin-interacting domains. These domains are formed and delimited primarily by the interaction of CTCF with the cohesin complex, and proteins such as YY1, the Mediator complex, and others yet to be discovered. CTCF and the cohesin complex are pivotal to 3D structure formation (Rowley and Corces, 2018). The depletion of either factor has drastic effects on chromatin structure, with chromatin-interacting domains essentially disappearing (Nora et al., 2017; Rao et al., 2017). The most widely accepted explanation of how chromatin organizes 3D structure is through the loop extrusion model (Fudenberg et al., 2017). This model proposes that cohesin rings create loops by actively extruding DNA until the cohesin complex contacts two CTCF-binding sites in convergent orientation to serve as anchors. This simplifies the underlying mechanism of chromatin organization, but many questions remain unanswered as to how these domains are regulated temporally and in a cell type-specific manner and the repertoire of factors that participate in this process.

Although most chromatin domain boundaries are enriched by CTCF and cohesin, the majority of CTCF-bound sites are found elsewhere in the genome (Merkenschlager and Nora, 2016). Furthermore, CTCF and cohesin binding sites are significantly conserved among cell types, yet many of them, as well as many chromatin-interacting domains, display cell type-specific patterns and changes during differentiation as a result of stage-specific transcription factors (Narendra et al., 2016; Pękowska et al., 2018; Stadhouders et al., 2018).

Together with CTCF, YY1, cohesin, and Mediator complexes are also implicated in defining chromatin architecture at

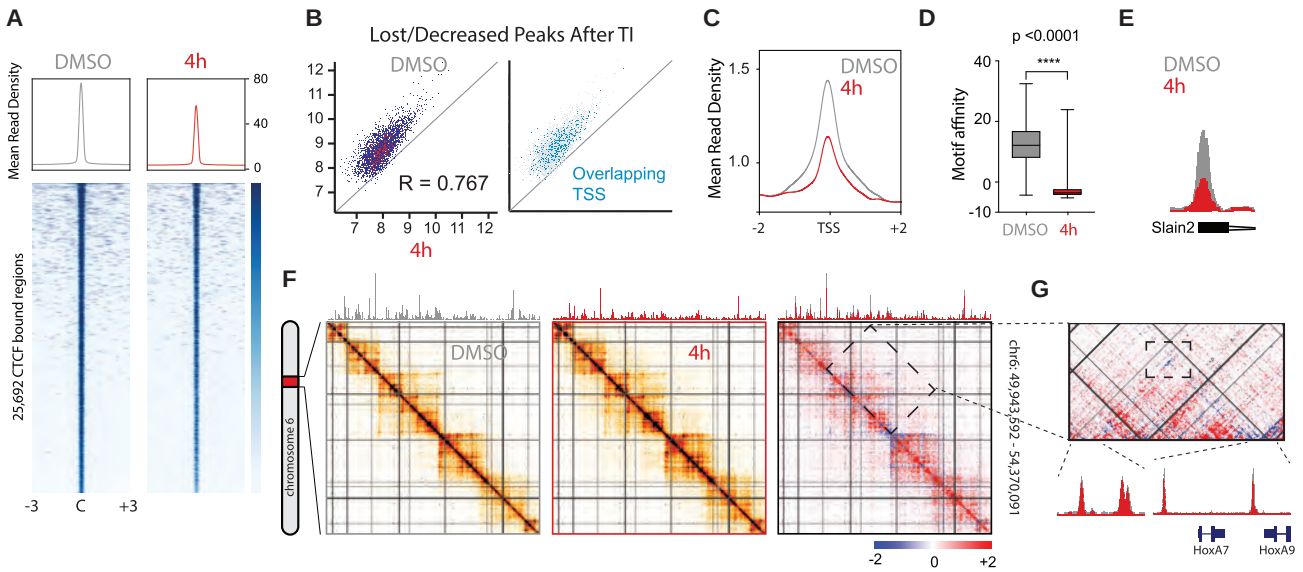

Figure 1. Transcriptional Inhibition Disrupts CTCF Binding Predominantly in TSS

Transcription was inhibited in mESCs for 4 h with co-incubation of DRB and triptolide. Cells incubated with DMSO served as control.

different topological ranges and all of these proteins bind RNA (Lai et al., 2013; Li et al., 2013; Phillips-Cremins et al., 2013; Saldaña-Meyer et al., 2014; Sigova et al., 2015). A growing number of examples demonstrate that RNA can recruit and either stabilize or destabilize protein binding to chromatin, as in the case of the PRC2 complex or YY1, respectively (Beltran et al., 2016; Kaneko et al., 2014a, 2014b; Sigova et al., 2015; Xiao et al., 2019). Furthermore, both CTCF and YY1 can form dimers and oligomers in an RNA-dependent manner, which may account for the regulation of far *cis*-interactions on chromatin (Saldaña-Meyer et al., 2014; Weintraub et al., 2017).

Here, we sought to identify the functional relevance of CTCF-RNA interactions using two strategies: (1) inhibiting transcription and (2) rescuing the loss of wild-type endogenous CTCF through the expression of RNA binding-deficient mutants. We concentrated on three distinct levels of regulation: (1) gene expression using single-cell RNA sequencing (RNA-seq) and bulk RNA-seq; (2) chromatin binding via ChIP-seq; and (3) chromatin structure via 5C and Hi-C. We demonstrate that decreased RNA binding to CTCF disturbs its stability on chromatin with direct and likely indirect effects on gene expression and 3D chromatin organization.

RESULTS

Transcriptional Inhibition Disrupts CTCF Binding to Chromatin

To unbiasedly test if RNA binding is integral to CTCF activity genome-wide, we first performed chromatin immunoprecipitation followed by deep sequencing (ChIP-seq) after transcriptional inhibition (TI) by treating mouse embryonic stem cells (mESCs) with both DRB and triptolide. This treatment, which inhibits initiation and elongation of transcription and promotes degradation of RNAP II (Bensaude, 2011), had no impact on CTCF protein levels (Figure S1A). Nonetheless, we detected an overall modest decrease in CTCF association with chromatin genome-wide (Figure 1A). Similar results were observed after depleting RNA by incubation with RNase A (Figure S1B). Because CTCF is widely present throughout the genome within both intragenic and intergenic regions (Bonev and Cavalli, 2016), we next focused on the specific genomic distribution between individual CTCF-binding sites in the control versus those sites whose binding was significantly decreased after TI and RNase A treatment (Table S1). We found that CTCF-binding sites within transcription start sites (TSSs) and promoters were the

most significantly affected (Figures 1B, 1C, S1B, and S1C). To quantify the affinity of those affected sites, we used DeepBind, a deep-learning algorithm that has been trained on numerous ChIP-seq datasets and can be used to score the affinity of any given sequence for the CTCF motif. Remarkably, sites perturbed by TI were those with motifs with significantly lower affinity compared with a random sample of stable CTCF-bound regions ($p < 0.0001$, Mann-Whitney test; Figure 1D).

Regarding chromatin structure, 5C experiments targeting a 4 Mb region showed that throughout this region (chr6: 49,943592–54,370,091), CTCF binding was decreased together with a general increase in chromatin interactions (Figures 1F and S1D). Remarkably, the chromatin loop whose right anchor resides at the *HoxA* cluster boundary was disrupted (Figures 1G and S1E), without the loss of CTCF binding in the boundary, as illustrated by the overlapping ChIP-seq tracks (Figure 1G, bottom). These results favor the hypothesis that the role of CTCF in 3D chromatin structure is subject to at least two levels of regulation: (1) direct binding to chromatin and (2) regulation of CTCF-CTCF interactions in complex with RNA molecules to form chromatin loops at sites surrounding the *HoxA* cluster and probably others throughout the genome.

High-Resolution Mapping of RNA-Binding Regions (RBRs) in CTCF

The observations above are suggestive but cannot distinguish between a direct disruption of CTCF-RNA interactions or the various possible indirect effects of inhibiting transcription. To directly test the former case, we first defined putative RNA binding-deficient mutants. We focused on two regions detected by RBR-ID (He et al., 2016): one overlapping part of zinc finger 1 (ZF1) (aa 264–275; KTFQCELCSYTCPR) and another within ZF10 (aa 536–544; QLLDMHFKR), the latter having been identified previously through biochemical mapping of CTCF (Saldaña-Meyer et al., 2014) (Figure 2A; Table S2). Henceforward, the deletion of these 14 and 9 amino acids from ZF1 and ZF10, respectively, will be denoted as ZF1Δ and ZF10Δ.

Given that homozygous deletion of CTCF is embryonically lethal (Kemp et al., 2014; Moore et al., 2012), we induced the rapid degradation of endogenously tagged CTCF-GFP using the auxin-inducible degron (AID) system as previously described (Nora et al., 2017) and rescued the cells with either wild-type (WT) or RNA binding-deficient CTCF mutants; degradation of CTCF without rescue was lethal after 2–4 days (Nora et al., 2017). To bypass this issue, we transduced cells with lentivirus containing a vector encoding an internal ribosomal entry site (IRES) that allows a WT or mutant version of CTCF and the red fluorescent protein mCherry to be simultaneously expressed from a single mRNA transcript. We then sorted the successfully infected cells (mCherry positive and GFP negative; Figure 2B) to obtain a pooled population of steady-state rescues after degradation of the endogenous CTCF protein via AID (Figures 2B and S2A).

Although both ZF1Δ and ZF10Δ mutants rescued the lethality of endogenous CTCF depletion and had comparable levels of expression (Figures 2C and S2B), the cells exhibited a significantly slower proliferation rate relative to the WT rescue but presented no drastic changes in their cell cycle (Figures S2C–S2E). These results suggested that an important biological role of CTCF involves ZF1 and ZF10. Our previous report on CTCF-RNA interactions shows that an internal deletion (aa 574–614) within the RBR-ZF10 (aa 520–727) displays significant defects in self-association but no defects in binding to the cohesin complex (Saldaña-Meyer et al., 2014). ZF1Δ also retained its ability to interact with the cohesin complex, with apparently the same efficiency as that of ZF10Δ and WT CTCF (Figure 2C). We then performed the rescues in the absence of auxin and probed for the capacity of endogenous CTCF to co-precipitate the rescue proteins using an antibody against GFP (endogenous CTCF was readily distinguishable from the rescues given the molecular weight differences). Both mutants displayed defects in interaction with endogenous CTCF, reflecting a defect in self-association (~60%) compared with the WT rescue (Figure 2D).

To directly test the RNA-binding capacity of these mutants, we used photoactivatable ribonucleoside-enhanced cross-linking and immunoprecipitation (PAR-CLIP). The WT rescue showed robust binding to RNA molecules, whereas both ZF1Δ and ZF10Δ mutants displayed drastic reductions in binding, as evidenced by a significantly decreased signal in radiolabeled RNA compared with the WT rescue (Figure 2E). Notably, naturally occurring mutations in endometrial and breast cancer within ZF1 (H284N) and ZF10 (C528S) target the histidine or cysteine residues that are essential for zinc binding in C_2H_2 type ZFs (Kemp et al., 2014) (Figure 2F). Surprisingly, point mutations within ZF1 (H284N) or ZF10 (C528S) had no detectable defect on RNA binding (Figures 2E and 2F). These results suggest that CTCF binding to RNA is not just a consequence of simple RNA affinity to its ZFs but instead requires a structural conformation or binding of other components that are disrupted independently by deletion of the respective RBRs in ZF1 and ZF10.

Deletion of RBRs in CTCF Disturbs Gene Expression

To test if the presence of RNA binding-defective mutants had any effect on gene expression, we subjected the rescue cell lines to single-cell RNA-seq (scRNA-seq). Principal-component analysis (PCA) showed similarities between the different rescues but also underscored the clear distinction between each population of cells (Figure 3A; Table S3). Further analysis on the differential expression represented as heatmaps showed that downregulated genes are similar in both mutant rescues, but distinct clusters of genes are upregulated for ZF1Δ and ZF10Δ (Figures 3B and S3A).

scRNA-seq allows us to monitor the variability and consistency of the phenotypes we observe at the single-cell level, but it is not regularly used to test differential expression, because of the lower sequencing depth per cell (Rizzetto et al., 2017). Given these limitations, we also performed regular bulk RNA-seq and compared the two approaches. The differentially expressed genes (DEGs) for ZF1Δ and ZF10Δ rescue cell lines showed good overlap (687 genes, false discovery rate [FDR] < 0.05) even at different thresholds of significance (215 genes, FDR < 0.001) between bulk and scRNA-seq (232 genes) (Figure 3C). Comparing all DEGs from both RNA binding-deficient mutants with all DEGs from cells depleted of CTCF for 24 and 48 h provided similar overlaps (824 genes, FDR < 0.05) (Figure 3C; Table S4). Remarkably, all these different DEGs

(E) PAR-CLIP of stably expressed WT and mutant CTCF in mESCs. Autoradiography for ^{32}P-labeled RNA (top) and control western blot (middle and bottom).

(F) Schematic representation of ZF1 and ZF10 of CTCF; mutations found in breast and endometrial cancer that alter zinc binding are shown in black; mutations that do not alter zinc binding are in blue, and RBR-ID deletions are in brackets.

displayed a distinctive similarity with promoters and/or gene bodies containing CTCF-binding sites, a feature that is significantly lower for randomly picked genes (Figure 3D). Furthermore, using DeepBind to examine the motif affinity of CTCF sites at TSSs and intragenic regions of DEGs, we observed a significantly lower score compared with control sites (Mann-Whitney test, $p < 0.001$; Figure 3E). Considering the binding profile of CTCF on the TSSs of DEG, we can distinguish at least two groups: one that has CTCF binding enriched at or near TSSs and one without it in the WT situation (Figure S3B). It was previously shown that after 24 h of CTCF depletion, downregulated genes are enriched for CTCF-binding sites at TSSs (Nora et al., 2017), yet our results suggest no distinction between down- and upregulated genes.

These data indicate that although both ZF1Δ and ZF10Δ have similar deficiencies in RNA binding (and self-association), yet retain efficient interaction with the cohesin complex (Figure 2), they appear to engender distinct gene expression profiles that partially but do not completely overlap with each other and with acute depletion of CTCF.

Deletion of RBRs in CTCF Disturbs Its Chromatin Binding

Next, we focused on the genome-wide binding of the mutant rescues. Findings from ChIP-seq experiments reflect those presented above for TI and RNase A digestion (Figures 1 and S1). To identify specific differences between rescues, we used the R package DiffBind, which incorporates statistical analyses developed for RNA-seq (DESeq2) that have been modified to analyze ChIP-seq data. We observed that most binding sites were unchanged between conditions (Figure S4A; Table S5). Importantly, we found 2,528 differentially bound sites in ZF1Δ and 2,823 in ZF10Δ, of which only 174 were shared (FDR = 0.05, log2 fold change > 1) (Figures 4A, S4A, and S4B).

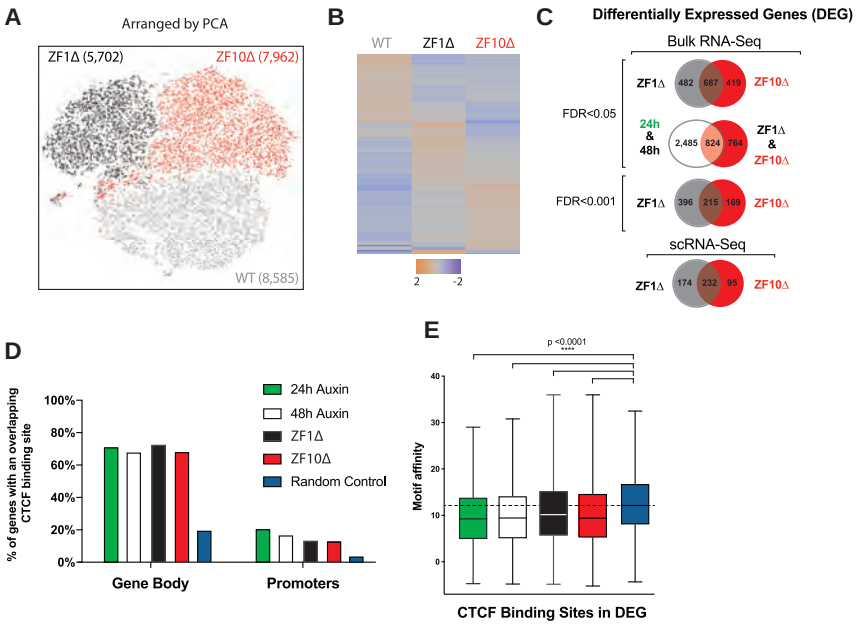

Figure 3. Gene Expression Defects Are Partially Preserved between RBR Deletions

(A) Principal-component analysis (PCA)-based representation of single-cell RNA-seq data for rescue cell lines from WT (gray), ZF1Δ (black), and ZF10Δ (red). Each dot represents a single cell, and dots are arranged on the basis of PCA. The final number of cells sequenced per condition is noted in parentheses.

(B) Heatmaps depicting differentially expressed genes from scRNA-seq.

(C) Venn diagrams showing the overlap between differentially expressed genes for the different conditions and levels of significance.

(D) Bar graph illustrating the percentage of genes that have at least one CTCF-binding site for CTCF in the promoter region or gene body.

(E) Boxplot showing the motif affinity scores for CTCF-binding sites within DEG represented in (B) compared with a random sample of genes (Mann-Whitney test, $p < 0.0001$).

Furthermore, this differential binding seems to be mediated by a change in enrichment from an adenine to a guanine in the eighth position of the CTCF consensus sequence in ZF1Δ, but not for ZF10Δ (Figure 4B). This base is part of a triplet that ZF6 binds, suggesting that the binding site change is not a direct effect of the mutation (Hashimoto et al., 2017). Notably, we found that the CTCF-binding sites lost in the ZF1Δ rescue were located primarily at promoters, whereas ZF10Δ mutations were located mainly in intronic and intergenic regions. However, both binding sites correlated with a lower motif affinity compared with control sites (Mann-Whitney test, $p < 0.0001$; Figures 4C, 4D, and S4C).

By integrating ChIP-seq and RNA-seq results, we can appreciate that the decrease in promoter binding can directly correlate with the change in gene expression, especially for ZF1Δ, which exhibited a more drastic decrease in CTCF binding. In some instances, ZF10Δ also resulted in reduced binding to promoters, as in the case of the *Cdkn2a* gene (Figures 4E, 4F, and S3B). Taken together, these results suggest that although many similarities exist between ZF1Δ and ZF10Δ, the preference for specific sequences in the genome can partially account for their different phenotypes. This and the other differences observed are likely a result of the deletions disrupting RNA-dependent interactions with other proteins.

Deletion of RBRs in CTCF Disturbs 3D Chromatin Structure

To study 3D chromatin conformation, we performed Hi-C and generated approximately 6 billion Hi-C contacts from each rescue cell line (~2.0 billion per condition) (Figures S5A and S5B). First, we focused on chromatin loops that are evident in Hi-C maps by the appearance of a higher frequency spot at the corner of a chromatin-interacting domain (a region that interacts more frequently than expected), indicative of a CTCF-CTCF-mediated chromatin loop.

To quantify the differences between mutants, we used the aggregate peak analysis (APA) method (Durand et al., 2016), which superimposes the signals from all loops (peak pixels), giving a combined signal for each condition. The genome-wide APA signal was strong for the WT rescue (2.38), while it was decreased for both ZF1Δ (1.18) and ZF10Δ (1.93) (Figures 5A and 5B). These decreases directly correlated with a lower number of annotated loops for the mutants (Figure 5C). For the WT rescue cells, we annotated 9,578 loops. Strikingly, loops mostly disappeared in the ZF1Δ rescue, whose binding sites are specifically lost at promoters, with a loss of ~70% of loops (Figure 5C) that was obviously evident by visual examination. For ZF10Δ, for which the affected binding sites are located primarily within intergenic regions, we annotated 7,668 loops, and although most loops were intact as determined by visual examination, the pixel intensity was reduced compared with WT loops (Figures 5A–5C). By integrating ChIP-seq and Hi-C maps, we observed at least two general types of loops exhibiting either (1) the loss of CTCF binding on at least one anchor (Figures 5D and S5C) or (2) loop disruption without the loss of CTCF binding at either anchor (Figures 5E and S5D).

Using Arrowhead to annotate chromatin-interacting domains, we observed a modest reduction in the two mutants, with ZF1Δ being the most affected, having fewer but larger domains; similar results were obtained using Hicratio. We annotated 6,501 and 3,311 chromatin-interacting domains for WT, 5,310 and 3,054 for ZF1Δ, and 5,749 and 3,118 for ZF10Δ using Arrowhead and Hicratio, respectively (Figure S5F; Table S6). Chromatin-interacting domains were also called using Crane insulation scores (Crane et al., 2015) at 40 kb bin resolution with an insulating window of 103 or 500 kb, both of which identified similar numbers of chromatin domains (Figure S5F).

Next, we tested if there were any changes in the interaction frequency within conserved chromatin-interacting domains. We classified these domains in terms of decreased, increased,

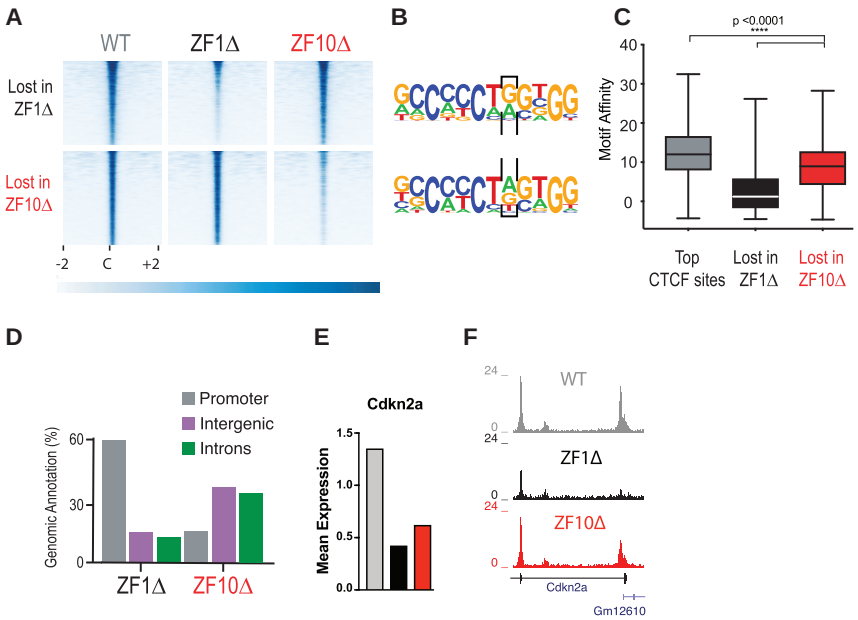

Figure 4. Deletion of RBRs in CTCF Disturb Its Chromatin Binding

(E and F) Mean expression levels for differentially expressed gene *Cdkn2a* (E) and corresponding ChIP-seq tracks (F) under each condition.

or stable activity (FDR < 0.1). Regardless of the algorithm used to call chromatin-interacting domains, we observed that compared with the WT rescue, both mutants had a predominantly increased interaction frequency in domains with altered activity (Figure 6A; Figure S5E), a trend that reflected the 5C results from TI and RNase A conditions (Figures 1F, 1G, S1D, and S1E).

Importantly, about 60% of ZF1Δ sites with decreased binding were located in gene promoters. An obvious assumption would be that CTCF is functioning as a transcription factor in these cases. Nonetheless, ZF1Δ presented the most striking phenotype of chromatin loop disruption. Thus, we analyzed the frequency at which TSSs are found within chromatin loop anchors. By overlapping all TSSs with the 9,578 annotated loops for the WT rescue, we found that 14% of loop anchors overlapped with a TSS, and of those, the majority were delimited by CTCF binding on each side of a chromatin-interacting domain called by Arrowhead (Figure S5G), a significantly higher enrichment than the 3% overlap seen in the random control. These results suggested that CTCF can function as both a transcription factor and an insulator at the same time. Indeed, such is the case for some DEGs for ZF1Δ or ZF10Δ that are contained within a chromatin-interacting domain that is disrupted along with loss of CTCF in their promoter region, which also serves as an anchor for a chromatin loop (Figure 6C).

Next, we attempted to correlate gene expression with the increased activity within chromatin-interacting domains. To do this, we assigned a DEG (FDR < 0.05, log2 fold change > 1) to a common chromatin-interacting domain when its promoter overlapped with the domain. We assessed statistical significance for downregulated or upregulated DEG for each mutant. Only the downregulated genes for ZF1Δ showed a significant correlation with increased interactions within a chromatin-interacting domain (Figure 6B).

Finally, we focused on genomic compartmentalization using PCA and hierarchical clustering, which reveals spatial segregation into A "active" and B "inactive" chromatin compartments. Neither RNA binding-deficient mutant rescue showed changes in the plaid pattern, as defined by the eigenvectors of the Hi-C correlation map, or in compartment domains, compared with the WT control (Figure S6). This finding is consistent with previous observations revealing that genomic compartmentalization relies on mechanisms independent of CTCF and cohesin (Nora et al., 2017; Rao et al., 2017).

The results above indicate that the formation of chromatin loops requires CTCF to properly interact with RNA, and mutations in its RBRs disturb their formation with direct and indirect effects on gene expression and chromatin organization (Figure 6D).

DISCUSSION

We previously demonstrated the ability of CTCF to bind large numbers of RNAs (Saldaña-Meyer et al., 2014), findings that were subsequently corroborated by others (Kung et al., 2015). In this study, we were able to dissect a fundamental and general role for RNA binding to CTCF. Importantly, we describe a clear co-dependency of CTCF-RNA interaction and chromatin binding that affects both 3D chromatin structure and transcription.

Some examples exist of individual RNAs that have important and specific functions, and we expect that more will surface in the future, especially for different cell types or during specific stages of development and differentiation. Regardless, we favor the view that most RNA molecules, not only non-coding (nc) RNAs, have a structural and stabilizing role inside the nucleus, as well as the potential to mediate or increase protein-protein interactions without showing any obvious sequence specificity.

The concept of RNA as a structural component of the nucleus originated in 1989, when the Sheldon Penman group reported that the nuclear matrix fibers collapse and aggregate after treatment with RNase A or actinomycin D in detergent-extracted cells. They proposed that RNA is a structural component of the nuclear matrix, which in turn might organize the higher order

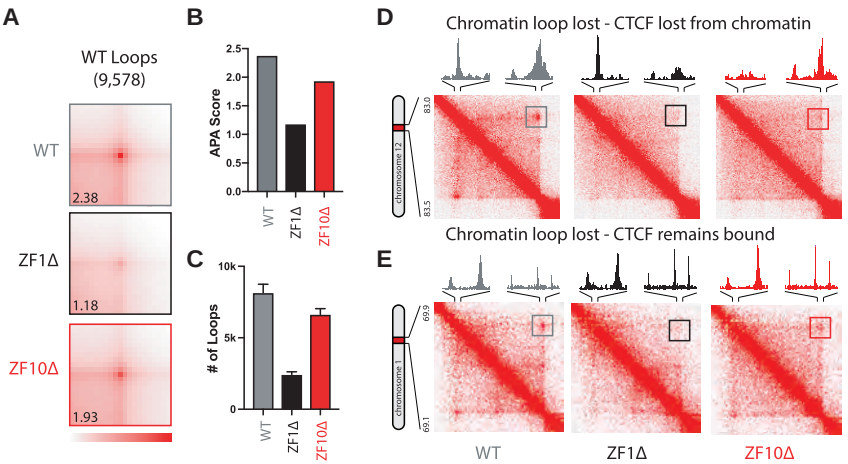

Figure 5. RBR Mutants Disturb Chromatin Loops

(A) Aggregate peak analysis (APA) was used to measure the aggregate strength of chromatin loops annotated by HICCUPS on the WT rescue. Loop strength is indicated by the extent of focal enrichment at the center of the plot. APA scores are shown on the bottom left.

(B) Bar graph representing APA scores between rescue conditions.

(C) Bar graph representing the number of chromatin loops annotated by HICCUPS for each individual condition.

(D) Representative contact matrix (at 5 kb resolution) shows that the chromatin loop in the WT rescue (left) disappears in the ZF1Δ (middle) or loses strength in ZF10Δ (right), while CTCF binding is lost at one of the anchors.

(E) Same as (D), but in this example CTCF remains bound under all conditions.

structure of chromatin (Nickerson et al., 1989). More recently, Hall et al. (2014) showed that RNAs transcribed from repetitive LINE1 elements stably associate with interphase chromosomes and are stable under TI. Furthermore, the loss of these nuclear RNAs from euchromatin disrupts proper chromatin condensation, underscoring the putative structural role for transposons including LINEs and other repetitive sequences that together constitute more than half of the human genome (de Koning et al., 2011; Hall et al., 2014).

CTCF is highly conserved across species (Heger et al., 2012; Vietri Rudan et al., 2015), and the presence of its 11 ZFs suggests that it can bind DNA in multiple ways (Filippova et al., 1996; Nakahashi et al., 2013). The 20 bp DNA core motif (Holohan et al., 2007; Kim et al., 2007; Schmidt et al., 2010; Xie et al., 2007) was suggested to be engaged by ZFs 4–7 *in vivo* (Nakahashi et al., 2013). This motif is present in most of the known CTCF-binding sites identified by ChIP-seq, and the nonspecific engagement of ZFs other than 4–7 with the flanking DNA sequence was proposed to stabilize CTCF binding (Nakahashi et al., 2013). Recently, the crystal structure of overlapping stretches of CTCF's ZFs bound to the core motif was resolved, showing that ZFs 3–7 engage the major groove of the core DNA motif. Importantly, it also revealed the lack of a specific function in DNA recognition and binding for ZF1, ZF10, and ZF11 (Hashimoto et al., 2017). Furthermore, mutating the histidine of ZF1 was previously shown to modestly affect the binding of CTCF to chromatin (Nakahashi et al., 2013). Our results show that a comparable point mutation did not affect RNA binding, but a deletion within ZF1 had a significant decrease in both RNA and chromatin binding (Figures 2, 3, and 4). Last, point mutations in ZF1 or ZF10 that do and do not affect the binding of ZFs to DNA are found in cancer (Figure 2F) (Kemp et al., 2014). In the context of this study, together these data suggest that the main property of ZF1 and ZF10 is binding to RNA rather than DNA.

Thus far, CTCF binding to DNA seems unaffected by other factors, as the knockdown of most of its binding partners is ineffectual. One exception is the general transcription factor II-I (TFII-I), which seems to stabilize CTCF binding at promoter regions (Peña-Hernández et al., 2015). In the context of our observations under TI (Figure 1), the knockdown of TFII-I most likely affects the transcription of its target genes, and hence the decrease in CTCF binding might be an indirect effect of disrupting transcription. Here, we showed that the CTCF-binding sites affected are those whose sequence diverged from the core DNA-binding motif (Figures 1D, 3E, and 4C), suggesting that this difference can have important roles in regulatory mechanisms, with RNA binding at its core.

CTCF was originally described as a TF, and there are several examples showing that CTCF binding to gene promoters is necessary for proper transcription of tumor suppressor genes, such as BRCA1, RB, TP53, and p16INK4a (Butcher and Rodenhiser, 2007; De La Rosa-Velázquez et al., 2007; Soto-Reyes and Recillas-Targa, 2010; Witcher and Emerson, 2009). Yet because CTCF was described as having a role as an architectural protein, little attention has been afforded to its role as a TF. Most arguments against CTCF being important for gene expression rest on the relatively small number (~200–400) of genes that are affected upon its knockdown or even its acute depletion using an AID (Nora et al., 2017; Zuin et al., 2014). In this context, our ZF1Δ and ZF10Δ rescue cell lines also exhibited a modest number of DEGs, although this varied depending on the threshold applied: ~1,000 genes (FDR < 0.05) to ~400 genes (FDR < 0.001).

Additionally, when analyzing the relative occupancy of CTCF as measured by ChIP-seq, promoter regions have significantly less occupancy compared with its overall binding sites (Figures 1A–1C) (Weintraub et al., 2017). CTCF-binding sites with low occupancy that diverge from the core DNA motif were associated with regulated binding during mESC differentiation (Plaschaert et al., 2014). In our study, we noticed that CTCF-binding sites within DEGs share these same characteristics, and chromatin binding is destabilized in both ZF1Δ and ZF10Δ rescue cell lines compared with WT (Figures 4D and 4E).

It is our view that CTCF has a significant role in regulating gene expression on the basis of the following observations: (1) Hemizygous mice for CTCF succumb to cancer in 80% of animals tested, highlighting that chronically lower levels of CTCF have

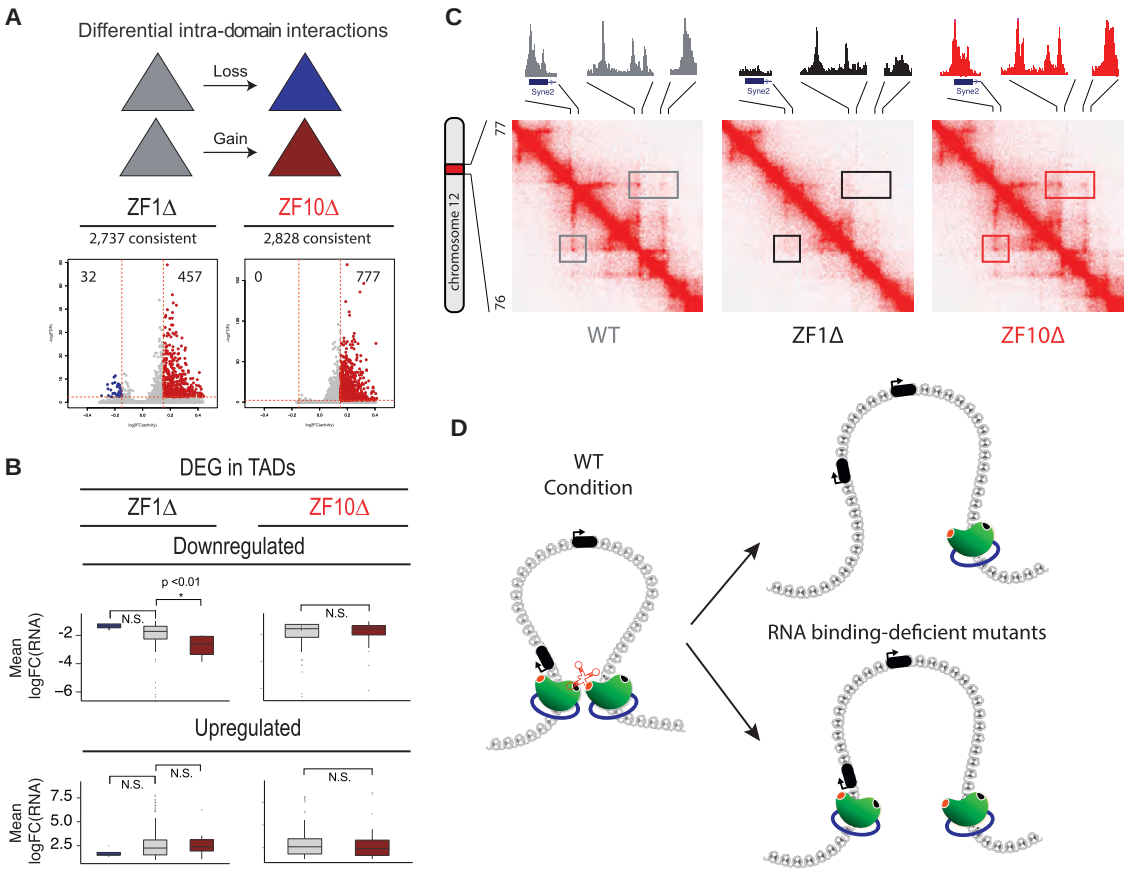

Figure 6. RBR Mutants Disturb Chromatin Loops

(A) Intra-domain interaction changes in WT versus ZF1Δ and WT versus ZF10Δ for common domains. CTCF mutant rescues are associated with gain (red) and loss (blue) of intra-domain interactions.

(B) Boxplots representing the correlation between DEG and chromatin domains whose interactions are increased. Only downregulated genes for ZF1Δ are significantly correlated with increased intra-domain interactions, while all others are not significantly correlated.

(C) Representative contact matrix (at 5 kb resolution) show that the chromatin loop anchor on the left overlaps with the promoter of the *Syne2* gene. In the WT rescue (left), the loop disappears in the ZF1Δ (middle) and is stable in ZF10Δ (right), while CTCF binding is lost only at the promoter and anchor for ZF1Δ. Syne2 is upregulated only under the ZF1Δ condition.

(D) Graphical representation of a chromatin loop formed by two CTCF proteins (green) and cohesin rings (blue), stabilized by an RNA in the WT condition (left diagram). Two outcomes are observed for the RNA binding-deficient mutants (ZF1Δ and ZF10Δ): (1) the loop is lost and a CTCF protein loses its binding to chromatin (top, right diagram), or (2) both CTCF proteins remain bound to chromatin yet the chromatin loop is still lost (bottom, right diagram).

clear dramatic effects on the biology of the cell and seem to be a hallmark of carcinogenesis (Kemp et al., 2014). (2) DEGs have significantly more CTCF-binding sites in their promoters and gene bodies (Figure 4B). (3) CTCF orientation at promoters is in the same direction as transcription and these form loops with internal CTCF-binding sites close to exons. These loops are prevalent and significant for alternative splicing (Ruiz-Velasco et al., 2017). We also found that a significant number of TSSs overlap with anchor sites delimiting chromatin-interacting domains, suggesting that CTCF can function as both a TF and an insulator at the same time (Figure S5G). (4) Differences between cell-type specificity of CTCF binding fit with the transcription trapping hypothesis: RNA contributes to the maintenance and recognition of its binding site for certain TFs such that "transcription of regulatory elements produce a positive-feedback loop that contributes to the stability of gene expression programs" (Sigova et al., 2015). All these features together underscore the relevance of CTCF as a TF and the interplay between transcription and chromatin organization.

In this study, we provide new insight into the relevance of CTCF-RNA interactions. We demonstrate that chromatin looping requires not only CTCF binding to chromatin but also to RNA. The reduced looping capability observed in RNA binding-deficient mutants causes an overall increase in interactions, highlighting the need for RNA molecules to stabilize the appropriate connections. Specifically, both ZF1Δ and ZF10Δ show an increase in interactions within chromatin-interacting domains (Figure 6A). These results suggest that altered *cis*-interactions and chromatin loops that are formed throughout the genome alter cell proliferation (Figure S2B). Furthermore, gene expression alterations are enriched at boundary regions (Figure S6E), possibly through new or disrupted promoter-enhancer contacts

or aberrant inter-domain interactions, suggesting that these are important regulatory regions.

We previously hypothesized that RNA molecules would stabilize CTCF-CTCF loops *in vivo* after describing that CTCF self-association was RNA dependent *in vitro* (Saldaña-Meyer et al., 2014). In our previous study, we termed the RBR (aa 520–727) as the region of CTCF from ZF10 to the end of the C terminus and a deletion within that RBR (aa 574–614) was found to be necessary for CTCF self-association and affected RNA binding *in vitro* (Saldaña-Meyer et al., 2014). Unexpectedly and in contrast to *in vitro* results, PAR-CLIP on full-length CTCF with the internal deletion resulted in only a modest reduction in RNA binding, compelling us to pursue further mapping of RBRs that are now presented in this study. In parallel to this study, Hansen et al. (2019) (in this issue of *Molecular Cell*) showed that the internal deletion in the RBR had significant defects on self-association and clustering but the RNA-binding defect is more modest than the ZF1Δ and ZF10Δ mutants. Regardless, half of the chromatin loops were disrupted in this mutant (Hansen et al., 2019). Together, these two studies suggest that there are several regions within CTCF than can associate with RNA and likely with other factors, which together contribute to the stability of CTCF binding to chromatin and to the formation of chromatin loops.

Many questions remain to be explored if transcription is considered to be a main factor contributing to the regulation of chromatin-interacting domains in a temporal and cell type-specific manner. Perhaps other RNA-binding proteins can account for specific structural roles. Many chromatin-interacting domains are gene poor, or the genes they contain are largely silenced. In these cases, the contribution of nascent RNA as a structural component appears untenable. Yet it is possible that abundant long-lived transcripts such as those from repetitive regions (Hall et al., 2014) could have a general function in chromatin organization of these repressed regions. On the basis of the large number of RNA interactors that are pulled down with CTCF (Kung et al., 2015; Saldaña-Meyer et al., 2014), we envision that these interactions might be highly redundant. Of note, experiments performed to date have examined interactions between bulk RNA and CTCF and, importantly, have yet to be designed to detect potential specificity of the interacting RNA in the context of distinct CTCF DNA-binding sites. Determining exactly how CTCF interacts in complex with DNA and RNA as well as with its protein partners will be an exciting new research avenue. Advances in technical approaches will be needed to improve our understanding of these highly complex regulatory mechanisms.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCES TABLE
- LEAD CONTACT AND MATERIALS AVAILABILITY
- EXPERIMENTAL MODEL AND SUBJECT DETAILS
  - Mouse ESC culture
- METHOD DETAILS
  - Transcriptional inhibition
  - RNase A treatment
  - Rescue cell line generation
  - Cell isolation and flow cytometry
  - PAR-CLIP
  - ChIP-seq
  - Bulk RNA-seq
  - Single-cell RNA-seq library preparation
  - Hi-C library preparation
  - Definition of regulatory regions
- QUANTIFICATION AND STATISTICAL ANALYSIS
  - Bulk RNA-seq Analysis
  - Single-cell RNA-seq Analysis
  - ChIP-seq Analysis
  - *De Novo* Motif Discovery

LEAD CONTACT AND MATERIALS AVAILABILITY

Further information and requests for resources and reagents should be directed to and will be fulfilled by the Lead Contact, Danny Reinberg (Danny.Reinberg@nyulangone.org).

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Mouse ESC culture

E14Tga2 (ATCC, CRL-1821) mESCs were grown in standard medium supplemented with LIF, 1 uM MEK1/2 inhibitor (PD0325901, Stemgent) and 3 uM GSK3 inhibitor (CHIR99021, Stemgent); rescue cell lines were also grown with 500mM of indole-3-acetic acid (IAA, chemical analog of auxin) in the medium as in Nora et al. (2017).

METHOD DETAILS

Transcriptional inhibition

mESCs were incubated with a combination of transcriptional inhibitors (Triptolide 1 μM and DRB 100μM) for 1 or 4 hours. After treatment cells were immediately harvested for immunoblot, ChIP and 5C experiments.

RNase A treatment

The treatment was performed as in Beltran et al. (2016). Briefly, mESCs nuclei were permeabilized with 0.05% Tween-20 in PBS for 10 min at 4C, washed once and resuspended in PBS and finally incubated with RNase A (1 mg/ml) or a mock reaction for 30 minutes. After treatment cells were immediately harvested for ChIP and 5C experiments.

Rescue cell line generation

HEK293T to cells were grown to ~90% confluency, split 1:4 and grown for one day. Cell were then transfected with pLVX-EF1a-IRES-mCherry encoding CTCF WT, ZF1Δ, ZF10Δ, H284N or C528S along with their respective packaging vectors. After 4 hours of transfection the medium was changed to complete DMEM and finally to ESC culture medium after 32-40hr of transfection. Then, the viral supernatant was harvested, filtered through 0.45um syringe filter and added polybrene to 8μg/μl. Added the mix to cells and spin infect (500 g X 60min). Change medium the next day. Sorted for mCherry positive cells after ~2 days of infection for each condition.

Cell isolation and flow cytometry

Single-cell suspensions were prepared passing through 40-μm cell strainers (BD Biosciences) and sorted for mCherry+ mESCs using SY3200 cell sorter. For cell cycle analysis, Click-It Edu AlexaFluor 488 Flow Cytometry Assay (Invitrogen) was used following manufacturing protocol and counterstaining with Propidium Iodide. Stained cells were assayed with BD LSRII flow cytometer and all results were analyzed using FlowJo software.

PAR-CLIP

PAR-CLIP was performed as in Saldaña-Meyer et al. (2014) with some modifications. Briefly, cells were grown under standard conditions and pulsed with 400 mM 4-SU (Sigma) for 2 h. After washing the plates with PBS, cells were cross- linked with 400 mJ/cm2 UVA (312 nm) using a Stratalinker UV cross-linker (Stratagene). Whole nuclear lysates (WNLs) were obtained by fractionation and nuclei were then incubated for 10 min at 37°C in an appropriate volume of CLIP buffer (20 mM HEPES at pH 7.4, 5 mM EDTA,

150 mM NaCl, 2% EMPIGEN) supplemented with protease inhibitors, 20 U/mL Turbo DNase (Life technologies), and 200 U/mL murine RNase inhibitor (New England Biolabs). After clearing the lysate by centrifugation, immunoprecipitations were carried out using 200 μg of WNLs, CTCF antibody, in the same CLIP buffer for 4h at 4°C and then added protein G-coupled Dynabeads (Life Technologies) for an additional hour. Contaminating DNA was removed by treating the beads with Turbo DNase (2 U in 20 mL). Cross-linked RNA was labeled by successive incubation with 5 U of Antarctic phosphatase (New England Biolabs) and 5 U of T4 PNK (New England Biolabs) in the presence of 10 mCi [^{32}P] ATP (PerkinElmer). Labeled material was resolved on 8% Bis-Tris gels, transferred to nitrocellulose membranes, and visualized by autoradiography. The same membrane was then blocked with TBS-T and 5% milk and blotted for CTCF and Lamin-B.

ChIP-seq

ChIP-seq experiments were performed as described previously (Gao et al., 2012). Briefly, cells were fixed with 1% Formaldehyde. Nuclei were isolated using buffers in the following order: LB1 (50 mM HEPES, pH 7.5 at 4C, 140 mM NaCl, 1 mM EDTA, 10% Glycerol, 0.5% NP40, 0.25% Triton X; 10 min at 4C), LB2 (10 mM Tris, pH 8 at 4C, 200 mM NaCl, 1 mM EDTA, 0.5 mM EGTA; 10 min at RT), and LB3 (10 mM Tris, pH 7.5 at 4C, 1 mM EDTA, 0.5 mM EGTA, and 0.5% N-Lauroylsarcosine sodium salt). Chromatin was fragmented to an average size of 250 bp using a Diagenode Bioruptor. Chromatin immunoprecipitation was performed with CTCF or K27ac antibodies. ChIP-seq libraries were prepared using the Kapa Library Prep Kit.

Bulk RNA-seq

Total RNA from ESCs was isolated with TRIzol (Life Technologies). Stranded libraries were then prepared with 2 μg of total RNA as starting material using TruSeq Stranded mRNA kits following the manufacturer's instructions.

Single-cell RNA-seq library preparation

Single-cell RNA-seq libraries were prepared using the Chromium Controller (10X Genomics). Briefly, single cells in 0.04% BSA in PBS were separated into droplets and then reverse transcription and library construction was performed according to the 10X Chromium Single Cell 30 Reagent Kit User Guide and sequenced on an Illumina Novaseq 6000.

Single-cell RNaseq analysis was performed for three 10X libraries (WT, ZF1Δ and ZF10Δ rescues) and sequenced on a paired-end 26/98 Illumina NovaSeq 6000 S2 run. Per-read per-sample FASTQ files were generated using the bcl2fastq Conversion software (v2.20) to convert BCL base call files outputted by the sequencing instrument into the FASTQ format. The 10X Genomics analysis software, Cell Ranger (v2.1.0), specifically the "cellranger count" pipeline, was used to align reads from the generated FASTQ files to the mouse reference genome mm10, generate gene-barcode expression matrices, and perform clustering and differential gene expression analysis. The outputs of the three conditions (WT, ZF1Δ and ZF10Δ) from the "cellranger count" pipeline were aggregated using the "cellranger aggr" pipeline of Cell Ranger, normalizing the combined output to the same sequencing depth and recomputing the gene-barcode matrices and expression analysis accordingly for the aggregated data.

Hi-C library preparation

Hi-C libraries were constructed using the Arima kit following the manufacturer's instructions. Briefly, cells were crosslinked with 2% formaldehyde to obtain 1-5 μg of DNA per Arima-HiC reaction. Importantly, the crosslinked cell pellet for each Arima-HiC reaction should not occupy more than 20 μL of volume in the sample tube and be devoid of any residual liquid. The Arima kit uses an enzyme cocktail that cuts at the following motifs, where '^' is the cut site on the + strand: ^GATC, G^ANTC (N can be either of the 4 genomic bases). Because a digested end produced by one enzyme can be ligated to a digested end produced by the other enzyme, there are 4 possible ligation junction signatures in the chimeric reads: GATC-GATC, GANT-GATC, GANT-ANTC, GATC-ANTC. All enzymatic reactions were made in PCR tubes and incubation was performed using a thermocycler. Libraries were prepared using the Kapa Library Prep Kit with a modified protocol provided by Arima.

Definition of regulatory regions

Enhancers

For Figures S1C and S3B. Typical-enhancer coordinates were downloaded from Whyte et al. (2013)

5C Library Preparation

5C was performed as in Narendra et al. (2016). Briefly, 5C primers were annealed at 48°C for 16hrs atop the 3C libraries from each sample. 1fmol of each primer was used in the annealing reaction with 1 μg of 3C template and 1 μg of salmon sperm DNA. 16 separate annealing reactions were performed per sample, along with control reactions with individual components removed. Forward and reverse primers that annealed to adjacent regions of the 3C template were ligated with 10U of Taq ligase for 60' at 48°C. Successfully ligated forward-reverse primer pairs were then amplified in 6 separate PCR reactions per annealing reaction, using primers specific to the T7 and T3 overhangs. PCR reactions from the equivalent initial sample were then pooled, purified, and run on a gel to ensure the control reactions did not show an amplification product. Libraries were then generated from the purified PCR product to allow for deep sequencing.

QUANTIFICATION AND STATISTICAL ANALYSIS

Bulk RNA-seq Analysis

Raw sequencing files were aligned against the mouse reference genome (GRCm38/mm10) using tophat 2.1.1 and differentially expressed genes were called using DESeq2 with adjusted p values 0.05 and 0.001.

Single-cell RNA-seq Analysis

Sequencing data was demultiplexed using the 10X Genomics Cell Ranger software (version 2.0.0) and aligned to the mm10 transcriptome. Unique molecular identifiers were collapsed into a gene-barcode matrix representing the counts of molecules per cell as determined and filtered by Cell Ranger using default parameters. Normalized expression values were generated using Cell Ranger using the default parameters.

ChIP-seq Analysis

Raw sequencing files were aligned against the mouse reference genome (GRCm38/mm10) using Bowtie2 (version 2.3.4.1) (parameters: -N 1 -k 1 -q -x). Ambiguous reads were filtered to use uniquely mapped reads in the downstream analysis. PCR duplicates were removed using Picard-tools (version 1.88). MACS version 2.0.10 was used to call narrow peaks (parameters: -g 1.87e9–qvalue 0.01). To create heatmaps we used deepTools (version 2.4.1) (Ramírez et al., 2016). We first ran bamCoverage (–binSize 50–extendReads 200 -of bigwig) and normalized read numbers to RPKM or to the spike-in *Drosophila* DNA (–scaleFactor sf), obtaining read coverage per 50-bp bins across the whole genome (bigWig files). We then used the bigWig files to compute read numbers centered on CTCF peaks called by MACS, on TSSs or enhancers (computeMatrix reference-point–sortRegions descend–sortUsing mean–averageTypeBins mean). Finally, heatmaps were created with plotHeatmap (–colorMap = 'Blues'–sortRegions = no).

We used the DiffBind package to identify CTCF sites with significant increase or decrease in binding affinity (Parameters: summits = 250, FDR < 0.01, log2FoldChange > 1).

De Novo Motif Discovery

De novo motif discovery was carried out using the Homer pipeline (Heinz et al., 2010) using coordinates for peaks lost in ZF1Δ and ZF10Δ conditions (findMotifsGenome.pl -size 200).

Motif Analysis

To quantify the affinity of each CTCF motif instance identified from our ChIP-seq data we used DeepBind (Alipanahi et al., 2015), a deep learning algorithm that has been trained on large amounts of ChIP-seq data and can be used to score the affinity of any given sequence for the CTCF motif. 500 bp DNA sequences were used to score their motif affinity with DeepBind v0.11, using motif D00328.018 (CTCF).

Hi-C data processing and quality control

Processing

HiC-Bench (Lazaris et al., 2017) was used to align and filter the Hi-C data, identify chromatin-interacting domains, and generate Hi-C heatmaps. To generate Hi-C filtered contact matrices, the Hi-C reads were aligned against the mouse reference genome (GRCm38/mm10) by bowtie2 (Langmead and Salzberg, 2012) (version 2.3.1). Mapped read pairs were filtered by the GenomicTools (Tsirigos et al., 2012) tools-hic filter command integrated in HiC-bench for known artifacts of the Hi-C protocol. The filtered reads include multi-mapped reads ('multihit'), read-pairs with only one mappable read ('single sided'), duplicated read-pairs ('ds.duplicate'), low mapping quality reads (MAPQ < 20), read-pairs resulting from self-ligated fragments, and short-range interactions resulting from read-pairs aligning within 25kb ('ds.filtered'). For the downstream analyses, all the accepted intra-chromosomal read-pairs ('ds.accepted intra') were used.

The Hi-C filtered contact matrices were corrected using the ICE ''correction'' algorithm (Imakaev et al., 2012) built into HiC-bench. Chromatin-interacting domains were annotated in all conditions using Arrowhead at 10kb resolutions using default parameters (Durand et al., 2016). We also assessed chromatin loops with aggregate peak analysis (APA). We analyzed the data at 10kb resolution (-r 10000 -x 42 -k KR). HiC heatmaps for regions of interest were generated in juicer.

Chromatin domains and boundaries were called using Crane (Crane et al., 2015) at 40 kb bin resolution with an insulating window of 103 kb and 500kb. We also called domains using the Hicratio algorithm (Lazaris et al., 2017) at 40kb resolution.

Quality Control

Quality assessment analysis shows that the total numbers of reads per biological replicate for each condition ranged from ~600 million reads to ~1.1 billion. The percentage of reads aligned was always over 98% in all samples. The proportion of accepted reads ('ds-accepted-intra' and 'ds-accepted-inter') was ~40%, which in all cases was sufficient to annotate chromatin loops with HICCUPS.

Downstream Analysis

The data was aligned against the mm10 reference genome. All contact matrices used for further analysis were KR-normalized. Chromatin loops were annotated for all conditions using HiCCUPS (Durand et al., 2016). Loops were called at 5kb and 10kb resolutions and merged using default parameters.

Compartments

Compartment analysis was carried out using the Homer pipeline (Heinz et al., 2010) (v4.6). Homer performs a principal component analysis of the normalized interaction matrices and uses the PCA1 component to predict regions of active (A compartments) and inactive chromatin (B compartments). Homer works under the assumption that gene-rich regions with active chromatin marks have similar PC1 values, while gene deserts show differing PC1 values. HiC filtered matrices were given as input to Homer together with H2K27ac peaks for compartment prediction. H2K27ac was used by Homer as prior information of active regions.

To determine if significantly altered compartments were present in the mutants, we used Homer's getHiCcorrDiff.pl pipeline to correlate the interaction profile of each locus in the mutants to the interaction profile of that same locus in the wild-type condition. As a result, no significant altered compartment region was identified. We generated density plots to compare the cis-eigenvector 1 values of the mutants and the wild-type by using 50kb genomic bins. Pearson correlation coefficients were also calculated ('Cor' function in R).

Intra-domain interactions

We used the 'domains-diff' pipeline present in HiC-Bench to assess statistically significant intra-domain interactions.

First, the domains-diff pipeline identifies overlapped or positionally consistent domain (common chromatin-interacting domains). This approach establishes a minimum domain length parameter (default: 10 bins) and extends either side of the domain by 3 bins (+/−120 kb in 40kb resolution). chromatin-interacting domains across two samples are considered positionally consistent if their boundaries are as close as 3 bins. The boundaries of the common chromatin-interacting domains are then set to those which yield the largest domain. The set of common domains between any two samples s_1 and s_2 is denoted as T. In the next step, a paired two-sided t test is performed on each single interaction bin within each common domain between the two samples. It calculates the difference between the average scores of all interaction intensities within such domains. A multiple testing correction by calculating the false-discovery rate per common domain (using the R function p.adjust with method = "fdr") is also calculated.

$$Chromatin-interacting\ domain(t) = \left(\frac{\sum i \in I_t\ ^{S}2i}{\#I_t}\right) - \left(\frac{\sum i \in I_t\ ^{S}1i}{\#I_t}\right)$$

for each $t \in T$, and I_t being all intra-domain interactions for domains t.

We classified the common domains in terms of increased, decreased or stable intra-domain interactions by using FDR < 0.1 and absolute domain interactions change > 0.15. A minimum common domains length of 240 kb was considered in the intra-domain interactions differential analysis (6 bins).

Gene expression analysis in Common domains

To assess the correlation of RNA expression with the intra-domain activity status of the common domains in the ZF1 and ZF10 mutants, we assigned a differentially expressed gene (FDR < 0.05) to a common domain when its promoter overlapped with a common domain (overlap > 1 bp). Then, the mean fold change of the RNA expression inside each common domain was computed for upregulated and downregulated DEGs, separately, and compared between the common domain groups (increased-activity, decreased-activity, stable-activity). Statistical significance was assessed by performing a wilcoxon test (unpaired) and boxplots were generated in R.

Annotation of the differential CTCF sites

We used the ChIPSeeker library to annotate the differential CTCF sites obtained in the DiffBind analysis. Annotation packages: 'TxDb.Mmusculus.UCSC.mm10.knownGene' and 'org.Mm.eg.db' (Bioconductor).

To annotate the CTCF differential sites in domains or boundaries we used the domains and boundaries obtained using Crane (w = 500kb). A CTCF site was assigned to a boundary if the complete CTCF peak was found within the boundary coordinates.

Contribution of voltage-gated sodium channel β-subunits to cervical cancer cells metastatic behavior

Ana Laura Sanchez-Sandoval and Juan Carlos Gomora*

Abstract

Background: Voltage-gated sodium (Na_V) channels are heteromeric proteins consisting of a single pore forming α-subunit associated with one or two auxiliary β-subunits. These channels are classically known for being responsible of action potential generation and propagation in excitable cells; but lately they have been reported as widely expressed and regulated in several human cancer types. We have previously demonstrated the overexpression of $Na_V1.6$ channel in cervical cancer (CeCa) biopsies and primary cultures, and its contribution to cell migration and invasiveness. Here, we investigated the expression of Na_V channels β-subunits ($Na_V\beta$s) in the CeCa cell lines HeLa, SiHa and CaSki, and determined their contribution to cell proliferation, migration and invasiveness.

Methods: We assessed the expression of $Na_V\beta$s in CeCa cell lines by performing RT-PCR and western blotting experiments. We also evaluated CeCa cell lines proliferation, migration, and invasion by in vitro assays, both in basal conditions and after inducing changes in $Na_V\beta$s levels by transfecting specific cDNAs or siRNAs. The potential role of $Na_V\beta$s in modulating the expression of Na_V α-subunits in the plasma membrane of CeCa cells was examined by the patch-clamp whole-cell technique. Furthermore, we investigated the role of $Na_V\beta1$ on cell cycle in SiHa cells by flow cytometry.

Results: We found that the four $Na_V\beta$s are expressed in the three CeCa cell lines, even in the absence of functional Na_V α-subunit expression in the plasma membrane. Functional in vitro assays showed differential roles for $Na_V\beta1$ and $Na_V\beta4$, the latter as a cell invasiveness repressor and the former as a migration abolisher in CeCa cells. In silico analysis of $Na_V\beta4$ expression in cervical tissues corroborated the downregulation of this protein expression in CeCa vs normal cervix, supporting the evidence of $Na_V\beta4$'s role as a cell invasiveness repressor.

Conclusions: Our results contribute to the recent conception about $Na_V\beta$s as multifunctional proteins involved in cell processes like ion channel regulation, cell adhesion and motility, and even in metastatic cell behaviors. These non-canonical functions of $Na_V\beta$s are independent of the presence of functional Na_V α-subunits in the plasma membrane and might represent a new therapeutic target for the treatment of cervical cancer.

Background

Cervical cancer (CeCa) is the fourth most common cancer in women worldwide, with more than 500,000 new cases each year and an estimated 260,000 deaths, of which approximately 87% occur in developing countries [1]. Despite the implementation of vaccination against Human Papillomavirus infection, it will take decades before the impact on the cervical cancer incidence became clear, giving the natural history of this disease [2]. Therefore, it is necessary to better understand the biology of this type of cancer in order to improve the early detection and treatment.

Voltage-gated sodium (Na_V) channels are heteromeric transmembrane proteins that consist of a single pore forming α-subunit associated with one or more auxiliary β-subunits (Na_Vβs) [3]. These channels are known to be responsible for action potential generation and propagation in excitable cells, but they are also widely expressed and upregulated in a variety of human cancer types, including breast, prostate, colon, ovarian, lung, gastric, melanoma, astrocytoma and uterine cervix, where the Na_V α-subunit activity has been associated mainly, but not exclusively, with cell motility and invasiveness [4–14]. So far, four Na_Vβs (Na_Vβ1–Na_Vβ4) have been described. These are multifunctional type I transmembrane proteins that modulate Na_V α-subunit gating, localization and transit to the plasma membrane. Additionally, they possess a V-type immunoglobulin repeat in the extracellular domain similar to the family of neural cell adhesion molecules (CAMs), thus, their role as CAMs in a trans-homophilic and trans-heterophilic way, and with other molecules, in presence or absence of the α-subunits has been described in numerous reports and in different expression systems [15–22].

The role of Na_Vβs in cancer has also been studied, although not as widely as for the α-subunits. In prostate cancer (PCa), it has been found that the overexpression of Na_Vβs is associated with the increasing metastatic potential of PCa cell lines [23], and when overexpressing Na_Vβ2 in LnCaP cells, the cells acquired a fibroblastic-like morphology, became more invasive and had enhanced migration in vitro; in contrast, these cells had a reduced tumor volume in vivo [24, 25]. On the other hand, the overexpression of Na_Vβ3 in Saos-2 (osteosarcoma) and T98G (glioblastoma) cells, seems to activate an apoptotic pathway mediated by the tumor suppressor protein p53 [26]. However, most of the studies have been done in breast cancer, where it has been demonstrated that Na_Vβ1 is overexpressed in the low metastatic MCF-7 cell line vs highly metastatic MDA-MB-231 cells [27]. Overexpressing Na_Vβ1 in these last cells produced a drastic reduction on in vitro transwell migration and an increase in cellular adhesiveness. In contrast, MDA-MB-231 cells stably transfected with Na_Vβ1 produced larger tumors in an in vivo model compared with those generated by wild type MDA-MB-231 cells. In addition, overexpression of Na_Vβ1 induced a reduction in caspase activity in these cells [28]. More recently, the potential role of Na_Vβ4 as a metastasis-suppressor gene has been described in breast cancer cells, associated with the small GTPase RhoA activity and therefore with the cytoskeleton remodeling during migration and invasiveness [29].

We have previously demonstrated the overexpression of Na_V α-subunits in cervical cancer biopsies vs non-cancerous cervix, and furthermore, we reported the functional expression of these proteins in primary cultures derived from human cervical cancer biopsies and their contribution to the cell migration and invasiveness. Specifically, Na_V1.6 showed to be the most overexpressed α-subunit and the one responsible of the augmented invasive potential as the specific blockade of this channel was able to diminish the invasive potential with the same effectiveness as the blockade of all the Na_V α-subunits by TTX [14, 30]. In the present work, we investigated the electrophysiological activity of Na_V channels and the expression of Na_Vβs in three cervical cancer cell lines (HeLa, SiHa and CaSki) as well as their contribution to three metastatic cell behaviors: in vitro proliferation, transwell migration and invasiveness.

Methods

Cell lines and cell culture

Cervical cancer cell lines SiHa, CaSki (both HPV-16 positive) and HeLa (HPV-18 positive) were grown in DMEM supplemented with 10% fetal bovine serum (FBS), 100 U/ml penicillin, and 100 µg/ml streptomycin at 37 °C in a humidified 5% CO_2 incubator. All cell culture reagents were purchased from Gibco-Thermo Fisher Scientific (Waltham, MA). The three cell lines were authenticated by short tandem repeat profiling prior to the experiments (data not shown).

Overexpression and downregulation of Na_Vβs expression

Plasmids containing each of the Na_Vβs from rat were kindly donated by Dr. L. Isom (University of Michigan). Overexpression of each Na_Vβ in CeCa cells was achieved by transient transfections using the JetPEI transfection reagent (PolyPlus Transfection; Illkirch, France), according to the manufacturer's instructions. On the other hand, downregulation of Na_Vβs expression was performed using two or three different predesigned siRNAs (Sigma-Aldrich; St. Louis, MO) for each Na_Vβ (100 nM each); in all cases, we chose the one with the best efficiency. Optimal siRNA transfection conditions were stablished previously by using 50 nM of siGLO Green Transfection Indicator (Sigma-Aldrich), a fluorescent

siRNA for determining transfection efficiency. Efficiency of both experimental strategies to manipulate the expression levels of each $Na_V\beta$ was evaluated by RT-PCR and western blot (see Additional file 1).

Electrophysiology

Detailed methods for whole-cell patch-clamp recordings and protocols have been previously described [14, 30]. Sodium currents of native or transiently transfected CeCa cells were recorded at room temperature (20–23 °C) using an Axopatch 200B amplifier, a Digidata 1320A/D converter, and the pCLAMP 10.0 software (Molecular Devices; Sunnyvale, CA). As a positive control for sodium currents, we used transiently transfected CeCa cells with the $Na_V1.6$ channel.

Standard PCR (RT-PCR)

The $Na_V\beta$s mRNA expression levels of CeCa cell lines were assessed by RT-PCR with specific primers for each β-subunit and β-actin as control (Table 1) as described before [30]. Briefly, total RNA of each cell line was isolated with Trizol reagent (Invitrogen; Carlsbad, CA) and RT-PCR reactions were performed in a final volume of 25 µl using the Super-Script One-step RT-PCR kit (Invitrogen) with 250 ng of total RNA, 0.5 µl of enzyme mix, 0.2–0.5 µM of each primer, and 12.5 µl of 2X buffer containing 0.4 mM of each dNTP and 2.4 mM $MgSO_4$.

Real-time PCR (qPCR)

Total RNA was extracted using the RNeasy Mini Kit (Qiagen; Hilden, Germany), then reverse-transcribed with the High Capacity cDNA Reverse Transcription kit (Applied Biosystems; Foster City, CA) according to the manufacturer's instructions using 2 µg of total RNA in a final volume of 20 µl. Real-time PCR was carried out in a Rotor-Gene Q (Qiagen) using Custom TaqMan Gene Expression Assays (Applied Biosystems) as described before [14]. Briefly, 100 ng of cDNA, 0.4 µl of the TaqMan assay (Table 2) and 5 µl of TaqMan Universal PCR Master Mix (Applied Biosystems) were mixed in a final reaction volume of 10 µl for each qPCR reaction. At least three independent experiments were done, and each assay was performed in triplicate. The results were analyzed by the $2^{-\Delta\Delta Ct}$ method [31] using HPRT1 expression as the normalizing gene control and results are shown as relative expression values of $Na_V\beta1$ in HeLa cells.

Western blot

Total protein from native or transiently transfected CeCa cells was extracted 24, 48, 72 and 96 h post-transfection (with cDNA or siRNAs, for overexpression or inhibition of the $Na_V\beta$ expression respectively) using RIPA buffer (25 mM Tris–HCl, pH 7.4; 150 mM NaCl; 1% IGEPAL; 1% Sodium deoxycholate, and 1% SDS) supplemented with complete EDTA-free protease inhibitors (Roche, Switzerland), and quantified by Bradford assay. Equal amounts of protein (100 µg) were subjected to

SDS-PAGE, transferred onto a polyvinylidene difluoride membrane (Millipore, Billerica MA) and probed overnight with the following primary antibodies: rabbit anti-$Na_V\beta1$ (1:3000; LifeSpan BioSciences Inc.; Seattle, WA); rabbit anti-$Na_V\beta2$ (1:1000; LifeSpan BioSciences Inc.); rabbit anti-$Na_V\beta3$ (1:5000; Abcam; Cambridge, UK), rabbit anti-$Na_V\beta4$ (1:3000; Novus Biologicals; Littleton, CO) and a homemade mouse anti-β-actin antibody (1:1000) used as a loading control. Blots were subsequently probed with an anti-rabbit or an anti-mouse (as the case may be) secondary antibody conjugated with horseradish peroxidase (1:10,000; Santa Cruz Biotechnology; Dallas, TX) for 1 h at room temperature and visualized using the SuperSignal West Pico chemiluminescent substrate (Thermo Fisher Scientific). Signal intensity of immunoblots was calculated with ImageJ software.

Proliferation assays

Cell proliferation was determined using the colorimetric 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay. Briefly, cells were plated in 48-well microplates at an initial density of 2×10^3 cells per well. To measure cell proliferation at 24, 48, 72 and 96 h after seeding, 10 µl of MTT solution (5 mg/ml) were added in each well after replacing the culture medium with 200 µl of fresh culture medium. The cells were incubated at 37 °C, and 3 h later, cell culture and MTT solution were removed and 150 µl of dimethyl sulfoxide was added into the plate to dissolve formazan crystals. The absorbance at a wavelength of 562 nm was recorded using an Eppendorf AG 22331 Biophotometer (Eppendorf; Hamburg, Germany). For analyzing the role of $Na_V\beta$s on proliferation, after overnight incubation, cells were transfected with the respective cDNA to overexpress or the specific siRNA to downregulate each β-subunit expression, and finally, MTT assay was performed 24, 48, 72 and 96 h after transfection.

Cell cycle analysis by flow cytometry

The role of $Na_V\beta1$ on cell cycle in SiHa cells was assessed by flow cytometry after staining the cells with propidium iodide (PI; Molecular Probes, Life Technologies; Grand Island, NY). Briefly, 2×10^5 cells were seeded onto 12-well plates, incubated in normal conditions for 24 h, synchronized by serum-reduced conditions (0.2% FBS) for 48 h and then transfected with the specific cDNA or siRNA. After incubating for 48 h, cells were collected and fixed with ice-cold 70% ethanol, stored for at least 24 h at −20 °C, treated with RNase and stained with PI for 1 h at 37 °C. For each condition, 2×10^4 cells (singlets) were analyzed in an Accuri C6 cytometer (BD Biosciences; San Jose, CA), and the percentages of cells in each cell cycle phase were analyzed with FlowJo software (Tree Star; Ashland, OR) using the Dean-Jett-Fox algorithm by three independent tests for each condition. Appropriate gating was used to select the single cell population and used on all samples.

In vitro migration and invasion assays

Migration and invasion assays were done using culture inserts with 8-µm pore size membranes covered or not with Matrigel (Corning Inc., Corning, NY) for invasion and migration respectively. The upper compartment was seeded with 5×10^4 for migration and 1×10^5 cells for invasion in DMEM supplemented with 5% FBS, and the lower compartment was filled with DMEM supplemented with 15% FBS as a chemoattractant. The number of cells migrating or invading (according to the circumstances) over 48 h at 37 °C was evaluated using the MTT assay described before. Results were compiled as the mean of at least three repeats, each time done by duplicate, and compared with control conditions.

In silico immunohistochemistry (IHC) staining analysis

Expression of $Na_V\beta4$ in CeCa and normal cervical tissues was examined using the Human Protein Atlas (http://www.proteinatlas.org/) [32, 33], a Swedish-based online tool for human protein expression analysis. Representative CeCa and normal tissues cores were chosen for illustrative purposes.

Statistical analysis

All quantitative results are given as the mean ± S.D. Differences in means were tested with an unpaired two-tailed Student's *t* test.

Results

Cervical cancer cell lines do not express plasma-membrane voltage-gated sodium currents

Our previous results showed the functional expression of Na_V channels in CeCa primary cultures and specifically demonstrated the relevance of the $Na_V1.6$ channel in the invasiveness of cervical cancer [14, 30]. Thus, in order to further investigate the role of Na_V channels in the biology of CeCa, we intended to use CeCa cell lines for such experiments. However, we found that SiHa, CaSki and HeLa cell lines do not express functional Na_V channels at the plasma-membrane as determined by whole-cell patch-clamp experiments. ($n = 30$ cells total; see Additional file 2), even though we have previously shown that they do express the $Na_V1.6$ mRNA and at least one isoform of the $Na_V1.6$ protein [34].

Endogenous expression of $Na_V\beta$s in cervical cancer cell lines

In previous studies, we described the role of Na_V α-subunits in the invasive potential of CeCa primary cultures. In this work, we wanted to analyze the possible role of $Na_V\beta$s in different CeCa cellular processes. To that end, endogenous expression of $Na_V\beta$s was first evaluated by RT-PCR using specific primers for each subunit. In most of cases, the mRNA was abundant as evidenced by the generation of the expected amplicon for each β-subunit (Fig. 1a), suggesting the very likely presence of these proteins. Along with the expected bands, additional PCR amplicons were observed when analyzing the expression of $Na_V\beta2$ and $Na_V\beta4$ by RT-PCR (Fig. 1a). The ≈150 bp DNA fragment observed in the $Na_V\beta4$ line matches with a splice variant that has been already reported [23], that would produce a highly truncated protein (if translated) with an unknown functionality. The larger non-specific bands in $Na_V\beta2$ and $Na_V\beta4$ RT-PCR do not correspond to any reported variants of such isoforms, and we cannot

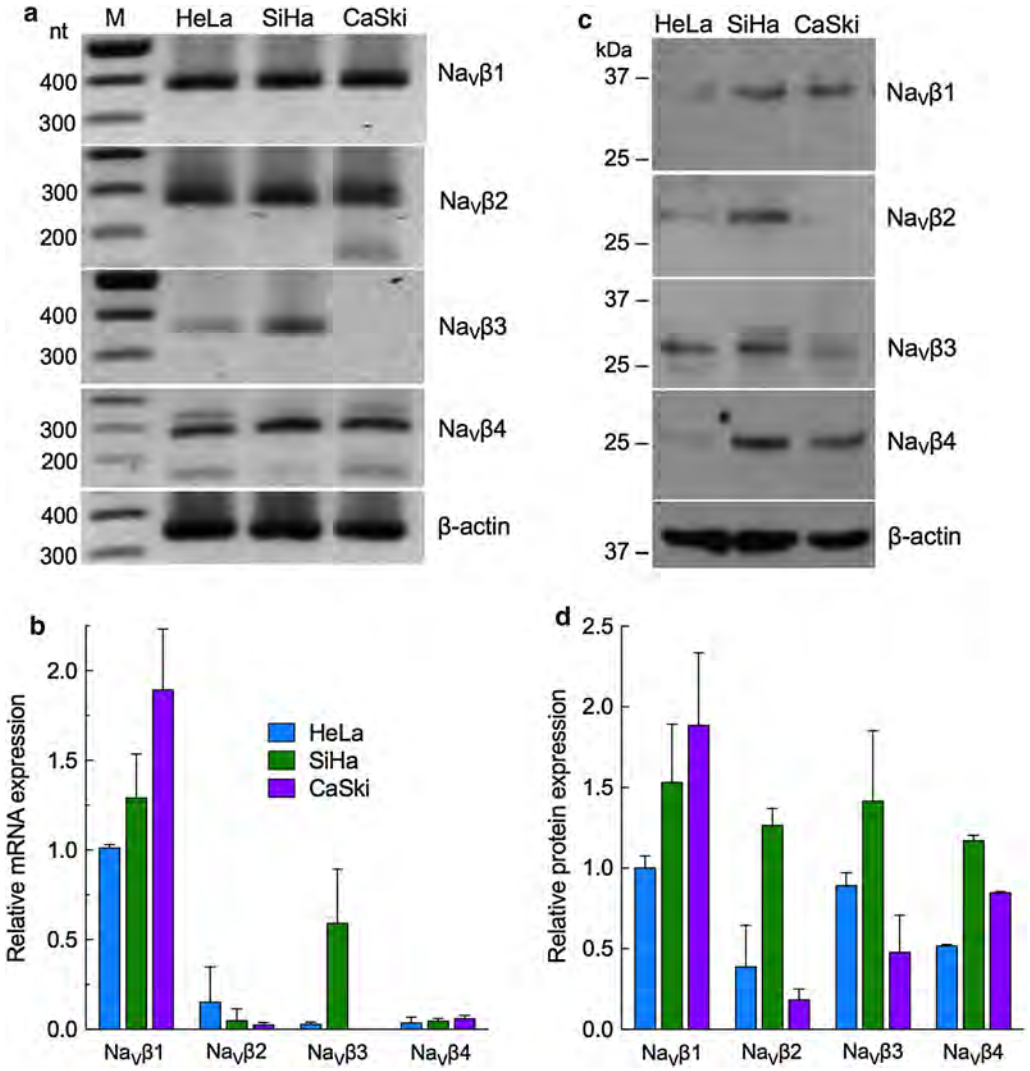

Fig. 1 Expression of $Na_V\beta$s in cervical cancer cell lines. **a** Total RNA isolated from CeCa cell lines was analyzed by conventional RT-PCR using specific primers for the indicated $Na_V\beta$ and β-actin as a loading control. M: molecular marker. **b** Quantitative differences in $Na_V\beta$s mRNA expression of CeCa cells analyzed by qPCR, normalized with HPRT1 mRNA levels and relative to $Na_V\beta1$ in HeLa. Each bar denotes mean ± S.D. of three independent experiments. **c** Western blot with 100 µg of total protein per lane from each of the cell lines indicated. Specific antibodies against each $Na_V\beta$ were used and β-actin antibody as a control for loading. **d** Quantified data for $Na_V\beta$s protein expression normalized with β-actin expression for each cell line, and relative to $Na_V\beta1$ expression in HeLa. Each bar denotes mean ± S.D. of three independent experiments

rule out the possibility of a non-specific amplification with these primers. A more detailed study is required to analyze the $Na_V\beta$s isoforms expressed in the CeCa cells and their potential function and/or contribution to the cancerous phenotype. Nevertheless, to carry out a more quantitative analysis of the $Na_V\beta$s expression levels in the different CeCa cell lines we performed qPCR experiments. Results exhibited substantial differences in $Na_V\beta$s mRNA expression, but in all cases, $Na_V\beta1$ showed to be highly expressed, whereas $Na_V\beta3$ displayed the lowest expression levels, except in SiHa cells (Fig. 1b). In addition, evaluation of protein expression by western blot for each $Na_V\beta$ indicates that the four $Na_V\beta$s are expressed in the three CeCa cell lines (Fig. 1c). Interestingly, SiHa was the only cell line that express very similar levels of all four $Na_V\beta$s (Fig. 1d). Also, SiHa and CaSki cells expressed significantly higher levels of $Na_V\beta1$ and $Na_V\beta4$ than HeLa cells. While $Na_V\beta3$ levels were similar among the CeCa cell lines, and $Na_V\beta2$ was the lees expressed except in SiHa cells (Fig. 1d). The western blot results suggest the absence of additional variants of $Na_V\beta$s isoforms, as we only observed the protein of the expected size.

Proliferation, migration and invasion of CeCa cell lines under basal conditions

In order to evaluate the metastatic potential of each CeCa cell line, we analyzed three key metastatic behaviors: proliferation, migration and invasiveness in vitro. HeLa cells demonstrated to be the most aggressive cell line as these cells proliferated, migrated and invaded the most, followed by SiHa cells, and CaSki cells (Fig. 2).

Increasing or decreasing the expression of $Na_V\beta$s is not enough to promote the functional activity of α-subunits in the plasma membrane

First, to evaluate the siRNA transfection efficacy, we used the siGLO Green Transfection Indicator, a fluorescent dye attached to a scramble siRNA, and analyzed the cells 24 h later by epifluorescent microscopy. The results indicated that almost 100% of the cells were transfected with the siRNAs, as can be appreciated in Additional file 3. Thus, we followed the same conditions to transfect the specific siRNAs against each of the $Na_V\beta$s.

It is well known that some of the $Na_V\beta$s are implicated in the correct trafficking of the Na_V α-subunits to the plasma membrane, as has been shown with the heterologous in vitro expression of $Na_V\beta1$ and $Na_V\beta2$ in Xenopus oocytes [15, 35], and in vivo with $Na_V\beta2$ knocked-out mice [36]. These evidences made us wonder if the sole overexpression or even the down regulation of the expression of $Na_V\beta$s was enough to promote the functional expression of the pore-forming sodium channels in the plasma membrane and therefore the appearance of voltage-gated sodium currents. To address this question, HeLa and SiHa cells were analyzed by the whole-cell patch-clamp technique 24, 48, 72 and 96 h after transfection to increase or decrease the expression of each of the $Na_V\beta$s. More than 130 cells were successfully investigated with this technique, but we did not find any voltage-gated sodium currents, suggesting that the regulation of the expression of $Na_V\beta$s is not enough to promote the functional activity of Na_V α-subunits in the plasma membrane (see Additional file 2).

Role of $Na_V\beta$s on proliferation

Next, we investigated whether the expression of $Na_V\beta$s had an effect on cell proliferation. This was evaluated in CeCa cell lines 24, 48, 72 and 96 h post-transfection with the cDNA or with the specific siRNA for each $Na_V\beta$ subunit to increase or to reduce the expression respectively. Only $Na_V\beta1$ had an effect on proliferation of SiHa cells: the overexpression of $Na_V\beta1$ increased cell proliferation, whereas its downregulation decreased cell duplication (Fig. 3a; center panels). This is similar to what was found

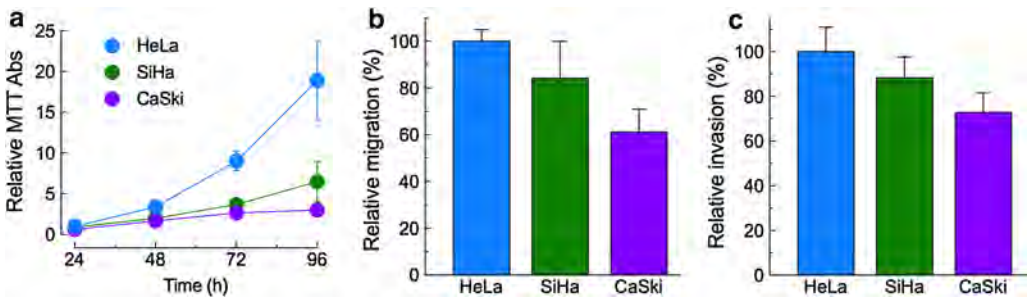

Fig. 2 Proliferation, migration and invasion of CeCa cells. **a** Proliferation was evaluated by MTT assays 24, 48, 72 and 96 h after seeding the cells (2×10^3 per well). Means ± S.D. of three independent experiments, each one done by triplicate. Migration (**b**) and invasion (**c**) of CeCa cells were assessed by Boyden transwell assays for 48 h. Results expressed as percentages of values obtained for HeLa cells. Means ± S.D. of three independent experiments, each done by duplicate. HeLa cells showed to be the most aggressive, as they proliferated, migrated and invaded the most

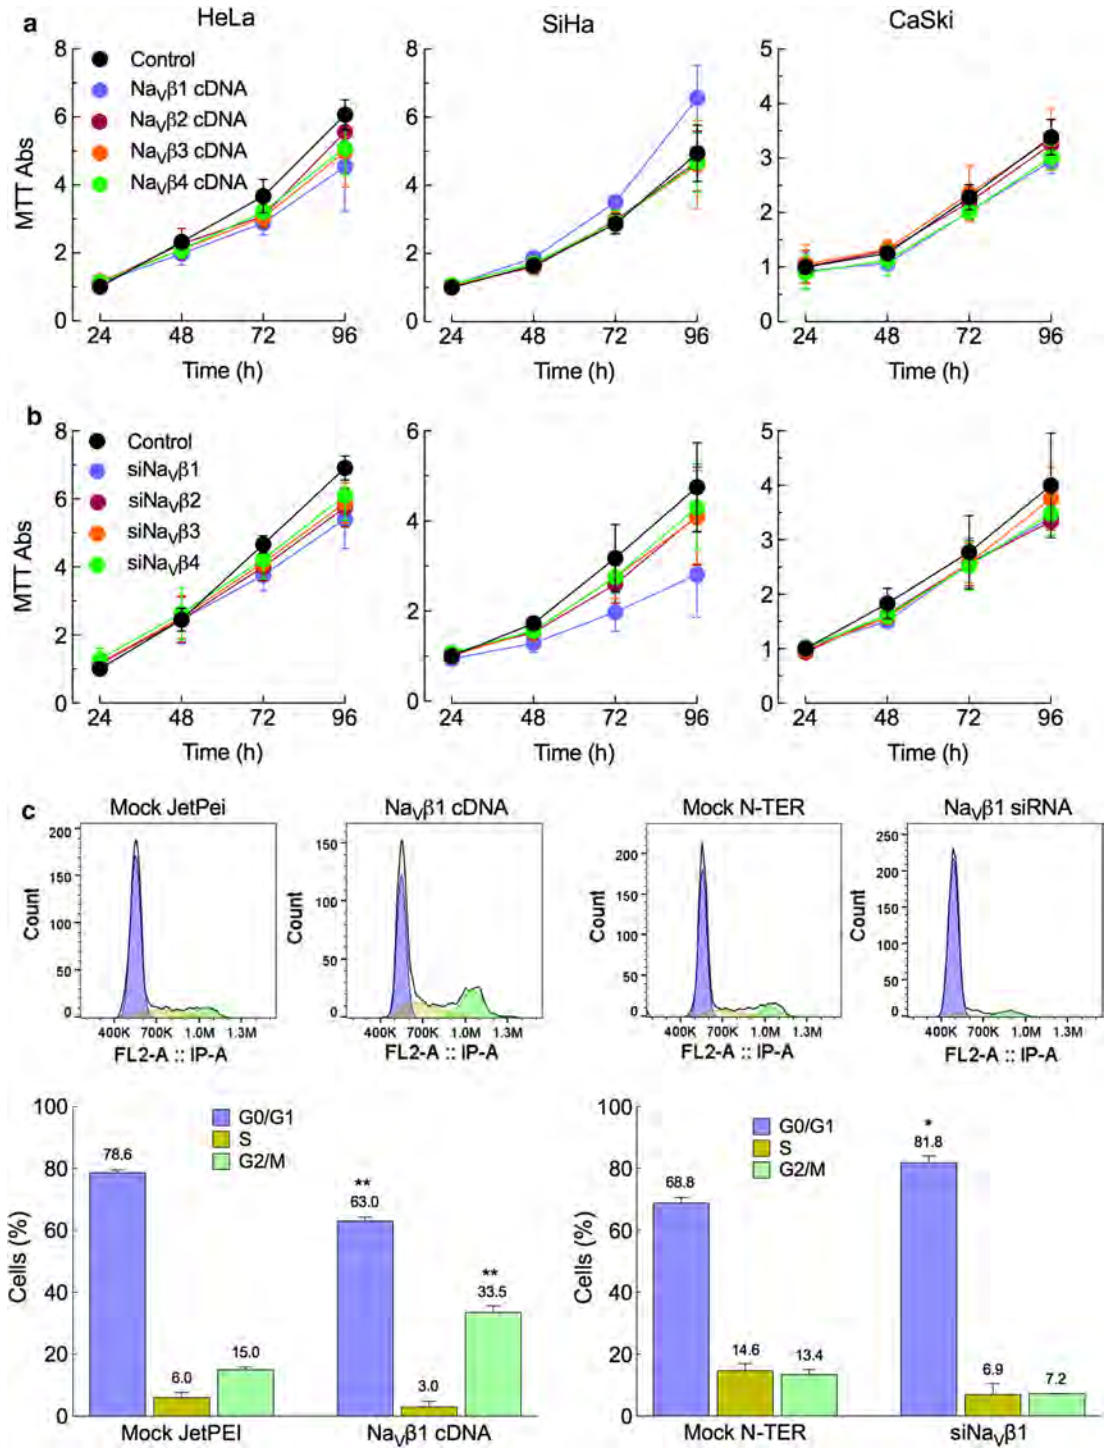

Fig. 3 Effect of $Na_V\beta$s on proliferation and cell-cycle of CeCa cells. Proliferation was evaluated by MTT assays 24, 48, 72 and 96 h post-transfection with plasmids (**a**) or with specific siRNAs (**b**) for the β-subunits. The results show the participation of $Na_V\beta1$ on proliferation of SiHa cells, as it increases when the protein is overexpressed and decreases when it is downregulated. The other three $Na_V\beta$s showed no effect on proliferation of SiHa cells, and none of the β-subunits were involved in proliferation of HeLa and CaSki cells. **c** Cell cycle analysis by flow cytometry in SiHa cells performed 48 h after transfection of synchronized cells with $Na_V\beta1$ cDNA or with the specific siRNA against this subunit. Cells were fixed with ice-cold 70% ethanol, stored for at least 24 h at − 20 °C, treated with RNase and stained with PI for 1 h at 37 °C. For each condition, 2×10^4 cells (singlets) were analyzed. Representative histograms of the control mock conditions and the transfected cells (upper panels) of three independent experiments summarized in the bar graphs (bottom panels) as means ± S.D. of the relative percentage of cells in each cell cycle phase. Significance: $^*P < 0.05$, $^{**}P < 0.01$

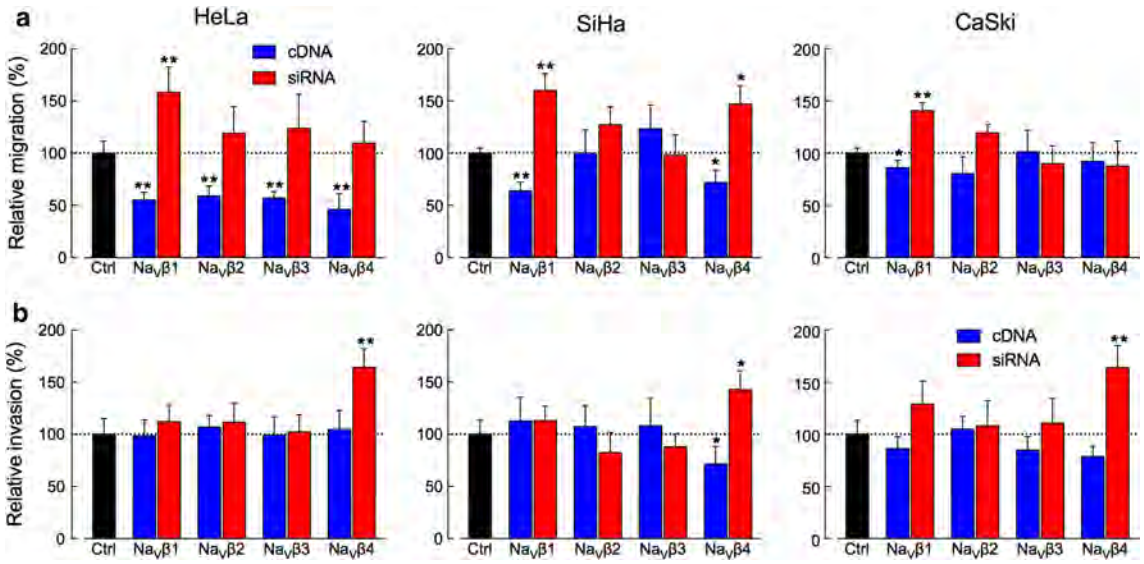

Fig. 4 Effect of $Na_V\beta$s on migration and invasiveness of CeCa cells. Migration (**a**) and invasion (**b**) experiments were performed with HeLa, SiHa and CaSki cells in Boyden transwell chambers for 48 h. Bars indicate mean ± S.D. of at least three independent experiments, each performed in duplicate and presented as a percentage of control conditions. Overexpression of $Na_V\beta$s in HeLa cells induced a reduction in approximately 50% in cellular migration, while the downregulation of $Na_V\beta1$ by siRNAs increased it in 58%. $Na_V\beta1$ is also involved in SiHa and CaSki migration. On the other hand, downregulation of $Na_V\beta4$ with siRNAs increased cellular invasiveness in the three cell lines. Significance: $^*P < 0.05$, $^{**}P < 0.01$

with the breast cancer cell line MDA-MB-231, where the overexpression of $Na_V\beta1$ in these cells led to the development of larger tumors in mice [28]. To corroborate this observation, we decided to perform a cell cycle assay by flow cytometry. First, for standardization purposes, SiHa cells were arrested at the G0/G1 phase by incubation in serum-reduced conditions for 24 and 48 h. To estimate the proportion of cells in different phases of the cell cycle, cells were stained with PI and analyzed by flow cytometry. Results show a consistent arrest of cells when treated for 48 h, as the proportion of the cells in G0/G1 phase increased significantly whereas the percentage of cells in G2/M phase was smaller compared to control (normal medium) conditions (see Additional file 4). Once synchronized cells were transfected with either cDNA or siRNA for $Na_V\beta1$ subunit under the experimental conditions indicated above. Results show a significant increase in the proportion of cells in G2/M phase when overexpressing $Na_V\beta1$ vs the control condition (JetPEI mock control), as well as a significant decrease in the proportion of cells in G0/G1 phase. In the same sense, the downregulation of the expression of $Na_V\beta1$ generated a significantly larger proportion of cells in G0/G1 phase, with no significant changes in the proportion of cells in G2/M phase compared with the N-TER mock control (Fig. 3b). These results suggest a positive role of $Na_V\beta1$ in the proliferation of SiHa cells, but not in HeLa or CaSki cells.

Role of $Na_V\beta$s on migration and invasion

The role of $Na_V\beta$s on in vitro migration and invasion of CeCa cell lines was evaluated 48 h post-transfection with the cDNA or with the siRNA for each β-subunit to overexpress or to downregulate the expression of $Na_V\beta$s respectively. Migration results show that overexpression of $Na_V\beta$s in HeLa cells induces a significant reduction in migration capability (around 50% in all cases), regardless of the type of $Na_V\beta$, accompanied by a tendency to increase the invasive capability when the $Na_V\beta$s are downregulated, being the effect of the treatment with siRNAs against $Na_V\beta1$ the most substantial (a 58% increment). In SiHa cells, a similar result was found with $Na_V\beta1$ and $Na_V\beta4$; a significant reduction on the migration capability (36% and 28% respectively) when they are overexpressed, and an increment (60% and 47% respectively) when they are downregulated, while the manipulation of the expression of $Na_V\beta2$ and $Na_V\beta3$ did not alter the migration of these cells. Finally, in CaSki cells, only $Na_V\beta1$ showed to have a role on cellular migration: the overexpression of this subunit decreased the migration by 14%, whereas the transfection with siRNAs increased it by 41% (Fig. 4a). It is worth of notice that only the effect of $Na_V\beta1$ (negative regulation) in migration remains constant and statistically significant in the three cell lines, suggesting a potential role of $Na_V\beta1$ in CeCa migration capability.

With regards to the in vitro invasion, results show that the downregulation of $Na_V\beta4$ increased the invasiveness of the three cell lines: 64% in HeLa, 43% in SiHa and 63% in CaSki cells. Accordingly, the overexpression of this protein induced a reduction on the invasiveness of SiHa and CaSki cells by 28% and 21% respectively, suggesting a potential role of $Na_V\beta4$ as an invasion suppressor. The rest of the $Na_V\beta$s did not significantly modified the invasion capacity of the CeCa cells (Fig. 4b).

Given all these results, we decided to corroborate whereas the diminished expression of $Na_V\beta4$ was associated with the presence of CeCa vs normal cervix tissues. For that purpose, we analyzed in silico the expression $Na_V\beta4$ in CeCa biopsies and normal cervical tissues from the Human Protein Atlas. Although the database only has a small number of IHC normal cervix and CeCa biopsies stained for $Na_V\beta4$ ($n=3$ for normal cervix, and $n=12$ for cervical cancer), the relationship between the expression of the protein and the presence or absence of cervical cancer is evident: the staining results indicate that three out of three normal cervix tissues have moderate $Na_V\beta4$ expression, while in the CeCa biopsies no signal of $Na_V\beta4$ was detected in twelve out of twelve cases (see Additional file 5). Taken together, these results strongly suggest that $Na_V\beta4$ expression is downregulated in CeCa, leading to an increase in the invasive capacity of the cells, and thus, the metastatic potential.

Discussion

For many years, $Na_V\beta$s were considered only as "auxiliary" Na_V subunits commissioned of regulating the α-subunit kinetics and cellular localization. Nowadays plenty of evidence shows the multifunctionality of these proteins, participating in a wide variety of cellular processes like cell adhesion, cytoskeleton remodeling, filopodia and invadopodia formation, transcriptional regulation, cell cycle regulation and even apoptosis [21, 29].

For the present work, we chose three different CeCa cell lines in order to cover a wide range of CeCa cases, and to analyze the potential role of $Na_V\beta$s in the malignant behavior of this disease. SiHa and CaSki cells are HPV-16 positive (the most frequently detected viral type in CeCa, found in approximately 57% of cases) whereas HeLa cells arise from a HPV-18 positive tumor (the second most frequent virus; 16% of cases) [37]. Furthermore, HeLa and SiHa cells derived from a primary tumor, while CaSki cells were taken from a metastatic tumor. In addition, the patients' ethnicity and the cellular origins of the three cell lines are different [38–40].

Here we demonstrated the presence (expression) of $Na_V\beta$s in the three different CeCa cell lines (Fig. 1), even in the absence of functional Na_V α-subunit expression in the plasma membrane (evidenced by whole-cell patch-clamp recordings, see Additional file 2), suggesting that their role in cancer cell biology is independent of the pore-forming Na_V α-subunit.

When we evaluated the aggressiveness of each cell line, by analyzing the basal proliferation, migration and invasiveness in vitro, HeLa cells demonstrated to be the most aggressive cell line, as these cells proliferated, migrated and invaded the most, followed by SiHa cells. CaSki cells were the less proliferative, and they migrated and invaded the less (Fig. 2). As far as we are concerned, this is the first report about the differences in the metastatic behavior among these CeCa cell lines.

We have previously reported the role of $Na_V1.6$ (the most overexpressed Na_V α-subunit in CeCa biopsies) in the invasiveness potential of CeCa primary cultures [14]. In agreement with our recent findings [34], in the present work we did not find voltage-gated sodium currents in any of the CeCa cell lines studied with the patch-clamp technique. This could be due to at least two possibilities: either the sodium channels are being correctly synthetized but are not reaching the plasma membrane for some unknown reason; or these cells are expressing a non-functional splicing variant. In this regard, it has been reported that $Na_V\beta$s participate in the appropriate traffic and localization of the Na_V α-subunits in the plasma membrane [15, 35, 36]. Moreover, it has been shown that $Na_V\beta2$ can be cleaved by secretases, generating small intracellular peptides capable of reaching the cell nucleus and promoting the transcriptional upregulation of genes including SCN1A, which encodes for $Na_V1.1$ [41, 42]. Hence, we thought that maybe by modifying the expression of these proteins we could promote the functional localization of conducting Na_V channels in the plasma membrane, however our results suggest this is not the case, as the manipulation of the expression of the $Na_V\beta$s in HeLa and SiHa cells was not enough to promote the appearance of voltage-dependent sodium currents (see Additional file 2). Yet, there are many other molecules such as hormones and growth factors that could be involved in the correct trafficking of the channel. In fact, we have examined the possibility that Na_Vs functional expression in CeCa cell lines could be regulated by β-estradiol or EGF, but we did not find sodium currents under any of the experimental conditions tested (data not shown). Another likely explanation could be related to the oxygen conditions in which the cell lines are cultured. It has been reported that hypoxia can change both the expression and activity of Na_Vs. Tumor cells usually experience severe hypoxia, which has been correlated with a more robust expression and activity of Na_Vs [43, 44]. On the contrary, CeCa cell lines have been cultured

in normoxic tissue culture conditions, which might have modified the Na_Vs expression and/or trafficking.

It is also possible that CeCa cell lines are expressing a non-conducting channel with a different and unknown function and/or localization in the cell. It remains to be investigated whether Na_V α-subunits are expressed in intracellular compartments, as well as their possible role in invasion. The existence of functional intracellular sodium channels has been demonstrated in macrophages where the activity of this sodium channel contributes to cellular invasion through a mechanism involving sodium ions release from cationic intracellular stores, followed by a subsequent mitochondrial calcium release mediated by the Na^+/Ca^{2+} exchanger, which in turn facilitates cytoskeletal remodeling and invadopodia formation [12]. In fact, recent data from our group suggests the presence of intracellular $Na_V1.6$ channels in CeCa cell lines [34]. However, more experiments are needed to fully elucidate this discrepancy between Na_Vs functional expression in CeCa primary cultures vs cell lines.

Regarding to the effect of Na_Vβs on cell proliferation, we found that only Na_Vβ1 had an effect on this process and only in SiHa cells: the overexpression of Na_Vβ1 increased cell proliferation, whereas the downregulation of the expression of this protein decreased it (Fig. 3a). This is in agreement with observations reported by Nelson et al. [28] demonstrating that Na_Vβ1 enhances breast tumor growth and metastasis in vivo, by increasing cell proliferation and reducing apoptosis. The fact that we only observed this effect in one out of three CeCa cell lines shows that it is a particularity of the cell line (SiHa) rather than a general role of Na_Vβ1 on proliferation in cervical cancer.

On the other hand, it has been suggested that Na_Vβ3 mediates a p53-dependent apoptotic pathway [26]. In breast cancer cells, for example, this subunit is totally absent, although it is normally expressed in non-cancerous breast cells (Sanchez-Sandoval et al., unpublished data). However, the overexpression or down regulation of this subunit did not alter the proliferation rate of the CeCa cell lines analyzed here, suggesting a lack of the pro-apoptotic activity of Na_Vβ3 in these cells. This might be related to the p53 protein status in CeCa cell lines. It has been reported that the association between the E6 protein (one of the two main HPV oncogenes) with p53 leads to the specific ubiquitination and degradation of p53 protein [45], therefore inactivating any pro-apoptotic effect due to the Na_Vβ3 expression in basal conditions. This is one of the several ways the HPV genome secures the growing of the tumor. However, the intermediate steps that Na_Vβ3 must undergo to promote apoptosis is still unknown, as well as why Na_Vβ3 had no pro-apoptotic effect in CeCa cells when overexpressed. A possible explanation could be the existence of a positive (and necessary) feedback regulation between p53 (or one of its multiple target genes) and Na_Vβ3, leading to a lack of pro-apoptotic activity of Na_Vβ3 in the absence of functional p53.

On the contrary, our migration experiments show a clear participation (negative regulation) of Na_Vβ1 on the ability of CeCa cells to perform transwell migration across of an 8 μm-pore membrane. When we induced the overexpression of this subunit, the migration rate decreased in the three CeCa cell lines, being HeLa cells the most affected (almost 50% inhibition in cell migration). Correspondingly, the inhibition of Na_Vβ1 expression by siRNAs led to significant increments in cell migration of HeLa, SiHa and CaSki cells (Fig. 4a). Thus, Na_Vβ1 could be acting as a cell adhesion molecule, promoting the cell–cell adhesion and therefore making it difficult to move across the membrane. It is also worth of notice that, among the three cell lines, HeLa have the lowest Na_Vβ1 expression compared to the other two CeCa cell lines (Fig. 1), and they also have the greatest migration capacity. In the same sense, CaSki cells are the ones with the bigger expression of Na_Vβ1, and the lowest migration behavior (Fig. 2b).

A study made on breast cancer cell lines revealed that the overexpression of Na_Vβ1 in highly metastatic MDA-MB-231 cells increased cell–cell adhesion and decreased in vitro migration, consistent with the proposed role of Na_Vβ1 as a cell adhesion molecule [27]. However, the *trans*-homophilic interactions through Na_Vβ1 can also mediate the process outgrowth in vivo, as in neurons, generating an elongated morphology and therefore potentiating metastasis, as has been reported for the same breast cancer cells but using mouse models instead of transwell experiments [28]. Something similar could be happening with CeCa cell lines. Thus, the persistent contribution of Na_Vβ1 in the three CeCa cell lines migration is indicative of its role as a negative regulator of the in vitro migration, regardless the HPV type present in the CeCa cell line. Although it remains to be investigated whether this behavior also occurs in vivo.

With respect to the contribution of Na_Vβs in invasiveness, our results show that downregulation of Na_Vβ4 expression resulted in a significant increase in the in vitro invasiveness of the three cell lines studied here (Fig. 4b), suggesting the role of this subunit as a metastasis suppressor protein. These observations agree with the in silico analysis of Na_Vβ4 expression performed with the Human Protein Atlas data: normal cervix biopsies show moderated Na_Vβ4 expression, while in CeCa biopsies it seems to be absent (see Additional file 5). Taken together, these results strongly suggest that Na_Vβ4 expression is downregulated in CeCa, which in turn increases the

invasive capacity of the cells. In accordance with this interpretation, out of the three CeCa cell lines studied in the present work, the HeLa cell line showed the lowest expression of $Na_V\beta4$ and the highest index of cell invasion.

In breast cancer cell lines, it has been found that increasing $Na_V\beta1$ expression promotes the overexpression of $Na_V1.5$, the main Na_V α-subunit involved in the invasiveness of this type of cancer [27]. However, according to our results, this is not the case for CeCa cell lines, as the overexpression of $Na_V\beta1$ or $Na_V\beta4$ did not promote the expression of conducting $Na_V1.6$ channels in the plasma membrane, the principal Na_V α-subunit involved in the invasive potential of these cells. Thus, we conclude that the pathways used by these proteins to induce cell migration and invasion, are independent of the activity of $Na_V1.6$ or other Na_V α-subunits in the plasma membrane of CeCa cell lines.

Other groups have also reported the downregulation of $Na_V\beta4$ expression in cancer vs normal tissue. This is the case of prostate cancer [23], papillary thyroid cancer [46], and breast cancer [29]. The latter study, performed by the group of Dr. Sebastien Roger at the University of Tours, reported solid evidence about the possible mechanistic pathway through which $Na_V\beta4$ prevents metastasis in cancer cells. They showed an increased activity of the small GTPase RhoA (crucial for cytoskeleton remodeling during migration and invasion) when $Na_V\beta4$ was silenced in breast cancer MDA-MB-231 cells. This effect was independent of $Na_V1.5$ channel activity, the main Na_V α-subunit implicated in BCa invasiveness. A similar mechanism might be taking place in CeCa cells: a downregulation of the $Na_V\beta4$ subunit that leads to an increased activity of RhoA and therefore, a more robust invasive potential, which is independent of the $Na_V1.6$ expression in the plasma membrane. However, we speculate that additional cellular mechanisms might be involved in this phenomenon, as the effects of $Na_V\beta4$ in cellular migration were not significant in our study, meaning that the sole change on cellular motility cannot explain the dramatic increase on cellular invasiveness when $Na_V\beta4$ is downregulated. A more recent study showed that $Na_V\beta4$ is downregulated in papillary thyroid cancer (PTC) compared with normal thyroid tissues. More interestingly, the authors also found that preserved $Na_V\beta4$ expression might independently predict favorable recurrence-free survival in classical PTC [46]. Altogether, these data reinforce the notion of using $Na_V\beta4$ as a biomarker for cancer metastasis and a potential new therapeutic target for the treatment of cervical cancer.

Conclusions

In conclusion, our results show that even though cervical cancer cell lines do not generate Na_V currents, they do express $Na_V\beta$ subunits, which could play a role in proliferation ($Na_V\beta1$ only in SiHa cells), migration ($Na_V\beta1$ in the three cell lines), and invasion ($Na_V\beta4$ in the three cell lines studied). The results support the recent knowledge about $Na_V\beta$s as multifunctional proteins involved in cell processes like ion channel regulation, cell adhesion and motility, and even in metastatic cell behaviors. Finally, the evidence presented here contributed to propose $Na_V\beta1$ and $Na_V\beta4$ as prognostic markers for cervical cancer tumor progression.

Abstract. The receptor for advanced glycation end products (RAGE) has been involved in the actions of inflammatory proteins such as S100 calcium binding protein B (S100B), among several others. Despite there being many studies available proposing several different modes of interaction between the receptor and the protein, it is necessary to reconcile these binding hypotheses. We evaluated the co-localization of RAGE and S100B in human umbilical vein endothelial cells (HUVEC's) exposed to acute pro-inflammatory lipopolysaccharide (LPS). Co-localization of the receptor and the protein in umbilical cells exposed to pro-inflammatory stimuli was analyzed using an immunofluorescent assay. RAGE was present in umbilical cells, and its co-localization with S100B was stimulated in the presence of LPS. Our findings suggest an interaction between these proteins, possibly producing early inflammatory responses in umbilical cells. The understanding of the molecular mechanisms of this recognition is relevant to characterize the nature of the signaling associated with this receptor in inflammatory processes.
Keywords: Inflammation; Lipopolysaccharide; Molecular recognition; Co-localization; Umbilical endothelial cells.

Resumen. El receptor para productos finales de glucosilación avanzada (RAGE) ha sido involucrado en las acciones de proteínas inflamatorias tales como la proteína S100B unida a calcio (S100B), entre muchas otras. A pesar de los múltiples estudios disponibles que proponen diferentes modos de interacción entre el receptor y la proteína, es necesario reconciliar estas hipótesis. Se evaluó la co-localización de este receptor con la proteína S100B en células endoteliales de la vena del cordón umbilical humano (HUVEC's) expuestas de manera aguda al agente pro-inflamatorio lipopolisacárido (LPS). La co-localización del receptor y la proteína en células umbilicales expuestas al estímulo pro-inflamatorio se analizó mediante un ensayo de inmunofluorescencia. RAGE se presentó en células umbilicales, y su co-localización con S100B fue estimulada por LPS. Estos hallazgos sugieren el reconocimiento entre estas proteínas, posiblemente produciendo respuestas inflamatorias tempranas en células umbilicales. La comprensión de los mecanismos moleculares de este reconocimiento es relevante para caracterizar la naturaleza de la señalización asociada a este receptor en procesos inflamatorios.
Palabras clave: Inflamación; Lipopolisacárido; Reconocimiento molecular; Co-localización; Células endoteliales umbilicales.

Introduction

The receptor for advanced glycation end products (RAGE) binds multiple ligands, including advanced glycation end products (AGEs) [1,2], the high mobility group box-1 protein (HMGB1) [3-5], several members of the S100 calcium-binding protein family, notably S100B [6-9], and the amyloid β peptide [10,11], among several others, which are expressed in inflammatory disorders [6,12-14]. Several studies exploring this concept have been carried out in *in vitro* conditions with human cells from the immune system, as well as in murine models. These findings include the activation of the membrane surface RAGE receptor upon binding the DNA-HMGB1 complex, HMGB1 or S100B [15]. These interactions induce the expression of pro-inflammatory molecules such as interleukin 8 (IL8), RAGE, HMGB1, and the S100 protein genes [16,17]. In different disease models, such as lupus, diabetes, viral infections and cancer, changes in the levels of soluble RAGE (sRAGE) and membrane RAGE have been observed, suggesting a major role for this protein in the amplification of inflammatory responses [18]. Leukocytes have been the most frequently used cell preparation to study cell receptor-ligand interactions at the membrane level [19]. However, more recently, other cell types have been studied in inflammatory microenvironments, including epithelial and endothelial cells, fibroblasts, and other cells that can respond to various inflammatory stimuli or cell damage. The endothelial cells of veins and arteries can be in direct contact with these pro-inflammatory ligands through RAGE and other receptors, such as Toll-like or cytokine receptors, to activate the MAPK pathways. In turn, these kinases can regulate transcription factors linked to inflammation. The nuclear factor kappa B (NFκB) requires kinase activation to amplify the response to injury or infection. This knowledge is derived from observations of *in vitro* models that primarily use specific inhibitors or antibodies that block the binding of membrane receptors to their ligands on the cell surface, thus emphasizing the importance of these interactions for cell responses. For instance, in 2003, Treutiger *et al.* [20] demonstrated that the use of anti-RAGE antibodies reduced the adhesion of neutrophils to human umbilical vein endothelial cells (HUVEC's) via NFκB signaling in inflammatory conditions elicited by lipopolysaccharide (LPS) or tumor necrosis factor-alpha (TNF-α). Similar results were obtained when HUVEC's were pre-activated using AGE-albumin induction and exposed to proteins of the S100 family as RAGE ligands [6]. Affinity studies of the S100 family as RAGE ligands have also been reported using surface plasmon resonance (SPR) analysis, and a stoichiometry of 2:1 (S100:RAGE) was determined [7,8,21,22]. These studies also demonstrated that these interactions induce pro-inflammatory responses in cells (including HUVEC's and macrophages); however, the binding of RAGE to its ligands remains unverified at the cytochemical level. Therefore, in this study, we characterized the early co-localization of endogenous RAGE with endogenous S100B in HUVEC's challenged with the pro-inflammatory stimulus LPS. In order to confirm the co-localization of these proteins and their interactions. Since, it is known that the activation of RAGE induced by S100B constitutes an important pro-inflammatory pathway during the progression of acute and chronic inflammatory diseases [7,23,24], our study provides insights into the co-localization of these proteins in unstimulated and LPS-stimulated HUVEC's. Our results represent a basis for ongoing studies involving the entire RAGE-S100B complex and for novel approaches to interfere with inflammatory responses.

Experimental

Materials and Methods

Reagents

Primary antibodies against RAGE (Ab3611 for immunofluorescence assays against the V and C2 domains) and secondary antibodies were purchased from Abcam (Cambridge, MA, USA). The antibody recognizing S-100B (AB11178) was also purchased from Abcam.

Cell cultures and experimental treatments

Endothelial cells from the veins of human umbilical cords (HUVEC's) were obtained from eutocic births and caesarean sections, according to the procedure described by Jaffe [25]. Samples were obtained at the Hospital of Obstetrics and Gynecology "Dr. Luis Ayala Castelazo", IMSS, Mexico City, following a clinical protocol previously approved by the Ethics Committee of the Hospital. Cords were processed within the first 3 h after being obtained, washed and cleaned with sterile saline solution. Once collected, the veins were cut into 5 cm pieces in order to use samples of the same length. The veins were placed in containers with phosphate buffered saline (PBS) supplemented with antibiotic-antimycotic (penicillin/streptomycin 1.5%; GIBCO, Life Technologies, USA plus

ISSN-e 2594-0317

Amphotericin B, Biowest S.A.S., USA). The vascular endothelium was disaggregated enzymatically by adding 10 ml of 0.02 % collagenase (type 4, Worthington Biochemical Corporation) dissolved in PBS. Endothelial cells were dissociated and collected in fetal bovine serum (FBS, Invitrogen, Mexico). The cells obtained after enzymatic digestion were centrifuged at 800 × *g* for 5 min in a Labofuge 400 Heraeus Instruments centrifuge (Thermo Scientific, Waltham, Massachusetts, USA) using a rotor model 8179. The pellets were resuspended in M199 medium (GIBCO, Rockville, Maryland, USA) supplemented with 1 % glutamine (GIBCO), 0.1 mg/ml of endothelial growth factor (Biomedical Technologies Inc., Alfa Aesar, Ward Hill, Massachusetts, USA), 0.1 mg/ml of heparin (Sigma-Aldrich Co., St. Louis, Missouri, USA) and 10 % FBS. Streptomycin and penicillin were added in a 1 % dilution (GIBCO). All cells were maintained by incubation at 37° C with controlled relative humidity and 5 % CO_2. For experimental purposes, cells were dissociated from the culture dish with a trypsin/versene solution (GIBCO) for 2 min and reseeded in 48 or 6 wheel-plates at densities ranging from 30,000 to 50,000 cells per wheel for the 48 wheel-plates, or 250,000 for the 6 wheel-plates, in M-199 medium supplemented as previously mentioned. All experiments were performed 24 h later.

The assay for inflammatory activation is based on previous studies under *in vitro* and *ex vivo* conditions in HUVEC's and human umbilical veins stimulated with TNF-α [26]. In these cases, it is known that concentrations of 1-10 ng/ml during 2-6 hours of exposure induce the expression of adhesion molecules and pro-inflammatory cytokines that promote leukocyte adhesion in response to TNF-α. The concentration of LPS that we used in this study is the most commonly used in studies of leukocyte activation involving 2-12 h periods of exposure [27]. Endothelial cell activation was determined after induction with LPS (10 ng/ml). TNF-α (5 ng/ml) was employed in additional experiments as a positive control of inflammation; this concentration was determined from a concentration curve in a leukocyte/endothelial cell adhesion assay, ranging from 0.5 to 10 ng/ml. Endothelial cells were washed twice in PBS and placed in new culture medium with 10 ng/ml of TNF-α or LPS for 3 hours at 37 °C, 5% of CO_2 and 95% air. Immediately thereafter, all samples were washed and fixed for immunofluorescence assays. The observation and capture of images was performed with a LSM-50 Confocal Scanning Microscope (Carl Zeiss, Germany).

Immunofluorescence assay

RAGE and S100B were detected in HUVEC's exposed to inflammatory stimuli. The observation and analysis were performed using immunofluorescence staining with specific antibodies (Abcam Co., Cambridge, Massachusetts, USA). For the *in vitro* assays, HUVEC's were washed three times with PBS at pH 7.2, fixed in 4% paraformaldehyde (PFA) for 15 minutes, and washed three times with PBS. These preparations were incubated in 0.6 M glycine for 20 minutes, to remove the autofluorescence of aldehydes and washed three times with PBA (PBS albumin, 0.5%). Samples were then blocked for 20 minutes with PBA 1% to eliminate nonspecific reactions of the antibodies, and subsequently washed three times with PBA 0.5%. Immunoreactions were carried out diluting the mouse primary antibody specific for S100B 1:100 (SH-B1, ab11178, Biotech, Cambridge, UK), or the polyclonal rabbit antibody for RAGE (ab3611, Biotech) in PBA 1%, and cells or tissue slices were incubated for 1 hour at 4 °C. They were subsequently washed three times with PBA 1 %. The secondary antibodies (Alexa 647 for S100B and Alexa-488 for RAGE, Life Technologies) were diluted 1:400 and incubated with the samples for 1 h; afterwards, the preparations were washed with PBA 1%. Nuclei were stained blue with DAPI (Vectashield, Vector Laboratories, Inc., Burlingame, California, USA) and visualized using a fluorescent microscope (Floid Cell Imaging Station, Life Technologies).

Image processing

In order to estimate the co-localization of RAGE and S100B in cells, the merge area from the fluorescent labeling was analyzed by Otsu's method for segmentation of the region of interest [28]. A value of 50 is used as a threshold for the red and green color image components. Contours are found applying a Laplacian operator of 3 x 3 pixels to the binary image after segmentation. The area is represented by the number of pixels different to the background in the binary image. The average of the intensity is computed in the region of interest. Z-stack processing was also employed for depth improvement of images containing HUVEC's. This method is commonly used to improve the analysis of three-dimensional images, hence allowing more detailed recognition of cellular structures and better localization of proteins.

Statistical analysis

All experiments were carried out in duplicate. Mean ± standard error medium (S.E.M.) were determined for all parameters. Statistical significance among groups was determined by Student's t-test or one-way analysis of variance followed by Bonferroni's *post-hoc* analysis. Values of $P<0.05$ were considered as statistically significant.

Results

LPS induced an early and enhanced co-expression of RAGE and S100B in HUVEC's after 3 h of exposure

Fig. 1 shows the co-localization of RAGE and S100B in HUVEC's exposed for 3 h to pro-inflammatory stimuli induced by LPS or TNF-α (as a positive control). Cells were labeled for immunofluorescence in blue (DAPI nuclei), green (RAGE) and red (S100B). The first line corresponds to the sequence of untreated (control) cells, where moderate co-localization areas of both proteins can be observed in the merge (Fig. 1A). In addition, in these cells, the segmentation method revealed the specific points of co-localization evidenced by a labeling area (16230 pixels per field). Quantification of these co-localization areas was achieved also with the segmentation method (Fig. 1 A-B). The second sequence of images (second line) depicts the effect of LPS on RAGE and S100B co-localization; this treatment produced an increased number of labeled cells for both proteins when co-localized in the merge, as compared to untreated cells. Concomitantly, the RAGE and S100B co-localization areas (segmentation) in LPS-treated cells were enhanced when compared with control cells (186 % above the control). In the third line, the sequence of images shows that the exposure of cells to TNF-α produced a prominent RAGE and S100B co-localization (in the merge), as well as an increased labeling area (334 % above the control).

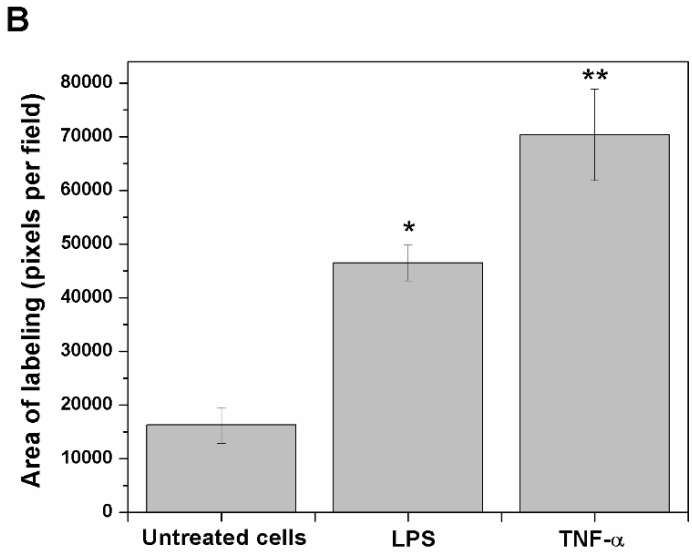

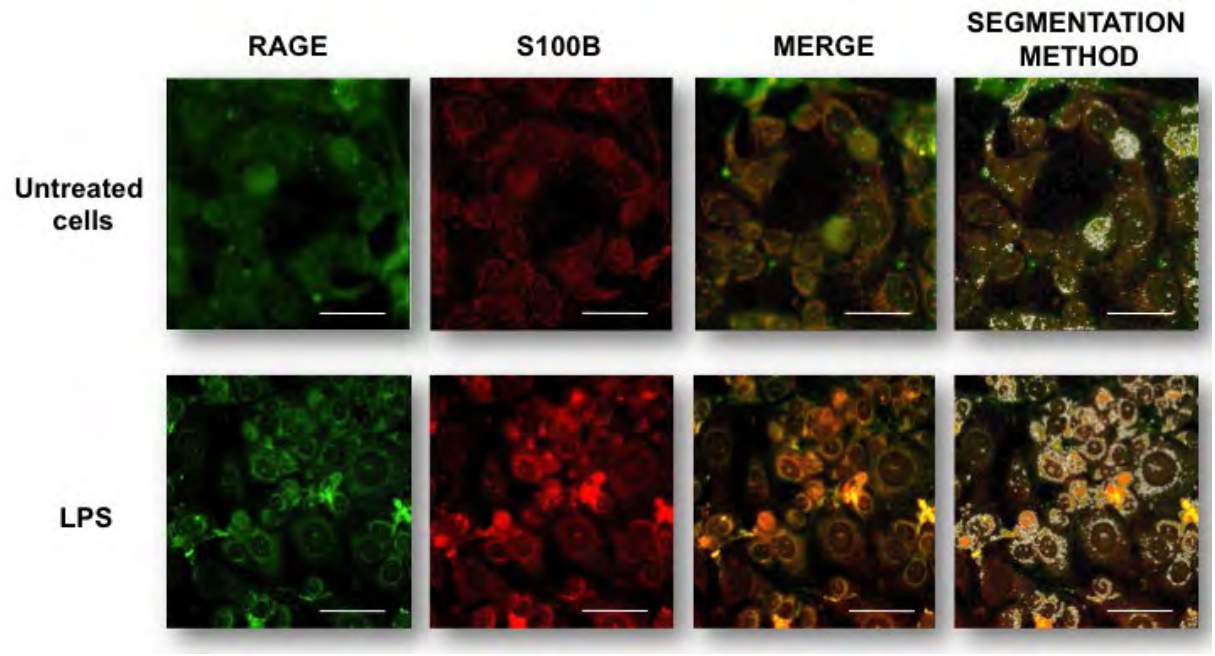

Fig. 1. RAGE and S100B co-localization in human umbilical vein endothelial cells (HUVEC's) obtained from umbilical cord. Cells were challenged with acute inflammatory stimuli (TNF-α [5 ng/ml] or LPS [10 ng/ml]). RAGE and S100B were detected early by immunofluorescence after exposure to pro-inflammatory agents for 3 h. In **A**, the localization of RAGE (green column) and S100B (red column) are shown. Nuclei were stained in blue (DAPI). In the fourth and fifth columns, the images show the co-localization (merge) and image analysis (segmentation algorithm) of both proteins, respectively. The horizontal bars indicate a length of 100 µm in all panels. In **B**, the graphic representation of the merge area (as percent) in untreated (Control) and TNF-α- or LPS-treated cells is shown. Bars represent quantification of two images per treatment. One-way ANOVA followed by Bonferroni's test; *p<0.05, **p<0.01, different from untreated cells.

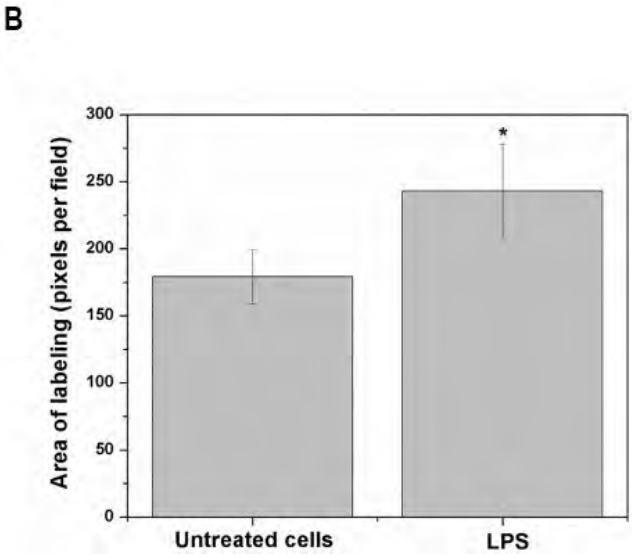

Fig. 2. Detailed images (20 μm bar scale) showing untreated cells (upper line) and LPS-treated HUVEC's (lower line). In **A**, Images correspond to three-dimensional reconstructions using the Z-stack to display the expression of RAGE (first column in green), S100B (second column in red) and the merge (third column). RAGE was constructed with 18 photos, whereas S100B was built up with 12 photos. The fourth column depicts the segmentation in the co-localization images. In **B**, the graphic representation of the merge area (as percent) in untreated (Control) and LPS-treated cells is shown. Bars represent quantification of two images per treatment. Student's t-test; *$p<0.05$, different from untreated cells.

Discussion

Endothelial dysfunction and inflammatory cell adhesion have been regarded as early and important factors in various pathologies. In fact, inflammation is a major event for both, the healing and the damaging processes. In turn, LPS is a pro-inflammatory molecule involved in the pathogenesis of inflammatory disorders. While chronic inflammation is more commonly associated with pathological stages, the characterization of acute inflammation is of major relevance since this event establishes the borders between healing and injury. How cells and tissues respond to acute inflammation is the clue to anticipate whether they will survive or initiate deadly cascades, leading further to tissue damage. Therefore, in this study we considered the early effects (3 h exposure) of LPS on HUVEC's in order to complement previous reports describing its actions on cell viability at different times (1 and 24 h) [29]. Further support for an early role of LPS and TNF-α as inflammatory promoters for HUVEC's can be found in related reports [30,31]. The response of endothelial cells *in vitro* was sensed after LPS stimulation upon the assumption that this pro-inflammatory molecule binds to Toll-like membrane receptors and RAGE, thereby inducing changes in their phenotype at short times [32].

Here, we demonstrated an early co-localization of RAGE and S100B proteins in HUVEC's subjected to inflammatory stimuli, thus suggesting that this interaction might eventually be responsible for inflammatory events through signaling cascades involving factors like NFκB [33]. In this regard, several studies have suggested that RAGE activation during inflammatory processes involving the S100B protein, is taking place [34]. Indeed, the elicited inflammatory cascades induced by RAGE probably perpetuate the organ dysfunction in inflammatory processes [6]. The interaction of these two proteins for triggering acute and/or chronic inflammation and its biological role has already been characterized [7,35,36]; yet, a still unresolved issue is the minimal size of the S100B-RAGE complex that can promote signaling, bringing together the cytoplasmic tails of the RAGE dimers.

Despite it being currently assumed that different ligands can bind to RAGE, directly or through other molecules (i.e., forming bridges with AGEs) [37], all possible interactions between these molecules or their effects on cells, have not been explored yet. RAGE activation by S100B is a major pro-inflammatory pathway occurring in acute and chronic inflammatory diseases [23,38]. Some members of the S100 protein family, such as S100B, are known to form active tetramers, hexamers or larger oligomers [7,39].

Article *J. Mex. Chem. Soc.* **2019**, *63*(1)
©2018, Sociedad Química de México
ISSN-e 2594-0317

The co-localized areas for RAGE and S100B could suggest either an increase in the expression of these proteins, or their mere re-location with additional interactions. It is therefore fair to mention that our results are focused exclusively on S100B from endothelial cells, where this protein can act as a chemokine that is subsequently released to the surrounding environment. Based on these conditions, the characterization of the interactions between RAGE and S100B and their effects are of major relevance, since they can serve for the design of more specific *in vivo* models of disorders involving inflammatory components.

Finally, the occurrence of the RAGE-S100B interaction in HUVEC's establishes the basis for the understanding of the inflammatory events taking place during the gestational and/or birth processes under normal or pathological conditions, though such interaction has also been described in other biological preparations, including different tumor cells, neurons, astrocytes, microglia, etc. This is relevant as RAGE has been shown to interact with several other ligands, including diverse members of the S100 protein family, thus participating in disorders like cancer, cardiovascular disease, CNS disorders, etc. [40,41]. Therefore, the many biological implications that the RAGE-S100B interaction represent for the compromise of physiological homeostasis deserves deeper and more detailed investigation in different biological scenarios

Acknolwedgements

The authors wish to thank the National Science and Technology Council of Mexico (CONACYT) for project No. 168692 and SEP-PRODEP. We also acknowledge the support of the Committee for Aid and Education in Neurochemistry (CAEN) in category 1B: Research Supplies for Use in the Applicant's Home Laboratory. We are particularly grateful to M.Sc. Ana María Soto-Estrada, I.Q. Tania Tapia-Esquivel and I.Q. Brenda Segura-Bailón for their fine and timely professional technical assistance.

Elimination of dysfunctional mitochondria via mitophagy is essential for cell survival and neuronal functions. But, how impaired mitophagy participates in tissue-specific vulnerability in the brain remains unclear. Here, we find that striatal-enriched protein, Rhes, is a critical regulator of mitophagy and striatal vulnerability in brain. In vivo interactome and density fractionation reveal that Rhes coimmunoprecipitates and cosediments with mitochondrial and lysosomal proteins. Live-cell imaging of cultured striatal neuronal cell line shows Rhes surrounds globular mitochondria, recruits lysosomes, and ultimately degrades mitochondria. In the presence of 3-nitropropionic acid (3-NP), an inhibitor of succinate dehydrogenase, Rhes disrupts mitochondrial membrane potential ($\Delta\Psi_m$) and promotes excessive mitophagy and cell death. Ultrastructural analysis reveals that systemic injection of 3-NP in mice promotes globular mitochondria, accumulation of mitophagosomes, and striatal lesion only in the wild-type (WT), but not in the Rhes knockout (KO), striatum, suggesting that Rhes is critical for mitophagy and neuronal death in vivo. Mechanistically, Rhes requires Nix (BNIP3L), a known receptor of mitophagy, to disrupt $\Delta\Psi_m$ and promote mitophagy and cell death. Rhes interacts with Nix via SUMO E3-ligase domain, and Nix depletion totally abrogates Rhes-mediated mitophagy and cell death in the cultured striatal neuronal cell line. Finally, we find that Rhes, which travels from cell to cell via tunneling nanotube (TNT)-like cellular protrusions, interacts with dysfunctional mitochondria in the neighboring cell in a Nix-dependent manner. Collectively, Rhes is a major regulator of mitophagy via Nix, which may determine striatal vulnerability in the brain.

striatal neuronal vulnerability | tunneling nanotubes | mitophagy ligand | SUMO-E3 ligase | mitophagosomes

Understanding mitophagy mechanisms and its dysregulation leading to pathological abnormalities in human diseases is a major challenge in modern biology. Reduced mitochondrial functions are linked to aging and many neurodegenerative disorders. Parkinson disease (PD) is the best example linked to mitochondrial dysfunction, because the most vulnerable neurons of PD, the substantia nigra pars compacta, show mitochondrial abnormalities. Familial PD genes, such as PTEN-induced kinase-1 (Pink1), parkin, and leucine-rich repeat kinase 2, are implicated in mitochondrial dysfunction (1–3). Decline in mitochondrial enzyme activity is reported more in Alzheimer disease and amyotrophic lateral sclerosis patients compared to control subjects (4). Impaired mitochondrial function is observed in Huntington disease (HD) as patients continue to drop weight, even though they have a high caloric intake (5). Oligomers of amyloid, mutant superoxide dismutase 1, and mutant huntingtin can affect mitochondrial membrane potentials and impair mitochondria trafficking and function (6–12). Despite these important studies, how mitochondrial dysfunction leads to selective neuronal vulnerability remains unknown. For example, although the familial PINK1 and parkin mutants are ubiquitously expressed (13), the mechanisms by which they elicit lesion in the substantia nigra remains largely unclear. Similarly, how mitochondrial toxins induce tissue-specific lesion in the brain is also unclear. It is well known that 3-nitropropionic acid (3-NP) promotes lesion in the striatum but not in the cortex or cerebellar neurons, resulting in HD-like motor deficits (14, 15). MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) or rotenone promotes substantia nigra pars compacta neurodegeneration, sparing the cortex or striatum, resulting in PD-like symptoms (16–18). The major difference between these toxins that promote brain region-specific lesion are that 3-NP blocks complex II, succinate dehydrogenase (SDH) (19), whereas rotenone and MPTP block complex I (NADH [nicotinamide adenine dinucleotide, reduced] dehydrogenase) (20, 21). Thus, what determines the substantia nigra neuron to MPTP-induced lesion and striatal neuron to 3-NP–induced lesion remains unclear. The differences in their brain penetrability may not account for the tissue-specific lesion, as these toxins block mitochondrial function throughout the brain and peripheral tissue. Therefore, although mitochondrial dysfunction is ubiquitous, it is insufficient to elicit selective neuronal death, suggesting that there are additional mechanisms that may play a role in the brain (22, 23).

Rhes belongs to a small GTPase (guanosine triphosphate hydrolase) family of proteins highly enriched in the brain's striatum, which controls psychiatric, cognitive, and motor functions. Rhes is induced by thyroid hormones and can inhibit the cAMP/PKA (cyclic adenosine monophosphate/protein kinase A) pathway, dopaminergic signaling, and N-type Ca^{2+} channels (Cav 2.2) (24–27).

Significance

Damaged mitochondria are eliminated by lysosomes, a process called mitophagy. However, the brain tissue specific roles and mechanisms of mitophagy remain unknown. We report that Rhes, a protein highly enriched in the striatum, eliminates damaged mitochondria via mitophagy, a function that may regulate the optimum number and function of mitochondria in the striatum. However, when mitochondria are irreversibly damaged, as in the presence of 3-NP (an inhibitor of complex II, SDH), Rhes exacerbates mitophagy in association with Nix, a mitophagy receptor and promotes cell death. Intriguingly, Rhes can travel via membranous protrusions from a healthy cell to the neighboring cell and interacts with the damaged mitochondria via Nix. Collectively, Rhes acts as "mitochondrial surveillant," and excessive mitophagy may account for striatal vulnerability in brain.

Over the years, we have found several roles for Rhes in the striatum. Rhes can regulate the mammalian target of rapamycin complex 1 (mTORC1), SUMOylation, and HD toxicity in cell and mouse models (28–32). Independent studies show a link for Rhes in striatal toxicity in various models of HD (33–38). Rhes knockout (KO) mice are also resistant to 3-NP–induced striatal lesion (39). Yet the mechanisms by which Rhes promotes neuronal vulnerability in the brain remains unclear.

Here we report that Rhes is a critical regulator of mitophagy in the striatum. Using ultrastructure, biochemical, and cell and molecular biology tools, we demonstrate that Rhes up-regulates mitophagy via Nix receptor, leading to striatal cell death. Our study reveals mitophagy mechanisms by which Rhes might promote striatal vulnerability in the brain.

Results

Rhes Associates with Mitochondria and Lysosomes In Vivo and In Vitro. We took an unbiased approach by comparing our previously identified in vivo striatal interactome of Rhes (40) with a publicly available database of mitochondrial (www.mrc-mbu.cam.ac.uk/impi) and lysosomal proteins (41). We found 64 (3.5%) and 20 (1.8%) out of 307 high-confidence striatal interactors of Rhes with potential association to mitochondria (for example, Vdac1, Rhot1) and lysosomes (Atp6v0d1, Nid1), respectively (Fig. 1 *A* and *B*). Next, using sucrose gradient density, we separated organelles from the striatal brain tissue homogenate from wild-type (WT) and Rhes KO and found that endogenous Rhes cosedimented in mitochondrial (as detected by SDH subunit A [SDHA]) and lysosomal (Microtubule associated protein light chain 3 [LC3] and lysosome associated membrane protein 1) fractions in WT striatum, and, as expected, no Rhes signal was detected in KO (Fig. 1*C*). In order to further understand the Rhes's mitochondrial role, we employed striatal neuronal cell lines (also known as ST*Hdh*$^{Q7/Q7}$) isolated from the striatum of knock-in mice, which contain a targeted insertion of a chimeric mouse with human Htt exon 1 with 7 polyglutamine repeats (control) (42). These cells do not express endogenous Rhes (30, 43), so we think this is a suitable model for studying the function of exogenously added Rhes, as it is the only source of Rhes, and it would not compete with endogenous function of Rhes. Similar to endogenous Rhes in the striatum, the cultured striatal neuronal cell line expressing GFP-Rhes, not GFP alone (control), also cosedimented in the mitochondrial and lysosomal fractions (*SI Appendix*, Fig. S1*A*). Next, we carried live-cell time-lapse fluorescence confocal microscopy to determine Rhes interaction and function with mitochondria and lysosomes. We found that 1) Rhes interacted preferentially with globular mitochondria in primary striatal neurons processes (Fig. 1 *D*, *Insets d1*, *d2*, and 3D rendered images,

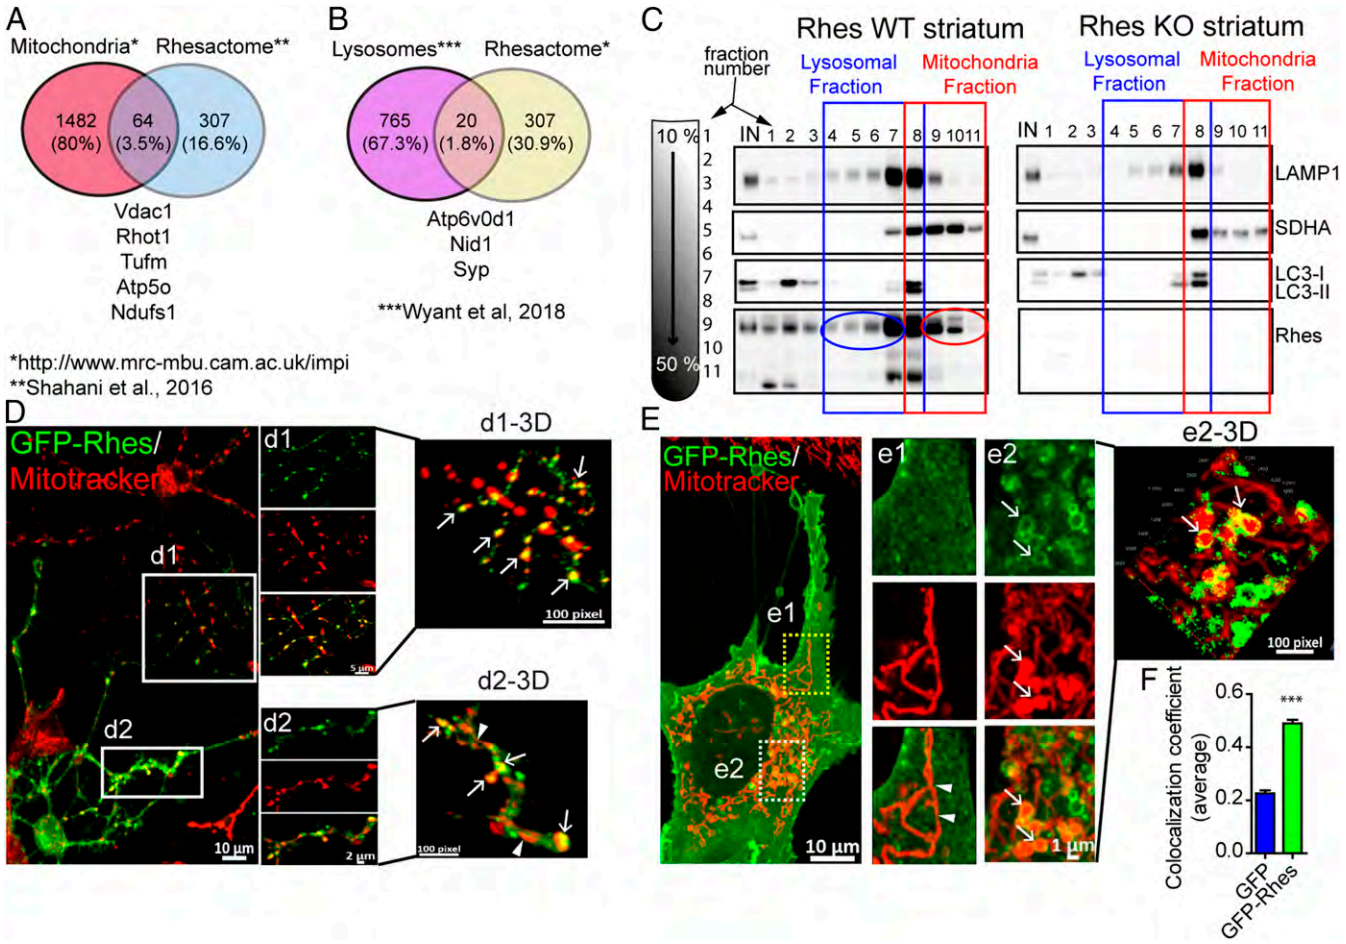

Fig. 1. Rhes associates with mitochondria and lysosome in vitro and in vivo. (*A* and *B*) Venn diagram showing mitochondrial and lysosomal proteins found in Rhes interactome in vivo, "Rhesactome," compared with available database of mitochondrial and lysosomal proteins (40, 41). d1-3D, *d2-3D*, arrows) and striatal neuronal cell line cytoplasm (Fig. 1 *E*, *Insets e1*, *e2*, and *e2-3D*) but not with the elongated mitochondria (Fig. 1 *D* and *E*, arrowheads); 2) Rhes formed a circular structure around the globular mitochondria (Fig. 1 *E*, *e2-3D*, arrow), and strongly colocalizes with it (Fig. 1*F*); 3) Rhes colocalizes with lysosomes in primary striatal neuronal processes (*SI Appendix*, Fig. S1 *B*, *Insets b1* and *b1-3D*, arrow) as well as striatal neuronal cell lines (*SI Appendix*, Fig. S1 *C*, *Inset c1-3D*, arrow and Fig. S1*D*); and 4) triple staining reveals Rhes localizes with both mitochondria and lysosomes in striatal neuronal cell (*SI Appendix*, Fig. S1 *E*, *Insets e1* and *e1-3D*). GFP alone did not show colocalization with mitotracker or lysosome in striatal neuronal cells or primary neurons (*SI Appendix*, Fig. S2). Next, we performed live-cell imaging of striatal neuronal cells transfected with GFP-Rhes (green) and costained with mitotracker (red) and lysotracker (blue) (Movie S1 with *Insets*). We found that GFP-Rhes was enriched with globular mitochondria, which becomes positive for lysosome in a time-dependent fashion (Movie S1, arrows). Intriguingly, enhanced GFP-Rhes signal intensity was associated with loss of mitotracker intensity, suggestive of mitochondrial degradation (Movie S1, arrow in GFP-Rhes). Collectively, these data indicated that Rhes associates with mitochondrial as well as lysosomal components in the intact striatum, primary neurons, and the striatal neuronal cell line, where we found stronger association with globular mitochondria.

Rhes Affects Basal Mitophagy but Not Mitochondrial Functions. Lysosomal localization of Rhes-positive globular mitochondria (Movie S1 and *SI Appendix*, Fig. S1*E*) leads us to investigate the role of Rhes in mitochondrial degradation or mitophagy. Using cycloheximide (CHX) chase experiments, we tested whether Rhes affects basal mitophagy. As expected, CHX treatment resulted in the degradation of SDHA (inner mitochondrial protein), VDAC1 (outer mitochondrial protein), and cytochrome C (intermembrane mitochondrial protein), whose levels were further diminished by GFP-Rhes compared to GFP-alone overexpression (Fig. 2*A*). Note that levels of mTOR or Bip were not altered by CHX between the groups in these cells, and down-regulation of LC3-II was similar between GFP-expressing and GFP-Rhes–expressing cells (Fig. 2*B*). To further confirm the role of Rhes in regulation of basal mitophagy, we assessed the mitochondrial mass by CHX chase experiment in striatal neuronal cells infected with validated adenovirus empty (Ad-null) or adenovirus-Rhes (Ad-Rhes) (32), using mitotracker green, a molecular probe that binds to mitochondria regardless of its membrane potential (44). We found that Rhes-positive cells stained with mitotracker green showed less fluorescent intensity in CHX treatment compared to control, indicating rapid mitochondrial degradation, suggesting Rhes regulates basal mitophagy (*SI Appendix*, Fig. S3 *A* and *B*). Next, we wondered, whether Rhes can affect overall mitochondrial functions. To test this, we used seahorse assay, which measures the mitochondrial respiratory functions. We infected striatal neuronal cell lines with Ad-null or Ad-Rhes. As shown in *SI Appendix*, Fig. S3 *C* and *D*, Rhes expression did not affect the mitochondrial functions basally or in the absence or the presence of oligomycin (an inhibitor of ATP [adenosine triphosphate] synthase), Carbonyl cyanide-4-(trifluoromethoxy)phenylhydrazone (FCCP, uncouples oxidative phosphorylation), or rotenone (complex I inhibitor). Similarly, Rhes expression did not affect FCCP-induced mitophagy (*SI Appendix*, Fig. S3 *E* and *F*). Thus, Rhes enhances basal mitophagy in CHX conditions, but may not affect the overall mitochondrial functions basally or in the presence of certain pharmacological modulators of mitochondria.

Rhes Diminishes Mitochondrial Functions and Up-Regulates Mitophagy in the Presence of 3-NP. To further assess the role of Rhes in mitochondrial functions, we investigated the effect of Rhes in the presence of 3-NP in seahorse assay. The rationale for testing 3-NP is 2-fold: 1) 3-NP is known to promote lesion selectively in the striatum, and 2) previously, we found that Rhes KO mice are totally prevented from 3-NP–induced striatal lesion compared to WT control (39). In sea horse assay, as in *SI Appendix*, Fig. S3*C*, Rhes alone did not affect mitochondrial function in vehicle conditions. But, in the presence of 3-NP, which diminished both the basal and maximal mitochondrial respiration, Rhes further potentiated

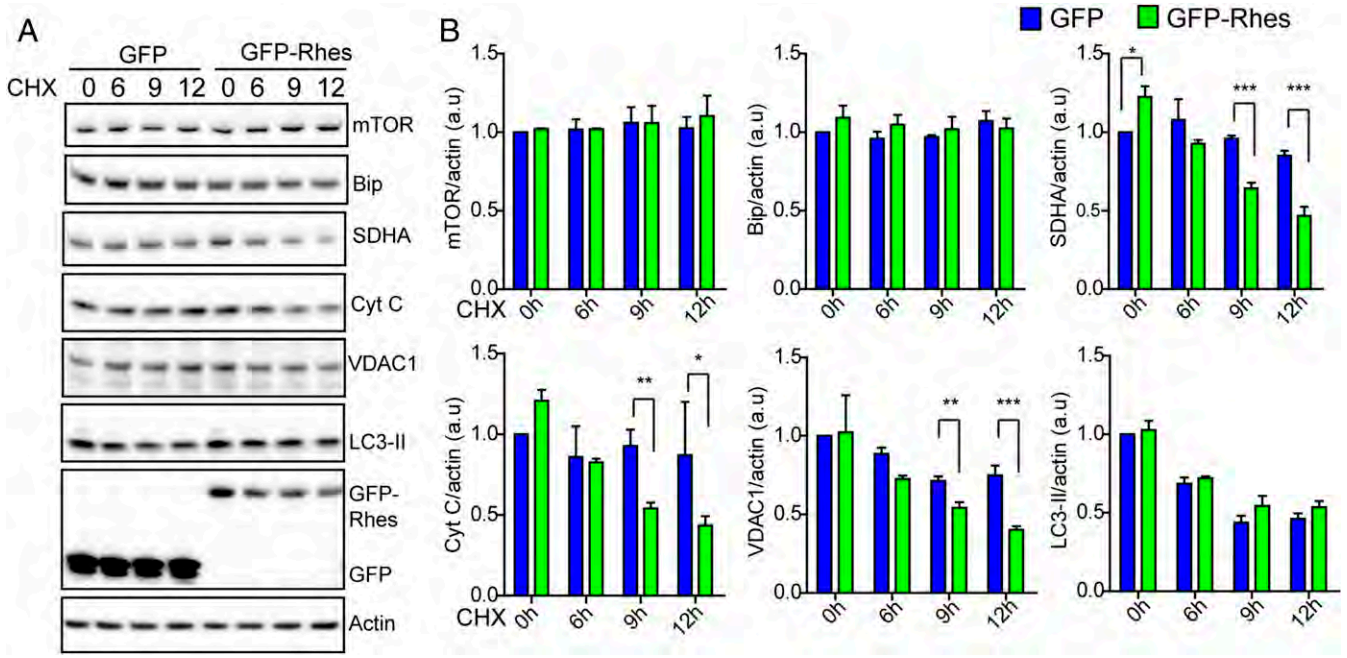

Fig. 2. Rhes regulates basal mitophagy. (*A*) Western blots from GFP-transfected or GFP-Rhes–transfected striatal neuronal cells treated with vehicle or cycloheximide (CHX, 100 μM) at indicated time point. Blots were probed with indicated antibodies. (*B*) Bar graph shows quantification of band intensities of indicated proteins in *A*. Protein levels were normalized to actin ($n = 3$, Student's t test; $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$; data are mean ± SEM).

the effect (*SI Appendix*, Fig. S4). This indicated that Rhes selectively worsens the 3-NP–induced mitochondrial dysfunctions, but not oligomycin, FCCP, or rotenone.

To investigate the mechanisms, we assessed the effect of Rhes on mitophagy in striatal neuronal cell line or primary striatal neurons using biochemical and confocal imaging approaches. We used cycloheximide chase experiment to assess the mitophagy, and Rhes markedly enhances mitophagy. As shown in Fig. 3 *A* and *B*, in GFP alone, there was a gradual loss of SDHA, in both vehicle and 3-NP conditions at 6, 9, and 12 h after CHX treatment. In the presence of GFP-Rhes, mTOR and Bip protein levels are not affected, but loss of SDHA is more rapid in vehicle and almost all (>90%) of SDHA was eliminated in 3-NP, which is also accompanied by enhanced LC3-II production (Fig. 3 *A* and *B*). Next, we transiently expressed GFP, GFP-Rhes WT, and GFP-Rhes C263S (mutant defective in membrane binding) in striatal neuronal cells by staining them with mitotracker and exposing them to vehicle or 3-NP (*SI Appendix*, Fig. S5). As expected, in vehicle-treated neuronal cells, we found that GFP-Rhes WT interacted with mitochondria (*SI Appendix*, Fig. S5, *Inset a4-2.5D*, arrow) and that mitotracker staining was observed throughout the GFP-Rhes WT–transfected (yellow arrowhead) and untransfected (blue arrowhead) neuronal cells (*SI Appendix*, Fig. S5, *Inset a3*). Contrary to this observation, in 3-NP–treated neuronal cells, the dispersed mitotracker staining was completely disrupted in the GFP-Rhes–transfected cells (*SI Appendix*, Fig.S5, *Inset a9*, yellow arrowhead) but not in untransfected neuronal cells (*SI Appendix*, Fig. S5, *Inset a9*, blue arrowhead). Also, in the presence of 3-NP, numerous globular mitochondria that were positive for Rhes were observed in GFP-Rhes–transfected cells (*SI Appendix*, Fig. S5, *Inset a10-2.5D*, arrow). Consistent with our previous work (28, 30, 45), we found that mutation of Rhes C263, which is a farnesylation consensus site, leads to its mislocalization into the nucleus (*SI Appendix*, Fig. S5, *Insets a5* and *a11*). Note that, in GFP-alone– or GFP-Rhes

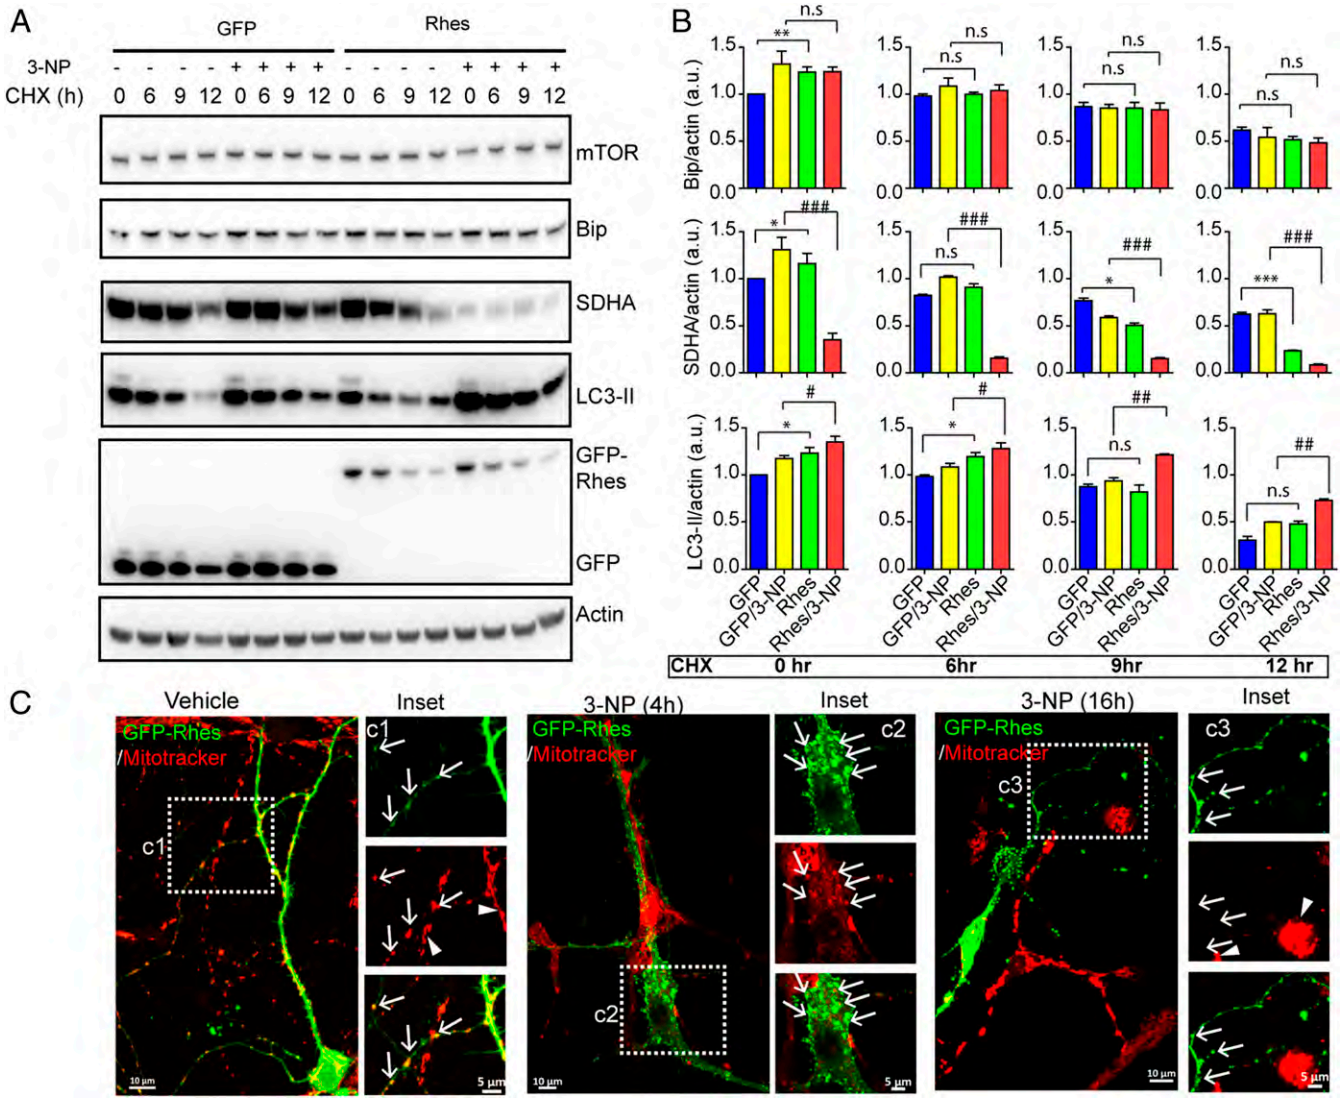

Fig. 3. Rhes promotes mitophagy in the presence of SDH inhibitor 3-NP. (*A*) Western blots of striatal neuronal cells transfected with GFP or GFP-Rhes, treated with vehicle or 3-NP (10 mM for 1 h) or with CHX (100 μM). (*B*) Bar graph shows the quantification of indicated proteins in *A* (*$P < 0.05$, **$P < 0.01$, ***$P < 0.001$, between GFP/vehicle and GFP-Rhes/Vehicle; $^{\#}P < 0.05$, $^{\#\#}P < 0.01$, $^{\#\#\#}P < 0.001$ between GFP/3-NP and GFP-Rhes/3-NP; 1-way ANOVA test followed by Tukey post hoc test; $n = 3$; data are mean ± SEM; n.s, not significant). (*C*) Representative confocal image and corresponding *Insets* of GFP-Rhes–transfected primary striatal neuron treated with vehicle or 3-NP (10 mM) at indicated time points. Cells were stained with mitotracker orange (red). Arrow indicates GFP-Rhes–positive neuronal processes colocalized with mitochondria in vehicle, and 4-h 3-NP–treated neuron but not in 16-h 3-NP–treated neuron. Arrowheads indicate that the mitotracker intensity is not affected in untransfected neighboring cell in the same field in either vehicle or 3-NP treatment.

Downloaded at instituto de Biotecnologia/UNAM on October 20, 2020

C263S-transfected cells, the mitotracker signal appears undisrupted, and no obvious association of GFP or GFP-Rhes C263S with mitochondria was observed in either vehicle (*SI Appendix*, Fig. S5, *Insets a2-2.5D* and *a6-2.5D*, arrowhead) or 3-NP–treated cells (*SI Appendix*, Fig. S5, *Insets a8-2.5D* and *a12-2.5D*, arrowhead). We further analyzed the mitotracker intensity by flow cytometry in striatal neuronal cells, infected with either Ad-null or Ad-Rhes, treated with vehicle or 3-NP. We found that mitotracker intensity was reduced by 30% in Ad-Rhes–infected cells compared to Ad-null infection after 3-NP treatment (*SI Appendix*, Fig. S6), indicating Rhes robustly diminishes mitochondrial intensity upon 3-NP treatment. Analogous to striatal cell lines, in primary striatal neurons, we also found that GFP-Rhes interacted with mitochondria (Fig. 3 *C*, *Inset c1*, arrow) and that mitotracker staining was observed throughout the GFP-Rhes WT-transfected and untransfected primary neuronal processes (Fig. 3 *C*, *Inset c1*, arrowhead). However, in 3-NP–treated primary neurons at 4 h, the mitotracker staining was reduced and globular mitochondria were surrounded by GFP-Rhes (Fig. 3 *C*, *Inset c2*, arrows). At a later time point of 3-NP treatment (16 h), mitotracker staining was almost completely abolished in the GFP-Rhes–transfected cells (Fig. 3 *C*, *Inset c3*, arrow) but not in untransfected neuronal cells (Fig. 3 *C*, *Inset c3*, arrowhead), indicating that Rhes diminishes mitochondrial functions in a time-dependent manner in the presence of 3-NP. Note that GFP-alone (control)–transfected primary neuron does not show reduction in mitotracker staining after 3-NP treatment (*SI Appendix*, Fig. S7). Together, these data indicate that Rhes exacerbates mitochondrial dysfunction and promotes mitophagy in the presence of SDHA inhibitor 3-NP.

Rhes Promotes Mitophagy Flux in the Presence of 3-NP. Next, we biochemically estimated whether Rhes alters the mitophagy flux in striatal neuronal cell lines in gradient fractionation (*SI Appendix*, Fig. S8*A*) and in total lysate (*SI Appendix*, Fig. S8 *B–E*). In Ad-null condition (control), as expected, we found an accumulation of SDHA in the mitochondrial fraction in the vehicle-treated groups (*SI Appendix*, Fig. S8*A*). Addition of 3-NP resulted in a robust accumulation of SDHA in the lysosomal fractions (compare green circles). Blocking autophagy with chloroquine (CQ), however, resulted in a diminished accumulation of SDHA and enhanced LC3-II levels in control, indicating that 3-NP might induce new mitochondrial production, in control condition. In Ad-Rhes, however, higher levels of SDHA were found in vehicle-treated conditions. Treatment of 3-NP in Ad-Rhes condition resulted in a reduction of SDHA levels in the lysosomal fractions (compare red circles). Cotreatment with CQ showed increased SDHA levels in lysosomal fraction, which is also accompanied by a rapid up-regulation of LC3 conversion (*SI Appendix*, Fig. S8*A*).

Apart from mitophagy, we also checked mitobiogenesis by investigating expression level of genes such as *Nrf1, Nrf2, Pgc1α*, and *Tfam* involved in the mitochondrial biogenesis in GFP-containing and GFP-Rhes–containing cells treated with 3-NP alone or in combination with CQ. We found that 3-NP treatment up-regulated the expression of mitobiogenesis regulatory genes, but the combination of 3-NP and CQ diminished their expression in both control and Rhes-containing cells (*SI Appendix*, Fig. S9). This indicates that the lysosomal activity is necessary for biogenesis in 3-NP–treated cells. Mitochondrial degradation and biosynthesis are tightly regulated processes (46). Thus, the reduced SDHA levels in 3-NP + Rhes are presumably due to higher degradation of mitochondria compared to biogenesis. This notion is consistent with enhanced abundance of SDHA in GFP-Rhes + 3-NP + CQ, compared to GFP + 3-NP + CQ (*SI Appendix*, Fig. S8*A*). Together, biochemical fractionation data suggest that Rhes up-regulates mitophagy flux in 3-NP condition.

In total lysate, in both vehicle-treated GFP-expressing and GFP-Rhes–expressing cells, we found there was no major difference in SDHA levels (*SI Appendix*, Fig. S8 *B* and *C*). Upon 3-NP treatment, however, there were increased SDHA levels in GFP-expressing cells, but, in GFP-Rhes–expressing cells, the SDHA levels were diminished, which is also accompanied by a rapid up-regulation of autophagy, as measured by increased LC3 conversion (*SI Appendix*, Fig. S8 *B* and *C*). Addition of CQ has further increased the SDHA and LC3-II levels in 3-NP condition (*SI Appendix*, Fig. S8 *D* and *E*). Together, these data indicate that Rhes increases autophagosome and lysosome accumulation around mitochondria and mediates mitophagy flux in the presence of 3-NP. Similarly, in immunocytochemistry, SDHA staining is also diminished in GFP-Rhes–transfected striatal neuronal cells, treated with 3-NP compared to vehicle treatment (*SI Appendix*, Fig. S10). Next, we investigated whether Rhes recruits lysosomes to globular mitochondria using lysotracker and GFP-LC3, by confocal microscopy. As predicted, we observed colocalization of lysotracker with GFP-Rhes–positive globular mitochondria (stained with mitotracker) in vehicle-treated cells, and this colocalization was further enhanced in the presence of 3-NP (*SI Appendix*, Fig. S11 *A* and *B*, arrow). The 3-NP–treated, GFP-alone–transfected cells also showed increase in colocalization between mitochondria and lysosomes, but only GFP-Rhes–positive cells show disrupted mitotracker staining (*SI Appendix*, Fig. S11, arrow). Similarly, there was an enhanced number of GFP-LC3 puncta (*SI Appendix*, Fig. S12 *A* and *B*, arrow) and increased colocalization between GFP-LC3 and mCherry TOMM20, a mitochondrial marker, in 3-NP–treated Myc-Rhes–expressing cells (*SI Appendix*, Fig. S12*C*). Thus, Rhes associates with mitochondria and lysosomes and activates mitophagy, upon 3-NP treatment.

Rhes Promotes the Formation of Mitophagosomes In Vivo. Since Rhes interacted with globular mitochondria and lysosomes (Fig. 1 and *SI Appendix*, Fig. S1) and modulates basal mitophagy which is further up-regulated in 3-NP (Figs. 2 and 3), we posited that Rhes may activate mitophagy in vivo. To test this thoroughly in vivo, we carried out behavioral, pathological, and ultrastructural analysis (using transmission electron microscopy) of the striatum in WT and Rhes KO mice after systemic injection of 3-NP (see experimental scheme, Fig. 4*A*). Consistent with our earlier report (39), 3-NP administration to WT mice promoted motor abnormalities that were diminished in Rhes KO mice (Fig. 4 *B–E*). The 3-NP also induced striatal-specific lesion in WT striatum, which was completely prevented in the Rhes KO striatum (Fig. 4*F*, arrowhead) (39). Microscopic analysis of the 3-NP–induced striatal-specific lesions found pyknotic nuclei and a diminished neuronal staining in WT mice, while KO striatum displayed healthy nuclei and normal neural staining (Fig. 4*F*, *Insets f1* and *f2*, compare WT and KO) (39). Thus, 3-NP promotes lesions selectively in the striatum of the WT mice but not in the Rhes KO striatum, a highly reproducible phenotype (39). To address why Rhes KO are resistant to 3-NP–induced lesion, we hypothesized that ultrastructural analysis might provide a clue. We carried out time-lapse ultrastructural analysis using serial corticostriatal section electron microscopy of the second and third days after systemic administration of 3-NP. On the second day (d2), we found no gross changes in the overall cell morphology or mitochondria ultrastructure between WT and KO, which were similar to control (Fig. 4 *G*, *Insets*). On the third day (d3), in WT, we found neuronal shrinkage and abnormal, swollen mitochondria with broken inner membrane and matrix in the striatum (Fig. 4 *G*, *Insets*, arrowhead). And, those abnormal striatal neuronal changes were completely absent in the Rhes KO (Fig. 4*G*). Mitochondrial circularity index (length/breadth) and area analysis showed that the frequency of circular mitochondria is high in Rhes WT compared to Rhes KO neuron after 3-NP treatment (Fig. 4*H*). Cortex from either genotype showed no lesion (*SI Appendix*, Fig. S13, arrowhead) or mitochondrial abnormalities (*SI Appendix*, Fig. S13,

Insets a1 and *b1*), indicating that 3-NP–induced lesion (arrow) and mitochondrial abnormalities (*SI Appendix*, Fig. S13, *Inset b2*) are selective to the striatum, and require Rhes. Further examination of ultrastructure revealed numerous mitophagosomes, where the mitochondria with cristae debris were engulfed within the double-layer membranes resembling autophagosomes (Fig. 4*I*, and arty rendering), and there was a diminished frequency of the number of healthy looking mitochondria, but enhanced swollen mitochondria and mitophagosomes in Rhes WT striatum, compared to Rhes KO (Fig. 4*J*). Thus, Rhes deletion prevents the formation of neuronal shrinkage, mitochondrial swelling, and induction of mitophagosomes by 3-NP treatment. All together, these data indicated that Rhes physiologically regulates 3-NP–induced mitochondrial dysfunction and promotes the formation of globular mitochondria and mitophagosomes, which coincides with worsening motor phenotype in vivo.

Rhes Diminishes Mitochondrial Potential ($\Delta\Psi_m$) and Promotes Cell Death in the Presence of 3-NP. To understand the mechanisms, and because Rhes can interact with VDAC1 (Fig. 1*A*), which is a component of membrane permeability pore, we rationalized that Rhes may affect mitochondrial potential ($\Delta\Psi_m$). To investigate this, we tested whether Rhes alters $\Delta\Psi_m$ using tetramethyl rhodamine (TMRM), a widely used cell-permeable fluorescent dye that binds mitochondria with intact $\Delta\Psi_m$. We infected striatal neuronal cell lines with Ad-null or Ad-Rhes for ~32 h and added TMRM. We quantified TMRM signal intensity using FACS (fluorescence-activated cell sorting) in vehicle or 3-NP treatment at 15 min, 30 min, and 2 h (Fig. 5*A*). Notably, TMRM (red) signals were not altered in vehicle condition in both Ad-null– and Ad-Rhes–expressing cells. But, in the presence of 3-NP, the TMRM signal intensity is rapidly diminished only in Ad-Rhes–expressing cells but not Ad-null in a time-dependent manner, indicating a rapid loss of $\Delta\Psi_m$ by Rhes (Fig. 5*A*). This effect is specific to Rhes WT, as GFP-Rhes C263S mutant failed to alter TMRM signal, which is like GFP control (Fig. 5 *B* and *C*). Next, as Rhes is required for 3-NP induced striatal lesion in vivo (ref. 39 and Fig. 4), we investigated whether Rhes modulates striatal cell death in vitro, using propidium iodide (PI) staining, a fluorescent dye that enters cells only when they are compromised (47), and FAC sorting. As shown in Fig. 5*D*, we found that Ad-null control expressing cells did not show changes in PI+ cells in either vehicle or 3-NP condition (~5 to 7%). Similarly, Ad-Rhes–expressing cells in vehicle did not show changes in PI+ cells (~5%). However, in Ad-Rhes and 3-NP condition, there was a robust increase in PI+ cells (~25%; Fig. 5*E*). To further establish that cell death effect is specific to Rhes WT, we FAC-sorted GFP alone, GFP-Rhes WT, and GFP-Rhes C263S cells and added vehicle or 3-NP (see scheme in *SI Appendix*, Fig. S14*A*). As shown in *SI Appendix*, Fig. S14 *B* and *C*, Rhes WT showed ~27% cell death as measured by PI staining in the presence of 3-NP, whereas GFP or GFP-Rhes C263S showed ~5 to 10% cell death. Collectively, these

data indicate Rhes diminishes $\Delta\Psi_m$ and promotes cell death in the presence of 3-NP.

Rhes Promotes Mitophagy, Disrupts $\Delta\Psi_m$, and Promotes Cell Death via Nix. To investigate the mechanisms by which Rhes may activate mitophagy, we considered whether Rhes interacts with well-known mitophagy modulators, such as Parkin, PINK1, DRP1 (Dynamin related protein 1), or Nix (48). In an affinity purification experiment, GST-Rhes did not interact with Parkin but readily interacted with mTOR (Fig. 6*A*), as shown in our previous report (28). We did not observe interaction of Rhes with either DRP1 or Pink1 (*SI Appendix*, Fig. S15 *A* and *B*). However, GST-Rhes readily interacted with Nix, a known mitophagy receptor (49) (Fig. 6 *B* and *C*). Rhes interaction with overexpressed Nix (Fig. 6*B*) or endogenous Nix (Fig. 6*C*), increases with 3-NP treatment; however, Rhes interaction with mTOR remains unaltered (Fig. 6*C*). GST-Rhes is also affinity-purified with LC3 without or with 3-NP and showed a consistent and enhanced interaction with Nix in the presence of 3-NP (Fig. 6*D*). Next, we found that the C-terminal SUMO E3 ligase domain (171 to 266 aa), but not the N-terminal GTPase (1 to 181 aa), or the fragment (147 to 216 aa) interacted strongly with Nix (Fig. 6*E*). Additionally, we found that membrane-binding defective mutant Rhes C263S, but not GTP-binding mutant (Rhes S33N), fails to interact with Nix (*SI Appendix*, Fig. S15*C*). Interaction of Rhes with mTOR, on the other hand, seems to be more toward the N-terminal side of Rhes (Fig. 6*E*). Thus, Rhes associates strongly with Nix in the presence of 3-NP, and the binding requires intact membrane binding domain.

Because Rhes interacted strongly with Nix, we hypothesized that Rhes may promote mitophagy via Nix. To test this hypothesis, we depleted endogenous Nix in the striatal cells using CRISPR/Cas9 tools. While GFP-Rhes promoted a significant loss of SDHA and increased LC3-II productions in CRISPR/Cas9 control cells, it completely failed to do so in CRISPR/Cas9 Nix-depleted cells (Fig. 6 *F* and *G*), which resulted in ~90% depletion of Nix (*SI Appendix*, Fig. S19*A*). This finding indicated that Nix is essential for Rhes-induced mitophagy. Furthermore, when we reconstituted Nix in Nix-depleted cells, Rhes was able to restore mitophagy and increase LC-3 conversion (*SI Appendix*, Fig. S16 *A* and *B*), suggesting that Nix is critical for Rhes-mediated mitophagy. Consistent with this, in confocal data, we found that, in CRISPR/Cas9 control cells, upon 3-NP treatment, Rhes promoted rapid loss of mitotracker intensity, and formation of numerous globular mitochondria colocalized with GFP-Rhes (Fig. 6*H*, arrow). However, in Nix-depleted GFP-Rhes expressing cells, most of the mitotracker

(*I*) Bar graph shows the average of Pearson's coefficient of colocalization between GFP-Rhes and mitochondria in indicated groups ($n = 33$ to 37 cells per group; $^{**}P < 0.01$, $^{***}P < 0.001$ vs. Rhes/vehicle control CRISPR; $^{\#\#\#}P < 0.001$, $^{\$\$}P < 0.01$ between indicated groups; data are mean ± SEM; 1-way ANOVA followed by Tukey post hoc test).

Downloaded at Instituto de Biotecnología/UNAM on October 20, 2020

signal intensity remained unaltered by 3-NP treatment and colocalization between GFP-Rhes and mitotracker was significantly reduced (Fig. 6 *H*, arrows and *I*). In vehicle treatment, Rhes was unable to interact with globular mitochondria in Nix-depleted cells compared to control cells (*SI Appendix*, Fig. S16*C*, arrowhead). Together, these data suggest that Rhes interacts with globular mitochondria and promotes mitophagy via Nix.

Next, as Rhes decreases $\Delta\Psi_m$ in the presence of 3-NP, we wondered whether this process requires Nix. As shown in Fig. 7 *A* and *B*, while Rhes diminishes TMRM signals in control cells, this effect is not observed in Nix-depleted cells. Similarly, the observed Rhes-induced cell death in the presence of 3-NP in control cells was also markedly diminished in Nix-depleted cells (Fig. 7 *C* and *D*). Moreover, reconstitution of Nix significantly elevated Rhes-mediated cell death in 3-NP–treated cells (Fig. 7*D*). Nix is localized to endoplasmic reticulum (ER) as well as mitochondria (50). Using ER-targeted Nix, where transmembrane (TM) domain of Nix was replaced by CytoB, and mitochondria-targeted Nix, where TM domain was replaced with monoamine oxidase located in the outer mitochondrial membrane (50), we found Rhes affinity with both ER- and mitochondrial-targeted Nix (*SI Appendix*, Fig. S17 *A* and *B*). However, in a reconstitution FACS/TMRM experiment, we found that replenishing only the mitochondria-targeted Nix, but not ER-targeted Nix, restores the loss of TMRM signal by Rhes (*SI Appendix*, Fig. S17 *C* and *D*). Collectively, these data indicate that Rhes interacts with both ER- and mitochondrial-targeted Nix and disrupts $\Delta\Psi_m$ mostly via the latter.

Rhes Travels from Cell to Cell and Interacts with the Globular Mitochondria in the Neighboring Cells via Nix. We recently reported that Rhes induces the biogenesis of tunneling nanotube (TNT)-like cellular protrusion, "Rhes tunnel," through which Rhes travels from cell to cell (45). It is unknown whether intercellular signaling can regulate mitochondrial turnover. So, we considered whether Rhes can interact with damaged mitochondria in the neighboring cells. We designed an experiment in which we cocultured FACS-sorted GFP-Rhes–expressing cells (donor cells) with the acceptor cells that were exposed to 3-NP or vehicle (acceptor cells), followed by confocal imaging with mitotracker (see scheme in Fig. 8*A*). As expected, we found GFP-Rhes–positive TNT-like protrusions (closed arrow) and numerous GFP-Rhes (open arrow) in the neighboring cell in both vehicle-treated and 3-NP–treated cells (Fig. 8*B* and *SI Appendix*, Fig. S18). Interestingly, we found numerous GFP-Rhes puncta that were colocalized with globular mitochondria in cells that are exposed to 3-NP (yellow arrowhead) in control acceptor cell. But, when GFP-Rhes donor cells are cocultured with Nix-depleted acceptor cells, we do observe TNT-like protrusions (closed arrow) and numerous puncta (open arrow), but we failed to observe GFP puncta (white arrowhead) localization with globular mitochondria in the Nix-depleted acceptor cell treated

with 3-NP (Fig. 8*B*). Pearson's colocalization coefficient further confirmed a marked reduction in Rhes localization with mitochondria in Nix-depleted cells (Fig. 8*C*). This indicates that Rhes can travel from cell to cell and interact with damaged mitochondria via Nix. Thus, these data raise a possibility that Rhes can act as an intercellular mitochondrial surveillance factor.

Discussion

To date, the brain tissue-specific regulator(s) of mitophagy or its role in neuronal vulnerability remains poorly understood. By using neuronal and mouse model combined with electron and live-cell confocal microscopy, we have systematically investigated the role of Rhes in mitophagy. We found striatal-enriched protein Rhes promotes mitophagy via Nix, a known mitophagy receptor (49). Despite abundant and comparable expression of Nix in the striatum of both WT and Rhes KO mice (*SI Appendix*, Fig. S19*B*), the removal of damaged mitochondria via mitophagy requires Rhes demonstrating its "mitophagy ligand-like" capabilities in vivo. In addition, this study demonstrate the role of Rhes in intercellular surveillance of mitochondria through the cellular protrusion that we recently discovered (45) and lays a foundation for understanding the unprecedented complexity by which Rhes may signal mitophagy within and outside the striatum.

Half-lives of mitochondria in rat whole brain were estimated to be ~24 d (51). Striatum is considered to be one of the metabolically active regions of the brain (52); the exact half-life of mitochondria remains unknown. Although Rhes appears to regulate basal mitophagy, the functional relevance of this has yet to be determined. Rhes KO mice are hyperactive to dopaminergic drugs, but whether the lack of mitophagy may contribute to such hyperactive phenotype remains largely unknown. It has long been known that 3-NP elicits striatal-specific lesion (53, 54), and mechanisms such as oxidative stress and excitotoxicity were implicated (55, 56). Oxidative stress or excitotoxicity can also occur in the cortex; however, 3-NP

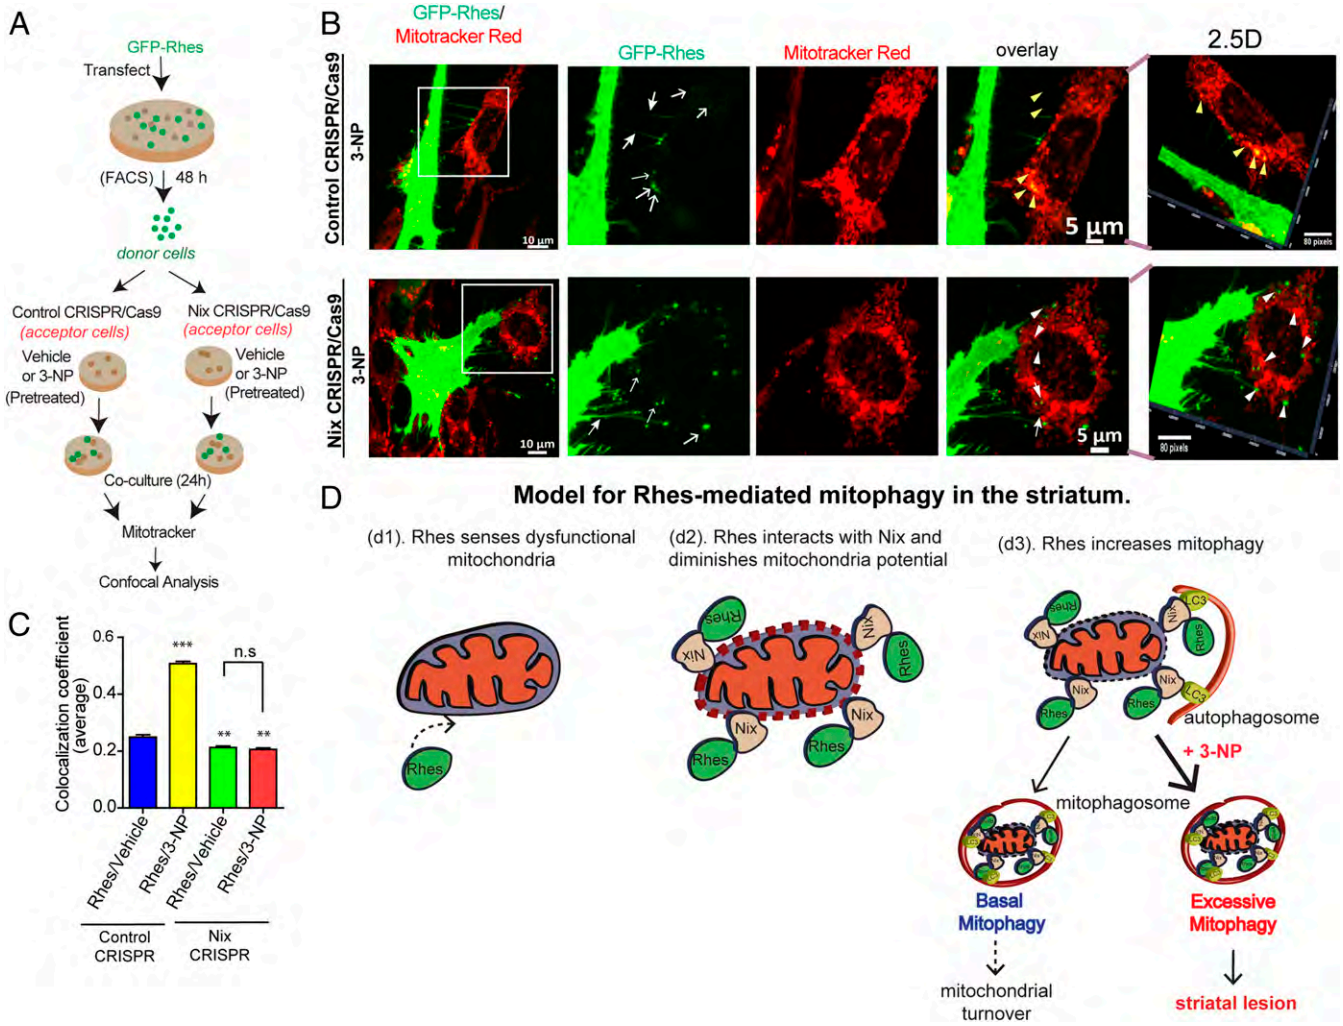

Fig. 8. Rhes travels Intercellularly and interacts with damaged mitochondria via Nix. (*A*) Experimental design for *B*. (*B*) Representative confocal image of GFP-Rhes (FAC-sorted) striatal neuronal cells (donor cells) cocultured with vehicle-treated or 3-NP–treated control or Nix-depleted (Nix CRISPR) cells (acceptor cells). *Insets* show the magnified region from selected area. Corresponding *Insets* were processed for 2.5-dimensional rendering. Closed arrow indicates Rhes-induced TNT-like protrusions. Open arrow represents GFP-Rhes puncta in acceptor cell. Yellow and white arrowheads indicate presence or lack, respectively, of colocalization of GFP-Rhes with mitotracker. (*C*) Bar graph shows average of Pearson's coefficient of colocalization between GFP puncta and mitotracker in neighboring acceptor cells where Rhes is transported from donor cell; $n = 72$ to 90 GFP-Rhes puncta per group were counted from 13 to 18 cells per group. $^{**}P < 0.01$, $^{***}P < 0.001$; 1-way ANOVA followed by Tukey post hoc test; n.s, not significant. (*D*) Model for Rhes-mediated mitophagy in the striatum. Rhes senses dysfunctional mitochondria (d1). Rhes interacts with Nix and diminishes membrane potential (d2). Rhes-Nix interaction recruits autophagosomes via LC3 and formation of mitophagosomes to promote mitochondrial degradation (d3). Basal mitophagy may lead to mitochondrial turnover; however, excessive mitophagy in the presence of mitochondrial toxin, 3-NP, may promote striatal lesion.

Downloaded at Instituto de Biotecnologia/UNAM on October 20, 2020

does not elicit lesion in the cortex (*SI Appendix*, Fig. S13). Therefore, the molecular details that contribute to 3-NP–induced striatal lesion has remained enigmatic. Now this study provides a clear molecular route for striatal lesion by 3-NP. Our data indicate that Rhes's role is to protect neurons by removing damaged mitochondria via mitophagy. However, upon exposure to mitochondrial toxin such as 3-NP, which irreversibly damages the mitochondria, the Rhes-mediated mitophagy processes are exacerbated that lead to depletion of the mitochondria and neuronal death (Fig. 8*D*). Because Rhes selectively mediates 3-NP–induced toxicity, it raises the question of whether Rhes contains special mechanisms to sense SDHA dysfunction in the brain.

Based on the data presented in this report, our current model predicts that Rhes may sense the dysfunctional mitochondria and binds to Nix to disrupt the $\Delta\Psi_m$ and initiate mitophagy. Rhes and Nix together may alter the membrane permeability pore, leading to the diminishment of $\Delta\Psi_m$. Nix alone cannot disrupt $\Delta\Psi_m$, because there was no difference in TMRM signal intensity between Nix WT and Nix KO cells with or without 3-NP (Fig. 7). Moreover, as mentioned above, Nix alone cannot elicit mitophagy in vivo because the levels of Nix between WT and Rhes KO striatum were similar (*SI Appendix*, Fig. S19*B*), and yet Rhes KO shows diminished mitophagy compared to WT (Fig. 4). Mechanistically, as loss of $\Delta\Psi_m$ is a major initial step in the mitophagy up-regulation, we hypothesize that altering the $\Delta\Psi_m$ by Rhes is the likely step to initiate mitophagy. Rhes's effect on mitophagy appears to be specific to 3-NP but not FCCP (Fig. 2 and *SI Appendix*, Fig. S3 *E* and *F*). How is this specificity accomplished? One possibility would be that Rhes, via yet unknown mechanisms, may particularly react to dysfunctional complex II of mitochondria. Analogous to this, some factors in the substantia nigra may sense MPTP- or rotenone- induced mitochondrial dysfunction related to complex I. Such tissue-specific regulator may set the stage for eliciting tissue-specific vulnerability through mitophagy. But the identity of such regulators in the substantia nigra remains unknown.

An earlier study showed that mitochondria from the axonal protrusions could be degraded in astrocytes via mitophagy, supporting the existence of intercellular mitophagy mechanisms in the brain (57). The implication that Rhes can travel from cell to cell and interacts with damaged mitochondria thus raises the intriguing possibility that Rhes may act like "mitochondrial surveillant" in the striatum. We imagine that Rhes "scans" for damaged mitochondria in the surrounding cells and travels there via TNT-like membranous tubes to eliminates them. Conceptually, such a process in brain sounds like "science fiction." Considering the complexity of brain, the surveillance ability of Rhes to monitor defective mitochondria may be needed for an effective coordination of billions of densely packed neurons in the brain. Collectively, this study reveals Rhes as a mediator of mitophagy and its impact on the regulation of striatal vulnerability. Development of therapeutic approaches that modulates mitophagy in the striatum may offer benefits for dysfunction related to the striatal region of the brain.

Materials and Methods

Cell Culture and Chemicals. Mouse normal striatal neuronal cells (ST*Hdh*$^{Q7/Q7}$) (42) were cultured in growth medium containing Dulbecco's modified Eagle's medium (Thermo Fisher Scientific) with 10% fetal bovine serum, 1% penicillin–streptomycin, as described in our previous work (30, 40, 58).

Generation of Nix KO Cell Line. Nix KO cell line was generated using Nix CRISPR/Cas9 plasmids from Santa Cruz Biotechnologies. First, we transfected the striatal neuronal cells with Nix CRISPR/Cas9 plasmid (SC-419357) or CRISPR/Cas9 control plasmid (SC-418922) in a 10-cm dish. After 48 h, we sorted the cells based on GFP fluorescence and recultured them. We passaged them 2 to 3 times and prepared lysate to confirm the Nix protein depletion by Western blotting using Nix antibody.

Mice. For in vivo experiments, we used Rhes KO mice, and we used C57BL/6J mice as a control group. Rhes KO mice were obtained from A. Usiello (25) and were backcrossed with C57BL/6J mice at least 8 generations; homozygous Rhes KO were used for all of the experiments. WT mice (C57BL/6) were obtained from Jackson Laboratory and maintained in our animal facility according to Institutional Animal Care and Use Committee at The Scripps Research Institute. The 3-NP injections were based on previous studies (14, 39). Briefly, 3-NP was dissolved in sterile phosphate-buffered saline (PBS; 0.1 M, 10 mg/mL), and pH was adjusted to pH 7.4 using sodium hydroxide. Mice received intraperitoneal injections twice a day (60 mg/kg doses), with 2 h between injections for 3 consecutive days. In this study, we used female and male mice; all of them were between 16 wk and 20 wk of age.

Inactivation of the quorum-sensing transcriptional regulators LasR or RhlR does not suppress the expression of virulence factors and the virulence of *Pseudomonas aeruginosa* PAO1

Martín P. Soto-Aceves,[1] Miguel Cocotl-Yañez,[2] Enrique Merino,[3] Israel Castillo-Juárez,[4] Humberto Cortés-López,[4] Bertha González-Pedrajo,[5] Miguel Díaz-Guerrero,[5] Luis Servín-González[1] and Gloria Soberón-Chávez[1,*]

Abstract

Pseudomonas aeruginosa is an environmental bacterium but is also an opportunistic pathogen. The aim of this work is to evaluate the contribution of *P. aeruginosa* LasR and RhlR transcriptional regulators of the quorum-sensing response (QSR) to the production of virulence factors, and to its virulence in a mouse abscess model. The QSR is a complex regulatory network that modulates the expression of several virulence factors, including elastase, pyocyanin and rhamnolipids. LasR, when complexed with the auto-inducer 3-oxo-dodecanoyl lactone (3O-C12-HSL), produced by LasI, is at the top of the QSR regulatory cascade since it activates transcription of some genes encoding virulence factors (such as the gene coding for elastase, *lasB*) and also transcription of both *rhlR* and *rhlI,* encoding the synthase of the auto-inducer butanoyl-homoserine lactone (C4-HSL). In turn RhlR, coupled with C4-HSL, activates the transcription of genes encoding for the enzymes involved in pyocyanin and rhamnolipid production. Several efforts have been made to obtain inhibitors of LasR activity that would suppress the QSR. However, these attempts have used chemical compounds that might not be specific for LasR inactivation. In this work we show that individual inactivation of either *lasR* or *rhlR* did not block the QSR, nor did it impair *P. aeruginosa* virulence, and that even a *lasR rhlR* double mutant still presented residual virulence, even lacking the production of virulence factors. These results show that the inhibition of either *lasR* or *rhlR* is not a straightforward approach to blocking *P. aeruginosa* virulence, due to the great complexity of the QSR.

INTRODUCTION

Pseudomonas aeruginosa is an environmental bacterium, but is also an important opportunistic pathogen that represents a health problem due to its high incidence of infection among hospitalized patients, its high intrinsic antibiotic resistance and the susceptibility of cystic fibrosis patients to severe lung infections caused by this bacterium [1, 2]. The pathogenesis of *P. aeruginosa* is dependent on the fine-tuned, coordinated expression and secretion of multiple factors, most of which are regulated at the transcriptional level by the quorum-sensing response (QSR) [3, 4].

The QSR is mediated by the bacterial production of auto-inducers (AIs), which are mainly acyl-homoserine lactones acting as signal molecules by interaction with transcriptional regulators. The *P. aeruginosa* QSR is dependent on two transcriptional regulators of the LuxR family, LasR and RhlR, which are arranged in a hierarchical regulatory cascade: LasR forms a complex with 3-oxo-dodecanoyl-homoserine lactone (3O-C12-HSL) produced by the LasI enzyme, and activates the transcription of several genes encoding virulence factors, such as *lasB*, that codes for elastase, and also of *rhlR*, *lasI* and *rhlI*. In turn, *rhlR* encodes the second quorum-sensing transcriptional regulator, while the product of *rhlI* is the enzyme that produces butanoyl-homoserine lactone (C4-HSL), which is among the AIs that interact with RhlR [5, 6]. RhlR, coupled with AIs, promotes the expression of genes responsible for the production of several

virulence factors, including rhamnolipids (RL) and pyocyanin (PYO). In addition, the *P. aeruginosa* QSR also involves the regulon that is dependent on the auto-inducer 2-heptyl-3,4-dihydroxyquinoline (PQS) and its precursor 4-hydroxy-2-heptylquinoline (HHQ), which interact with the transcriptional regulator PqsR that is a member of the LysR-family [3, 4]. LasR/3O-C12-HSL activates the transcription of *pqsR* [3, 4]. The virulence traits that are dependent on PqsR/PQS regulation are mainly produced by the enhancement of RhlR-dependent QSR, giving rise to a complex network of positive and negative interactions that exist between the LasR- and RhlR-dependent regulons [3, 4]. PqsE, which forms part of the PqsR/PQS regulon, produces a hitherto unidentified AI that interacts with RhlR and permits transcription activation of certain genes [6].

The current model of *P. aeruginosa* QSR was established almost exclusively by studying the type strains PAO1 (the strain used in this work) and PA14. However, it has been shown that there is a high phenotypic variability in the expression of the QSR among environmental and clinical *P. aeruginosa* isolates [7, 8], and that there is a high incidence of virulent isolates that have mutations in genes involved in the QSR, especially strains lacking a functional *las* system that are still able to produce virulence factors, which suggests a somewhat loosely based hierarchy [9–12].

The central role of the *P. aeruginosa* QSR in the establishment of pathogenic interactions by this bacterium has driven numerous research efforts to isolate compounds that might inhibit this complex genetic network. Most of the research has focused on blocking LasR transcriptional activity [13–16], because this protein has been hierarchically located in the highest part of the *P. aeruginosa* QSR [3, 4]. However, other targets, such as the transcriptional regulator RhlR [17], elastase activity [18], acyl-homoserine lactone synthesis [19] and the activity of the transcriptional regulator PqsR [20], have also been explored. Nevertheless, the specificity of the use of chemical compounds to block the activity of QSR proteins is questionable. That is why we decided to use mutants in the genes *lasR* and *rhlR*, or both genes and an antisense RNA, to specifically block *lasR* translation.

In the development of a strategy to block *P. aeruginosa* virulence through inhibition of the QSR, it is important to consider not only the variability of this genetic network among isolates, as mentioned previously, but also the undesired effects that might be encountered, such as promoting the selection of derivatives with increased virulence, as previously reported [12, 21]. In addition, it has been queried whether it is feasible to reduce *P. aeruginosa* virulence by interfering with the QSR, since there are many mechanisms that could cause resistance to this inhibition [22] or interfere with other regulons such as that encoding the type III secretion systems (T3SS), relevant for the virulence of this pathogen [23]. The importance of this secretion system can be seen with regard to the fact that the PA14 type strain has been shown to present increased virulence due to deregulated expression of T3SS caused by a mutation in the gene *ladS* [24].

The aim of this work is to evaluate the effect of specifically eliminating the expression of either *lasR, rhlR* or both genes (using deletion mutants) in the production of elastase, PYO, RL and virulence, using a murine cutaneous abscess model [25]. Our results show that elimination of eithet *lasR* or *rhlR* had a partial effect on the production of virulence-associated traits, while the double mutant completely lacked the expression of these factors but was still able to produce lesions in the murine model, albeit at a reduced level. We also evaluated an antisense RNA to interfere with the translation of *lasR*, but achieved only a low level of inhibition that did not affect the production of virulence factors.

We measured the secretion of effectors via T3SS in the Δ*lasR*–Δ*rhlR* double mutant compared to the PAO1 wild-type strain, and found that the ExoS and ExoT effectors in this double mutant are expressed and secreted at the same level as in the PAO1 wild-type strain. We thus conclude that the ability of this mutant to infect mice is due, at least in part, to the secretion of toxins by this secretion system. These results are compatible with the idea that virulence is multifactorial, and thus the contribution of single virulence factor, or even the QSR, to the establishment of an infection is variable [26].

METHODS

A more detailed description of the methods used in this work is included in the supplementary information section.

Microbiological methods

The strains and plasmids used in this work are shown in Table S1 (available in the online version of this article). In all experiments performed we used strain MPAO1, provided by the University of Washington (Table S1), referred to as PAO1. In order to rule out potential effects on virulence of an undetected mutation in *vfr*, we checked that the particular strain PAO1 that was used to select the described deletion mutants used in this work had no mutations in this gene (data not shown). The strains were routinely cultured in LB broth. To analyse phenotypic traits, cultures were inoculated at an optical density at 600 nm of 0.05 and were incubated for 16 (except for quinolones that were determined at 9 h), with continuous shaking (225 r.p.m.) at 37 °C.

Determination of the production of virulence factors and quinolones PQS and HHQ

PYO was extracted and its concentration was measured as reported previously [27]. Elastase activity was determined using the Elastin Congo Red protocol [28], with certain modifications. RL thin-layer chromatography was performed as reported previously [29]. Western blot for LasR detection was performed as reported previously [7]. Biofilm formation was measured in 96-well microtitre plates as previously described [30].

INFORME DE LABORES 2019

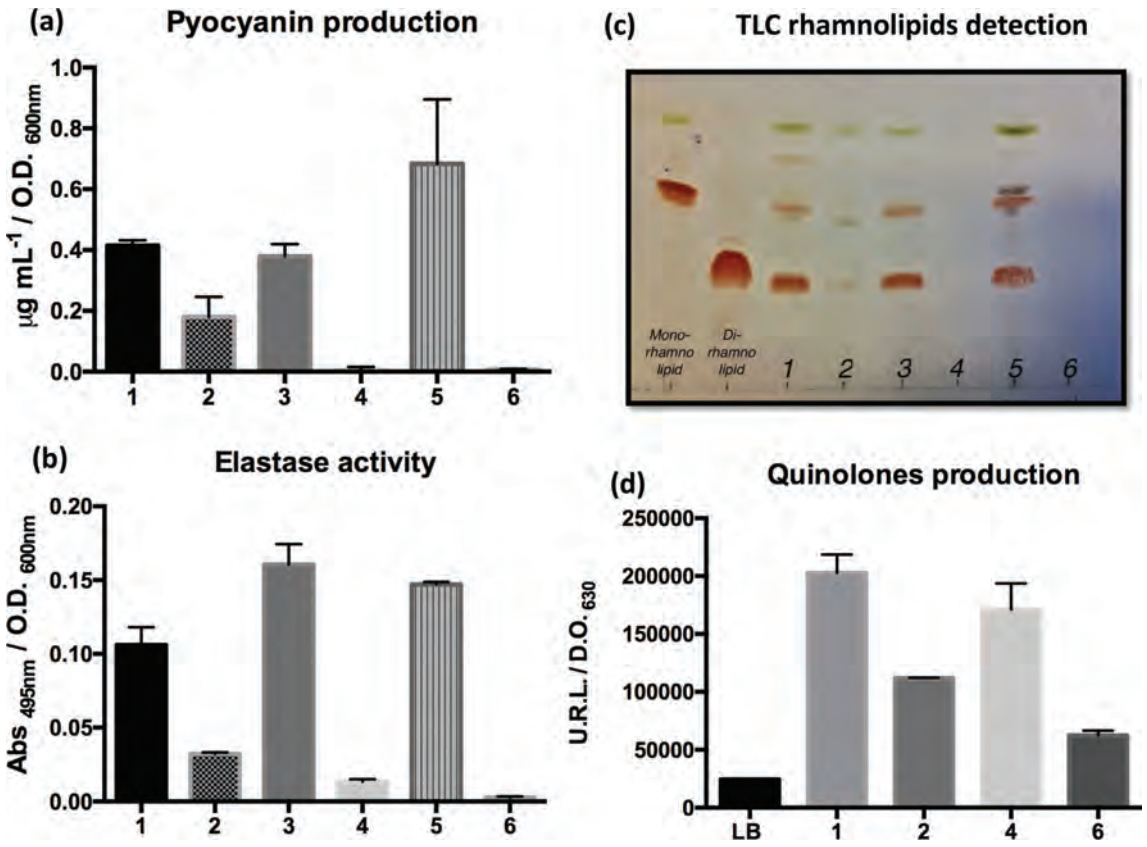

Fig. 1. Virulence factors and quinolone AIs production in *P. aeruginosa* PAO1 derivatives. Production of PYO (a), elastase (b), RL (detected on TLC plates) (c) and quinolones PQS and HHQ (d) in the PAO1 strain and its derived mutants in LB broth. Strains: 1) PAO1, 2) Δ*lasR*, 3) Δ*lasR*+pMT1(*lasR*), 4) Δ*rhlR*, 5) Δ*rhlR*+pGMYC(*rhlR*), 6) Δ*lasR*–Δ*rhlR*. The empty complementation vector (pUCP20) was also tested, showing no effect on any strain (data not shown). Results shown are the means of three biological replicates, and error bars denote standard deviation.

Bioluminescence to measure PQS and HHQ concentration was determined as previously reported [31].

DNA manipulation and construction of mutants

Oligonucleotides used in this work are listed in Table S2. DNA was purified and manipulated using standard techniques [32]. All plasmids were routinely maintained in *Escherichia coli* DH5α and were introduced by electroporation into *P. aeruginosa* as described previously [33]. The Δ*lasR* mutant was generated by construction and insertion of the pXLRt plasmid into the PAO1 strain following the protocol reported by Choi *et al.* [34]. The Δ*lasR*–Δ*rhlR* double mutant was also obtained with the same plasmid and technique but using the Δ*rhlR* mutant as recipient strain.

His-tagged ExoS protein purification and antibody production

The *exoS* gene was PCR amplified from PAO1 genomic DNA using primers exoS forward and exoS reverse, and cloned into the pET19b vector to generate plasmid pNEexoS. Animals used to produce antibodies were handled and cared for in accordance with the official Mexican guidelines, and with the approval of the local Animal Use and Care Committee (CICUAL) of the Instituto de Fisiología Celular, UNAM for protocol BGP70-15.

Type III protein secretion assay

The type III protein secretion assay was performed as reported previously [35]. Proteins were separated by 15 % SDS-PAGE, transferred onto a nitrocellulose membrane and probed for the presence of ExoS and ExoT by immunoblotting. ExoS antibodies recognize epitopes present on the ExoT protein.

Construction of the plasmid coding for the *lasR* antisense RNA, *lasR* translational fusion and *lasB* transcriptional fusion

Plasmid pLRL was constructed by cloning the annealed complementary primers 7582 and 7583 into the *Eco*RI and *Xho*I sites of pME6032 [36]. This sequence contains a region complementary to the *lasR* Shine Dalgarno (SD) sequence, since it has been reported that in most cases the strength of gene silencing coincides with RNAs having

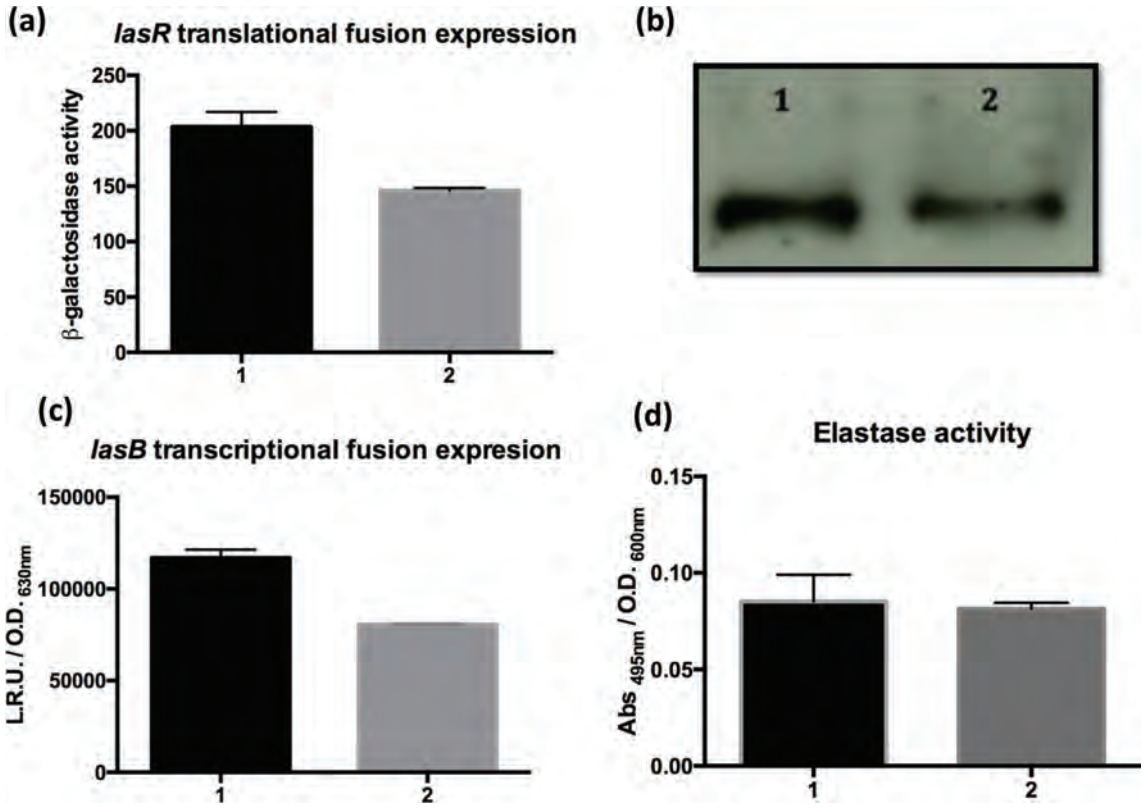

Fig. 2. Effect of the LRL antisense RNA on LasR expression and activity. (a) Effect of LRL on *lasR'-lacZ* translational fusion. (b) Western blot of LasR. (c) Effect of LRL on LasR transcriptional activity as measured by the expression of a *lasB-lux* transcriptional fusion. (d) Elastase activity in PAO1 with and without the expression of LRL. Strains: 1) PAO1 with pME6032 (empty vector), 2) PAO1 carrying pLRL (both strains also contain pSLR plasmid containing the *lasR'-lacZ* translational fusion). Results shown are the means of three biological replicates, and error bars denote the standard deviation.

sequences complementary to the SD sequence [37], and an intrinsic transcriptional terminator sequence.

Plasmids pSLR and pMLBX that encodes for a *lasR* translation and *lasB* transcriptional fusions, respectively, were constructed as described in the Supplementary Materials section.

Measurement of reporter fusion activity

Expression of LRL antisense RNA from pLRL was performed by the addition of 0.5 mM IPTG to cultures. β-galactosidase activity of the *lasR'-lacZ* fusion was measured using standard protocols [38]. Activity of the *lasB-lux* transcriptional fusion was measured using clear-bottomed 96-well black plates. Plates were incubated 18 h at 37 °C in Synergy HT (Biotek), and luminescence measurements were recorded automatically by the equipment every 0.5 h.

Determination of *P. aeruginosa* virulence by its ability to induce abscess in mice

Four- to eight-week-old CD-1 male mice were obtained from the General Vivarium of the Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México. The indications given in NOM-062-ZOO-1999 for the handling and use of laboratory animals, as well as regulations for the use and care of animals destined for research, were followed at all times. All animals were housed under standard conditions and were provided with food and water *ad libitum*. The mouse abscess model was derived as previously described [25, 39].

RESULTS AND DISCUSSION

Production of virulence traits by *lasR* and *rhlR* single mutants and a Δ*lasR*–Δ*rhlR* double mutant

We measured the production, in LB broth, of elastase, PYO, RL and quinolone AIs PQS and HHQ in the wild-type PAO1 strain and its derived Δ*lasR and* Δ*rhlR* mutants and Δ*lasR*–Δ*rhlR* double mutant (Fig. 1). We found that the three virulence factors are strictly regulated by the QSR, since their production was completely impaired in the double Δ*lasR*–Δ*rhlR* mutant. In addition, the production of PQS and HHQ was also impaired. However, *lasR* deletion did not completely impair production of the virulence factors and quinolones, which would be expected if the QSR had a strict regulatory hierarchy with LasR at the top of the

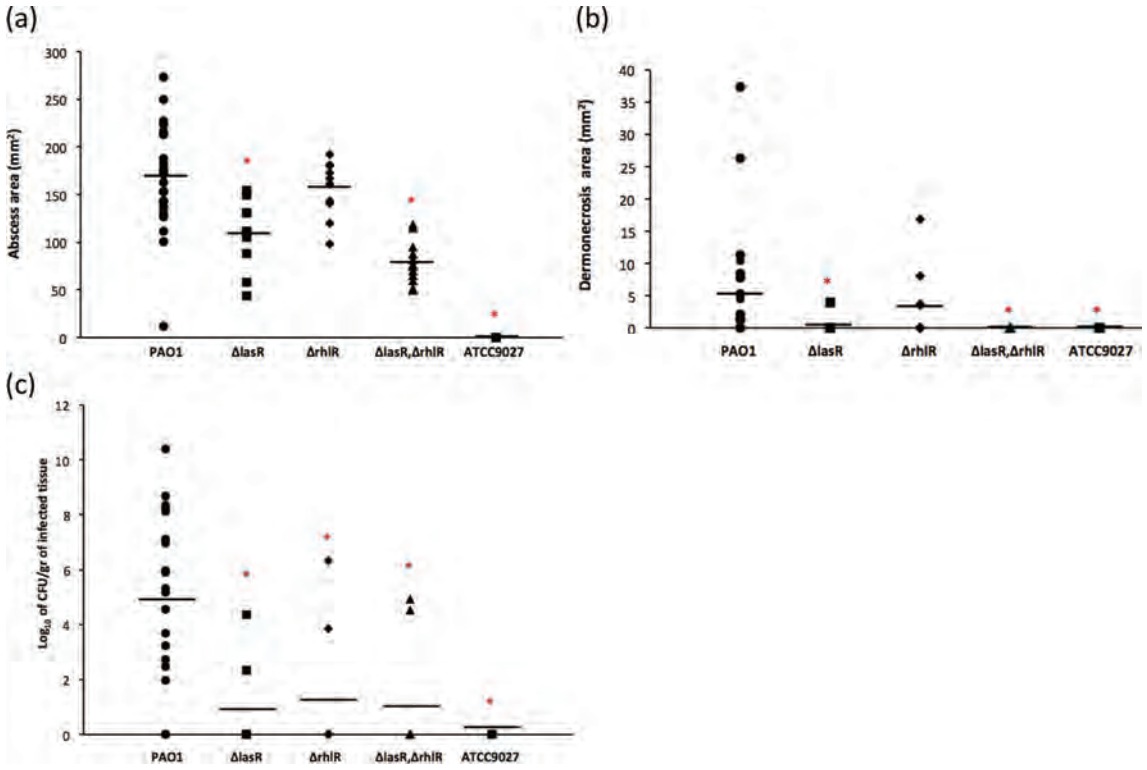

Fig. 3. Evaluation of virulence of *P. aeruginosa* strains by their formation of abscesses in mice. Points represent data for each abscess obtained after 4 days of inoculation with *P. aeruginosa* strains. Horizontal bars represent the mean of the results obtained (all animals in each experiment were inoculated with ~10^6 c.f.u. in a volume of 60 µl). Data were averaged for a minimum of two independent experiments with at least three animals per experiment. The number of animals inoculated with each strain was as follows: PAO1=22, Δ*lasR*=10, Δ*rhlR*=10, Δ*lasR*-Δ*rhlR*=10. For the avirulent ATCC 9027 used as negative control we performed one experiment with four animals. Red asterisks denote a significant difference from the wild-type (P<0.05). The results were analysed by the two-tailed Mann–Whitney test. (a) area of abscess; (b) extent dermonecrosis resulting from infection; (c) logarithm of bacterial c.f.u. g^{-1} recovered from damaged tissue. A file containing the complete dataset for all mice studied is provided, with the average and standard deviation for all experiments performed with each strain.

cascade as has been proposed [3, 4]. Moreover, the production of the three virulence factors was affected more in the Δ*rhlR* mutant that in the Δ*lasR* mutant; production of both PYO and RL was completely abrogated in the Δ*rhlR* mutant, revealing that RhlR coupled with its cognate AIs directly activates the transcription of the genes involved in RL and PYO production.

Even though the Δ*lasR* mutant had a more pronounced effect on quinolone production than the Δ*rhlR* mutant (which is in accordance with the participation of LasR/3O-C12-HSL in the expression of *pqsR*), it is clear that only the double Δ*lasR*–Δ*rhlR* mutant completely reduced the production of these AIs.

Taken together, these results show that there is considerable expression of the regulons Rhl and PQS that is independent of LasR/3O-C12-HSL, and that inhibition of the transcriptional activity of LasR is not sufficient to block the expression of *P. aeruginosa* QSR.

Selection of an antisense *lasR* RNA and its effect on LasR expression, *lasB* transcription and elastase production

In order to mimic the effect of a compound that would selectively inactivate LasR, we designed an antisense RNA that is complementary to the *lasR* messenger RNA comprising the SD sequence LRL. The expression of LRL in strain PAO1 caused reduced expression of a translational fusion of *lacZ* to the *lasR* gene, as evidenced by the lower levels of β-galactosidase (Fig. 2a), and also reduced the concentration of LasR (Fig. 2b). Furthermore, transcription of the *lasB* gene, which encodes for the elastase enzyme and is transcriptionally activated by LasR, was also decreased (Fig. 2c). However this reduction was not sufficient to diminish elastase activity (Fig. 2d). The limited effect of LRL on LasR expression, and the null effect of this reduction on the expression of LasR-dependent expression of elastase, show that LRL cannot be used to evaluate the effect of selective blocking of the LasR

INFORME DE LABORES 2019

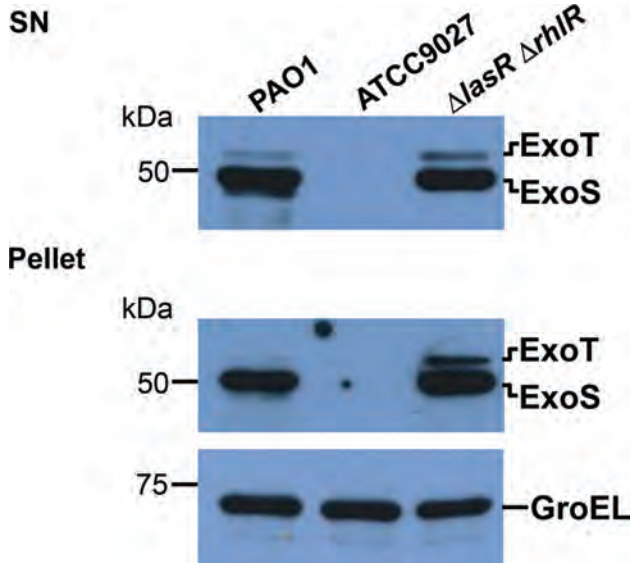

Fig. 4. Secretion of ExoT and ExoS by T3SS in PAO1 and its derived Δ*lasR*-Δ*rhlR* double mutant. The effectors ExoT and ExoS were detected by Western blot assay in whole cells (Pellet) and culture supernatant (SN) of the wild-type PAO1 strain and its derived Δ*lasR*–Δ*rhlR* double mutant. *P. aeruginosa* ATCC 9027, lacking T3SS, was used as negative control. Results are shown for one representative experiment repeated five times.

transcriptional regulator on the expression of virulence factors and the pathogenicity of *P. aeruginosa*.

The low efficiency of antisense RNAs on gene silencing in *P. aeruginosa* has been reported [40]. Even though in the present study the designed LRL RNA targeted the SD sequence as described for *E. coli* [37], this approach was insufficient to obtain good results. As native antisense RNAs rarely have a perfect base-pair match with the mRNA [41], these results reinforce the complexity of RNAs-mediated gene silencing in bacteria.

Effect of *lasR* and/or *rhlR* inactivation on *P. aeruginosa* virulence using a murine model of abscess formation

We evaluated the effect of the inactivation of LasR and RhlR transcriptional regulators using a murine model of abscess formation (Figs 3 and S1). Our results show that the QSR has a central role in *P. aeruginosa* pathogenicity, as previously reported using mutants in the *rhlI* and *lasI* single and double mutants in a burnt mouse model [42].

In the abscess model used in this work, the single Δ*lasR* mutant – and especially the Δ*lasR*–Δ*rhlR* double mutant – were attenuated but retained a high level of pathogenicity as judged by the size of the abscesses produced, the area of dermonecrosis and the number of bacteria recovered from damaged tissue (Fig. 3). These results differ from previously reported data using a burnt mouse model, which showed that the Δ*lasI*–Δ*rhlI* double mutant presented a more severely reduced virulence, even being avirulent [42]. This variation in results is probably due to the different pathogenicity models used, since the abscess model was designed to cause a local infection resembling a chronic, non-fatal situation [25] while the burnt model mimic an acute infection.

It was reported that, in the abscess model, the level of expression of genes involved in the production of phenazines such as PYO is reduced [25]. This finding might reflect the fact that the RhlR-dependent regulon is not induced, and this effect could explain why in our experiments the Δ*rhlR* mutant showed a significant reduction in neither abscess size nor the area of dermonecrosis compared to the wild-type strain (Fig. 3). However, it is clear that the RhlR-dependent regulon played an important part in the infection process in the abscess model considering that the Δ*lasR*–Δ*rhlR* double mutant showed reduced virulence compared to the Δ*lasR* mutant, and that the number of colony-forming units recovered from the abscesses caused by the Δ*rhlR* mutant was significantly less than that obtained from infections caused by the PAO1 wild-type strain (Fig. 3).

Because the ability to form biofilms has been implicated in *P. aeruginosa* infections [43], we wished to determine whether the deletion mutants in the QSR regulators would show a defect in biofilm-forming ability that correlated with their virulence. We found that the Δ*lasR* mutant and the Δ*lasR*–Δ*rhlR* double mutant showed decreased ability to form biofilm, while the Δ*rhlR* mutant produced more biofilm than the PAO1 strain (Fig. S2). It is highly likely that the increment in biofilm formation shown by the Δ*rhlR* mutant is due to increased production of exopolysaccharides involved in biofilm matrix formation in the absence of RL synthesis [44].

Secretion of type III effectors in PAO1 and its derived Δ*lasR*–Δ*rhlR* double mutant

In order to determine whether the remaining virulence of the PAO1 Δ*lasR*–Δ*rhlR* double mutant was due to secretion of the effectors ExoS and ExoT by T3SS, we compared the production and secretion of these toxins between strain PAO1 and its derived Δ*lasR*–Δ*rhlR* double mutant. It was apparent that the secretion of ExoT and ExoS is fully functional in the Δ*lasR*–Δ*rhlR* double mutant, and that this occurs at a level similar to that in the wild-type PAO1 strain (Fig. 4). These results suggest that the secretion of effectors by T3SS may cause the remaining virulence in the Δ*lasR*–Δ*rhlR* double mutant that is completely impaired in the QSR, since the effectors secreted by this system have been implicated in virulence levels using the same abscess model used in the present study [39].

Concluding remarks

Here we show that current opinion on the QSR hierarchy, with LasR at the top of the regulatory cascade as reported in the PAO1 type strain, should be revised since expression of RhlR-dependent virulence factors was not completely abrogated in a PAO1 Δ*lasR* mutant (Fig. 1). Moreover, we show

INFORME DE LABORES 2019

that *P. aeruginosa* PAO1 is able to induce abscess formation when lacking either one or both of the LasR and RhlR transcriptional regulators, albeit at a reduced level (Fig. 3). The remaining virulence of the Δ*lasR*-Δ*rhlR* double mutant may be due to the secretion of the effectors ExoT and ExoS by T3SS (Fig. 4).

Understanding of the molecular mechanism of *P. aeruginosa* pathogenicity is of considerable scientific and clinical importance. It is especially important to evaluate the role played by the QSR in this process, since significant efforts have been made to isolate compounds that inhibit this intricate regulatory network to reduce *P. aeruginosa* virulence. In this respect, it was recently reported that expression of genes involved in the QSR is at at a low level in human infections, thus questioning the importance of this regulon in *P. aeruginosa* pathogenicity and of the therapeutic impact of its inhibition [45].

The results presented here show that the development of a therapeutic approach towards the treatment of *P. aeruginosa* infections, based on the use of compounds that interfere with the production of virulence factors dependent on the QSR, and in particular those that are focused on LasR inactivation, should be taken with caution because (1) the hierarchy of this regulon is not very strict and (2) *P. aeruginosa* pathogenicity is multifactorial and several virulence factors participate, not all dependent on the QSR [26]. In addition the phenotypic variation in different *P. aeruginosa* isolates with respect to the production of virulence factors regulated by the QSR is considerable [7–10], and therefore the strategy developed by blocking this regulatory network using a type strain, such as PAO1 strain used in this work, might not be efficient with strains encountered in a clinical setting.

Funding information
This work was supported in part by grant No.IN201819 from Programa de Apoyo a Proyectos de Investigación e Innovación Tecnológica (Dirección General de Asuntos del Personal Académico–UNAM) and grant No.252269 from Consejo Nacional de Ciencia y Tecnología (CONACYT).

Descubrimiento de la proteína reguladora de apoptosis 2 como determinante en la muerte de células tumorales

*Juana Virginia Tapia-Vieyra y Jaime Mas-Oliva**
Universidad Nacional Autónoma de México, Instituto de Fisiología Celular, Ciudad de México, México

Resumen

El cáncer es una enfermedad multifactorial que constituye un problema de salud pública mundial. Las etapas avanzadas del cáncer de próstata están asociadas con el desarrollo de tumores independientes de andrógeno y un fenotipo resistente a la apoptosis que progresa a metástasis. Al estudiar células de cáncer de próstata de nódulo linfoide (LNCaP) independientes de andrógeno inducidas a la apoptosis por eliminación de suero, identificamos la activación de un canal catiónico no selectivo de 23pS de conductancia que promueve corrientes entrantes de Ca^{2+} así como las etapas finales de la apoptosis. El cDNAarp2 fue aislado e identificado del mismo tipo celular y el ARN mensajero fue expresado en ovocitos de Xenopus laevis, asociándolo con la activación de las corrientes entrantes de Ca^{2+} y la inducción a la apoptosis. El ADN complementario que codifica para la proteína reguladora de apoptosis 2 (ARP2) fue sobreexpresado en células LNCaP y células de ovario de hámster chino, induciendo apoptosis. Nuestra evidencia sugiere que la sobreexpresión y tránsito de la proteína ARP2 a la membrana celular permite una corriente de entrada de Ca^{2+} aumentada, iniciadora del proceso de apoptosis en células de tipo epitelial cuyo fenotipo muestra resistencia a la muerte celular programada.

PALABRAS CLAVE: *Apoptosis. Proteína ARP2. Carcinoma epitelial. Cáncer de próstata.*

Abstract

Cancer is a multifactorial disease that constitutes a serious public health problem worldwide. Prostate cancer advanced stages are associated with the development of androgen-independent tumors and an apoptosis-resistant phenotype that progresses to metastasis. By studying androgen-independent lymphoid nodule carcinoma of the prostate (LNCaP) cells induced to apoptosis by serum elimination, we identified the activation of a non-selective cationic channel of 23pS conductance that promotes incoming Ca^{2+} currents, as well as apoptosis final stages. arp2cDNA was isolated and identified to be of the same cell type, and mRNA was expressed in Xenopus laevis oocytes, which was found to be associated with the activation of incoming Ca^{2+} currents and induction to apoptosis. cDNA, which encodes the ARP2 protein, was overexpressed in LNCaP cells and Chinese hamster ovary cells, which induced apoptosis. Our evidence suggests that protein ARP2 overexpression and transit to the cell membrane allows an increased Ca^{2+} incoming current that initiates the apoptosis process in epithelial-type cells whose phenotype shows resistance to programmed cell death.

Introducción

El cáncer es una enfermedad multifactorial y la segunda causa de muerte de la población general en el mundo. Su causalidad está relacionada con los hábitos de vida, predisposición genética y estados psicológico y anímico de los individuos.[1] La prevalencia del cáncer ha aumentado en los últimos años, por lo que es un problema de salud que demanda un nivel muy alto de atención.[2,3] En el hombre, los porcentajes más altos de incidencia de cáncer ocurren en próstata, pulmón, bronquios, colon, recto y vejiga urinaria; en las mujeres, en mama, pulmón, bronquios, colon, recto, útero y tiroides. Lo anterior es un indicador de que los tipos de cáncer más comunes en hombres y mujeres, respectivamente, son de próstata y mama.[4] En los niños, la incidencia más alta en cáncer se observa en médula ósea, cerebro y nódulos linfoides.[5,6]

El cáncer epitelial es uno de los tipos más agresivos. Particularmente en el cáncer de próstata, el tratamiento dependerá de la etapa en que se identifique la enfermedad, sin embargo, es muy común que esta progrese y desarrolle un fenotipo de resistencia a la apoptosis y, por lo tanto, de independencia de la hormona, por lo que las células continúan la proliferación hasta alcanzar la metástasis, de ahí que resulte indispensable el desarrollo de nuevas estrategias terapéuticas que impidan que la enfermedad alcance etapas avanzadas.

Durante el proceso de apoptosis de numerosos tipos de células, el incremento sostenido de Ca^{2+} citoplásmico ha sido definido como determinante en el inicio de la muerte celular programada.[7] Considerando este fundamento, desde hace años hemos trabajado en el estudio de los mecanismos de control de la homeostasis del calcio citoplásmico y el impacto del nivel alterado de Ca^{2+} en diversos tipos celulares y neoplásicos.

Hemos podido demostrar que un nivel aumentado de calcio citoplásmico da como resultado el inicio de la muerte celular programada en líneas celulares epiteliales de cáncer de próstata y de ovario de hámster chino. En este sentido, nuestro grupo de investigación descubrió un canal catiónico no selectivo permeable a Ca^{2+} de 23pS de conductancia, expresado en condiciones de apoptosis inducida mediante eliminación del suero del medio de cultivo en células de cáncer de próstata de nódulo linfoide (LNCaP, *lymph node carcinoma of the prostate*) independientes de andrógeno.[8] Asimismo, se logró aislar el ADN complementario (ADNc) de células LNCaP que codifica para la proteína reguladora de apoptosis 2 (la cual denominamos ARP2), la cual al ser sobreexpresada induce a la apoptosis en ovocitos de *Xenopus laevis* y células LNCaP independientes de andrógeno, de donde originalmente fue aislada ARP2.[9] Se demostró que la sobreexpresión de ARP2 induce la apoptosis de células de ovario de hámster chino. Estos hallazgos demuestran que los niveles aumentados de Ca^{2+} son una condición indispensable para dar inicio a la apoptosis en diversas líneas celulares de tipo epitelial, por lo que esa proteína pudiera constituir en un futuro una excelente herramienta en el tratamiento de la enfermedad, al evitar la progresión hacia las etapas avanzadas que culminan con un proceso metastásico.

Cáncer de próstata

El cáncer de próstata es la segunda causa de muerte por cáncer en Estados Unidos y la quinta en el mundo.[10-12] La prevalencia de esta enfermedad se incrementa conforme la edad avanza. El cáncer de próstata es encontrado durante la autopsia en más de la mitad de hombres de Estados Unidos mayores de 50 años, aunque esta enfermedad haya sido la causa de muerte solo en 3 %. Es una enfermedad asintomática hasta la aparición de lesiones metastásicas que generalmente son descubiertas en tejido óseo. Las terapias iniciales para dar tratamiento incluyen cirugía, radiación, uso de inhibidores de la 5-alfa reductasa que promueve la formación de andrógenos más potentes a partir de testosterona.[13] Los métodos iniciales de tratamiento a menudo causan disfunción sexual, urinaria e intestinal.[14]

Desde el punto de vista molecular, esta enfermedad se manifiesta en etapas tempranas y tardías. En las primeras, la proliferación de las células prostáticas es lenta y dependiente de los andrógenos, por lo que durante el tratamiento con agentes quimioterapéuticos las células alcanzan a reparar el daño y continúan proliferándose. Con el tiempo, las células se independizan de las hormonas androgénicas para proliferar, por lo que culminan en el desarrollo de metástasis que lleva al paciente a la muerte.[15]

Apoptosis y enfermedad

La muerte celular programada o apoptosis es un evento celular intrínseco de relevante importancia en procesos como la homeostasis celular, el desarrollo

embrionario y el inicio y mantenimiento de varias enfermedades como el cáncer y la aterosclerosis.[16,17] Este mecanismo se desarrolla mediante dos vías; la del receptor de muerte celular y la vía mitocondrial.[18] A su vez, el proceso apoptótico se desarrolla en varias etapas: la primera se relaciona con los estímulos que disparan la muerte celular programada, la segunda involucra los procesos de transducción de las señales, en la tercera participan enzimas efectoras que se ocupan del desensamble celular, como las caspasas activas y, finalmente, en la cuarta ocurre la condensación de la cromatina, la degradación del ADN y la formación de los cuerpos apoptóticos.[18,19]

Existen diversas vías apoptóticas como la extrínseca o de receptor de muerte, cuya caspasa iniciadora es la caspasa 8, y la intrínseca o mitocondrial, que tiene como proteína intermediaria al citocromo C y a la caspasa 9 como iniciadora. Ambas pueden converger en el conjunto de caspasas efectoras, principalmente las caspasas 3 y 7, que se activan a través del autoprocesamiento o activación en cascada, por lo que las mismas caspasas se autoactivan y activan entre ellas.[20,21] Existe otra vía alternativa denominada de la perforina-granzima,[22,23] que corresponde a un complejo de serina proteasas importante en la apoptosis inducida mediante células T citotóxicas, activando vías independientes de caspasas.

Ca^{2+} como segundo mensajero determinante en el proceso de apoptosis

Las variaciones en la concentración del Ca^{2+} intracelular promueven el comienzo de eventos celulares como la regulación del metabolismo, la mitosis, la secreción de neurotransmisores y de hormonas, así como la contracción de miofilamentos, por lo que se considera un segundo mensajero determinante para las funciones celulares.[24,25] Los niveles de Ca^{2+} también están involucrados en los mecanismos regulatorios de la muerte celular programada apoptótica.[26,27] Un nivel de Ca^{2+} superior al basal se considera altamente tóxico, ya que genera la activación de proteasas y fosfolipasas que participan en el desensamble celular.[28] El incremento de Ca^{2+} puede ocurrir en etapas tempranas y tardías de la apoptosis, mediante la salida de Ca^{2+} del retículo endoplásmico y la entrada de Ca^{2+} al citoplasma a través de canales activados por liberación de Ca^{2+}.[7,29] Es necesario tener en cuenta que parte del Ca^{2+} intracelular se mueve al retículo endoplásmico a través de la bomba de calcio del retículo endoplásmico y el Ca^{2+} es liberado de estos almacenes por receptores inositol 1,4,5 trifosfato o receptores de rianodina. Adicionalmente, en diversos organelos intracelulares (como el aparato de Golgi, núcleo y mitocondria) existen sistemas especializados para el transporte de Ca^{2+}.[30]

El calcio entra a la célula a través de proteínas transmembranales llamadas canales de calcio.[31] El calcio pasa a través de los canales mediante mecanismos distintos dependiendo del tipo de canal o voltaje o bien a través de receptores; estas vías no requieren energía, a diferencia de las bombas de calcio que envían calcio citoplásmico al exterior de la célula a expensas de la utilización de adenosín trifosfato.

En colaboración con el doctor Agustín Guerrero del CINVESTAV, en el laboratorio del Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, para la obtención de registros electrofisiológicos se combinó técnica de fijación de membranas (*patch clamp*) y mediciones simultáneas de Ca^{2+} en célula única, con el propósito de estudiar la activación de canales permeables a Ca^{2+} mediante el uso de dos diferentes inductores: un ionóforo (ionomicina) y la eliminación del suero.[8] La última priva a las células de componentes nutricionales esenciales como proteínas, factores de crecimiento y vitaminas, induciendo a las células a la muerte.[32,33]

Los resultados demostraron la activación de un canal catiónico no selectivo y permeable a Ca^{2+} de 23pS de conductancia. Los niveles aumentados de Ca^{2+} indujeron a las células a la apoptosis, lo cual demostró que la activación de este canal promueve el desarrollo de la muerte programada de las células LN-CaP, lo que constituyen un importante hallazgo para la inducción de la muerte programada en este tipo celular (Figura 1).

Continuando con esta línea de investigación, en nuestro grupo se aisló, identificó y caracterizó cDNA*arp2*, que codifica para ARP2 de células LNCaP independientes de andrógeno, inducidas a la apoptosis mediante la eliminación del suero.[9] La secuencia de esta proteína muestra homología con el factor de empalme o *splicing* Prp8 (un componente del spliceosoma)[34] y funciones proapoptóticas en distintos tipos celulares (Figura 2). El mecanismo de corte y empalme de tipo alternativo es definido como una propiedad que prevalece en los organismos superiores para producir proteínas múltiples de un gen simple.[35,36] La actividad de unión a ubiquitina de la proteína Prp8 sugiere que algunos factores de corte y empalme para el pre-mARN pueden ser ubiquitinados para tener una interacción con Prp8.[37]

Las líneas negras indican los nucleótidos que no muestran homología entre los ADNc. Los espacios amarillos entre las líneas rojas corresponden a espacios vacíos de nucleótidos entre los ADNc. Las flechas negras señalan los nucleótidos 13 y 1309 de arp1 y arp2 y los nucleótidos 4591 y 5887 de Prp8. Tomada de referencia 9.*

Ovocitos de la rana *Xenopus laevis* inyectados con el mARN de *arp2* presentaron formación de ampollas a partir de las 12 horas de la inyección; se observó que estos cambios morfológicos aumentan cuando los ovocitos son tratados con tapsigargina (Figura 3A y 3B, respectivamente). También fue posible observar que los ovocitos sufrieron disminución en el potencial de membrana en reposo: de un valor control de −46.8 ± 6.6 mV pasaron a −5.9 ± 3.4 mV (5-8 ovocitos, dos ranas) (Figura 4). La incubación de las células con tapsigargina aceleró y aumentó los cambios morfológicos, siendo evidente la pérdida de la definición de los polos animal y vegetal, que se observó a las 36 horas de la inyección con el mARN *arp2* y ocho horas después de la incubación con tapsigargina (Figura 3B).

Los cambios morfológicos y la depolarización membranal observados en nuestro estudio han sido descritos en ovocitos de *Xenopus laevis* cuando son inyectados con citocromo C para disparar el

También se muestran los cambios en el potencial de reposo (Vm) observados entre los diferentes grupos de ovocitos (ocho control y seis inyectados). Todos los ovocitos de esta figura fueron del mismo donador; resultados similares fueron obtenidos de una segunda rana. Cnt = control, ns = no significativo, *p ≤ 0.05. Tomada de referencia 9.*

mecanismo apoptótico,[38] al igual que en ovocitos inyectados con la molécula proapoptótica Bcl-xs.[9,39] La tapsigargina, un fármaco que descarga los almacenes intracelulares de Ca^{2+} por la inhibición específica de la Ca^{2+}-ATPasa del retículo endoplásmico, provoca que se activen canales independientes de voltaje de la membrana citoplasmática (TRP, *transient receptor potential*).[40]

De esta forma hemos reunido evidencia suficiente de que ARP2 es promotora de la apoptosis en las células LNCaP independientes de andrógeno y en células epiteliales de ovario de hámster chino,[41] favoreciendo incrementos mantenidos de Ca^{2+} al interactuar directamente con canales de membrana permeables a Ca^{2+} o presentando una función de canal de membrana. Por otro lado, considerando la homología de la secuencia del ADNc que codifica para ARP2 con el factor de corte y empalme Prp8, hasta el momento se desconoce si esta proteína pudiera tener adicionalmente alguna participación en el ensamble o funcionamiento del spliceosoma o estar relacionada con los mecanismos de regulación de corte y empalme alternativo de los ARNm que codifican para las proteínas de la maquinaria apoptótica. Existe

un estudio en el que se observó que la proteína Prp8 se une a uno de los dominios del receptor a andrógeno de células de cáncer de próstata y, en consecuencia, pudiera estar interviniendo en la funcionalidad de este durante el desarrollo de la enfermedad.[42] Asimismo, se reportó que algunos factores de corte y empalme que conforman el spliceosoma están vinculados con el desarrollo de cáncer de mama, como el factor SNW1.[43]

Continuando con el proyecto, el ADNc que codifica para ARP2 fue clonado en un plásmido de expresión y transfectado a células LNCaP independientes de andrógeno y células de ovario de hámster chino. La sobreexpresión de ARP2 indujo a las células a desarrollar apoptosis, con impacto importante sobre la viabilidad celular y la activación de las caspasas efectoras 3 y 7, resultados comparados con los de células en inanición y tratadas con ionomicina.[41] En este estudio fue posible evidenciar mediante microscopia confocal que ARP2 inicialmente está localizado en la región perinuclear de las células y migra a lo largo del tiempo a la membrana plasmática[41] (Figuras 6). Tomando en cuenta nuestros resultados, consideramos que ARP2 se inserta en la membrana plasmática, con una función semejante a la de un canal de membrana, de esta forma constituye un blanco valioso para modular el flujo y la concentración de Ca^{2+} en el citoplasma de células de cáncer epitelial que muestran un fenotipo resistente a la apoptosis[41] (Figura 6).

Perspectivas

El mecanismo de apoptosis en fenotipos celulares malignos resistentes ha sido tema de amplio estudio en los últimos años. Debido al fuerte impacto del desarrollo del cáncer, es urgente la implementación de estrategias moleculares exitosas que apoyen los tratamientos contra esta enfermedad. Nuestro grupo ha demostrado que la sobreexpresión de la proteína ARP2 induce la muerte celular programada de diferentes tipos celulares: células de cáncer de próstata de nódulo linfoide independientes de andrógeno, de donde originalmente fue aislada, células de ovario de hámster chino, células de riñón embrionario humano

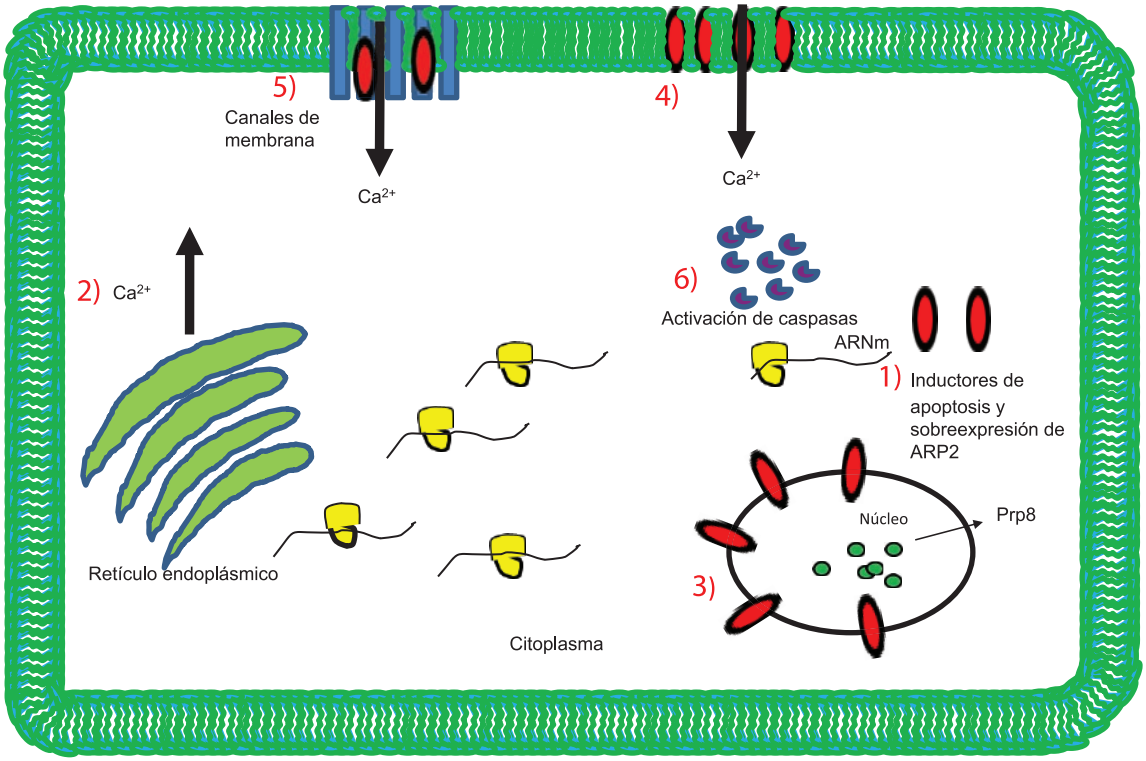

Figura 6. *Modelo de acción de ARP2.* **1:** *Inductores de apoptosis y sobreexpresión de ARP2;* **2:** *La sobreexpresion de ARP2 promueve incremento de Ca^{2+} proveniente de retículo endoplásmico y membrana citoplasmática;* **3:** *ARP2 localizada en membrana perinuclear en interacción con el complejo del spliceosoma, lo que promueve influjos de Ca^{2+};* **4:** *ARP2 insertándose en la membrana citoplasmática, con lo que forma posibles canales de membrana o regula la activación de canales permeables a Ca^{2+}* **(5)***; estos influjos de Ca^{2+} favorecen la actividad del complejo del spliceosoma y el desarrollo del mecanismo de apoptosis* **(6)**.

y células endoteliales de arteria coronaria (datos no mostrados).

Dadas las evidencias experimentales reunidas, consideramos que ARP2 pudiera estar contribuyendo durante su sobreexpresión al incremento de los niveles intracelulares de Ca^{2+} como una molécula mensajera o como una proteína insertada en la membrana que favorece la entrada de Ca^{2+}. Además de encontrarse en la región membranal, también observamos su localización perinuclear y debido a la homología con el factor Prp8 cabe la posibilidad de que esté participando en los mecanismos de corte y empalme alternativo de moléculas proapoptóticas.[44-46] En este sentido y tomando en cuenta de que la transcripción a través de mecanismos de corte y empalme alternativos son procesos moleculares altamente regulados por el nivel intracelular de Ca^{2+}, entre otros,[47,48] es factible pensar que ARP2 pudiera tener una doble función: en el control del flujo plasmático de Ca^{2+} y en mecanismos moleculares de corte y empalme alternativo.

Con fundamento en la evidencia de que genes de muerte celular están desregulados en el cáncer, fenómeno asociado con el control de sus patrones de corte y empalme alternativo, es justificado pensar que el proceso de apoptosis se manifiesta como una respuesta positiva a la quimioterapia.[49] Si tomamos en cuenta que la eficacia de los fármacos contra el cáncer puede también depender de la activación de la apoptosis o de una forma de inducción aguda de senescencia celular, consideramos que la sobreexpresión de la proteína ARP2 potencialmente podría ser empleada como una nueva herramienta en el tratamiento del cáncer de tipo epitelial.

INFORME DE LABORES 2019

Localization of chloride co-transporters in striatal neurons

Dagoberto Tapia, Paola Suárez, Mario A. Arias-García, Brisa Garcia-Vilchis, Miguel Serrano-Reyes, José Bargas and Elvira Galarraga

The ionic driving force for the chloride-permeable $GABA_A$ receptor is subject to spatial control and distribution of chloride transporters. NKCC1 and KCC2 are mostly expressed in neurons in a specific manner. In the striatum, the localization of these transporters in identified neurons is unknown. In this study, the expression of these transporters was found to be different between projection neurons and interneurons. NKCC1 immunoreactivity was observed in the soma of adult BAC-D1-eGFP+ and D2-eGFP+ striatal projection neurons (SPNs). KCC2 was not expressed in either projection neuron and immunoreactivity to this transporter was observed only in the neuropile. However, NKCC1 and KCC2 co-transporters were not localized in intracellular biocytin-injected dendrites of SPNs of the direct or indirect pathways (D1-SPNs and D2-SPNs). Experiments with PV^+ Cre transgenic mice transfected with Cre-dependent adeno-associated viruses containing tdTomato in the striatum showed a cell-type-specific distribution of KCC2 chloride transporter co-expression associated with PV^+ interneurons. Thus, depolarizing actions of GABA responses in adult projection neurons can be explained by the expression and somatic localization of the NKCC1 transporters. A somato/dendritic distribution of KCC2 expression was observed only in striatal interneurons and corresponds to the hyperpolarizing action of GABA recorded in these cells. This correlates the different roles for GABA actions in striatal neuronal excitability with the expression of specific chloride transporters. *NeuroReport* **30:457–462** **Copyright © 2019 Wolters Kluwer Health, Inc. Introduction

One parameter that can establish differences in the actions of GABAergic synapses is the ionic driving force for the chloride-permeable $GABA_A$ receptor.

The concentration of intracellular chloride ions in mammalian neurons is mainly controlled by two transporters.

NKCC1 accumulates chloride ions inside the cell using the sodium concentration gradient; KCC2 exports chloride outside the cell using the potassium concentration gradient [1,2]. Co-transporters are expressed in a cell-type-specific manner in the brain [3]. In the striatum, NKCC1 and KCC2 co-transporters are present [4], but their expression in specific striatal neurons is unknown. Reversal inhibitory potential is above the resting potential in all striatal projection neurons (SPNs) recorded by numerous studies using different techniques, including intracellular recordings and gramicidin patches [5–10]. GABAergic postsynaptic potentials have reversal potentials around −65 mV. Therefore, a depolarizing inhibition is present in all adult SPNs synaptic responses, considering chloride reversal potential. However, it is also well established that the expression of different chloride co-transporters can be distributed in separate compartments of the somato/dendritic membrane of a neuron, determining the polarity of the response to GABA [2,11–13]. In the present work, we studied the expression pattern among the SPNs and PV^+ interneurons of the co-transporters NKCC1 and KCC2, the subcellular anatomical distribution, and their role in regulating the different GABAergic responses in SPNs and PV^+ interneurons.

Materials and methods

All experiments were conducted in accordance with the international guidelines for the ethical use of experimental animals established in the NIH and detailed protocols were submitted and approved by the Institutional Committee for Laboratory Animals Care of the Instituto de Fisiología Celular, UNAM (NOM-062-Z00-1999; laboratory procedures EGP-41-14). Rodents were housed in a temperature-controlled, pathogen-free room, on a 12 : 12 light : dark cycle, and allowed food and water *ad libitum* to minimize the number of animals required to achieve statistical significance and the avoidance of animal suffering. Tg (Drd1-EGFP, $n=6$) X60Gsat/Mmmh (BAC-D1, GENSAT#: 000297-MU; Nathaniel Heintz, The Rockefeller University, New York City, New York, USA), Tg (Drd2-EGFP, $n=7$) S118Gsat/Mmnc (BAC-D2, 000230-UNC; Nathaniel Heintz, The Rockefeller University), C57BL/6 NCRL ($n=12$), and 12P2-*Pvalb*$^{tm1(cre)Arbr}$/J (PV-Cre, stock# 008069; Silvia Arber, Friedrich Miescher Institute, Basel, Switzerland and Jackson Labs, Bar Harbor, Maine, USA), PV-Cre mice ($n=5$), were used.

INFORME DE LABORES 2019

Slice preparation

Animals (45 postnatal day) were anesthetized, decapitated, and their brains were removed and submerged in an iced saline solution containing (in mM): 120 NaCl, 3 KCl, 25 $NaHCO_3$, 2 $CaCl_2$, 1 $MgCl_2$, and 11 glucose (33–35°C, 300 mOsm/l with glucose, pH 7.4, after bubbling with 95% O_2 + 5% CO_2). Briefly, and as described previously in detail, 350 µm thick parasagittal slices were cut [14] on a vibratome and left to equilibrate for at least 1 h at room temperature in the same saline. Thereafter, slices were transferred to a recording chamber and superfused continuously with the same saline at 33–35°C.

Identification of recorded neurons

Intracellular recordings were performed from spiny neurons of the dorsal neostriatum using sharp electrodes filled with potassium acetate 3 M and 1% biocytin (DC resistance 80–120 MΩ). SPNs were identified by their intrinsic electrophysiological properties during corticostriatal synaptic responses as described previously [9,14, 15]. In all cases, neurons were injected with biocytin-CY3 to determine the somato/dendritic morphology ($n = 13$).

Immunohistochemistry

Neurons obtained from BAC-D1 or BAC-D2-eGFP mice were identified as belonging to direct or indirect pathways. Thereafter, fixed slices were infiltrated with 30% sucrose and cut on a vibratome into 40-µm thick sections and incubated for 30 min with 1% bovine albumin to block nonspecific binding sites and for 36 h with a rabbit polyclonal antibody against NKCC1 1 : 1000 (59791; Abcam, Cambridge, UK) or KCC2 1 : 1000 (07–432; Millipore, Burlington, Massachusetts, USA), dissolved in PBS containing 0.25% Triton-X. The slices were then rinsed thrice with PBS and incubated with a goat versus rabbit secondary antibody 1 : 100 for 1 h. This antibody was conjugated with CY3 (Jackson immunoResearch, West Grove, Pennsylvania, USA). The specificity of antibodies was verified by negative experiments.

In the case of intracellular dendritic-injected biocytin, streptavidin conjugated with Cy3 1 : 200 was used and FITC for NKCC1 and KCC2 antibodies. Identification of PV-Cre^+ interneurons labeled with tdTomato and FITC for KCC2 antibody was used. Samples were mounted with vectashield (Vector Laboratories, Burlingame, California, USA) and observed in a confocal microscope Olympus FV-1000 [15].

Results

Projection neurons express the NKCC1 transporter on the soma

To investigate the expression pattern of the NKCC1 chloride transporter in the SPNs identified, we analyzed striatal confocal images from D2-eGFP BAC mice (Fig. 1a, in green) with the anti-NKCC1 antibody labeling (Fig. 1b, in red). Both D2-eGFP-positive neurons (arrow) as well as D2-eGFP-negative neurons 'putative D1-SPNs' (arrow head) co-express the red fluorescence labeling of the NKCC1 transporter (Fig. 1c, yellow and red).

The KCC2 co-transporter expression pattern was not found in either the soma of D2-eGFP-positive (arrow) or D2-eGFP-negative neurons (arrow head, Fig. 1d–f). The same results were found in D1-eGFP mice brain slices (Fig. 1g–l; also see Fig. 2a and c and Fig. 3a–c). Images from striatal D1-eGFP neurons (Fig. 1g, in green) labeled with NKCC1 antibody (Fig. 1h, in red). Again, both D1-eGFP-positive neurons (arrow) as well as D1-eGFP-negative neurons (arrow head) co-expressed the red fluorescence labeling of the NKCC1 transporter (Fig. 1i, yellow and red). The KCC2 co-transporter expression pattern was not found in either the soma of D1-eGFP-positive (arrow), D1-eGFP-negative neurons (Fig. 1j–l, arrow head), or green dendrites of D1-eGFP-positive cells (Fig. 1l).

However, the KCC2 was highly expressed in striatal neuropile (big arrows Fig. 1e and k), although it was not present in the somato/dendritic membrane of the SPNs (Fig. 2f). The somatic expression of the NKCC1 chloride co-transporter contributes toward understanding the known depolarizing synaptic effects of GABA in SPNs [9,10,14,15].

NKCC1 and KCC2 are not expressed in dendrites of SPNs

The electrophysiological reversal potential for GABA-induced currents has been reported to vary between different cellular compartments in some neurons [3,11–13]. Therefore, we explored the possibility of NKCC1 and KCC2 expressions in intracellular labeled dendrites of D1-SPNs and D2-SPNs identified by their different corticostriatal synaptic responses [9,10]. Neurons injected with biocytin-CY3 were examined for double labeling along the dendrites; at least four dendrites from the soma to the tip in each cell (52 dendrites of 13 cells; seven dSPNs and six iSPNs, half of them subsequently labeled for KCC2 or NKCC1) were quantified. From this quantification, we concluded that dendrites of SPNs do not express the NKCC1 or the KCC2 co-transporters.

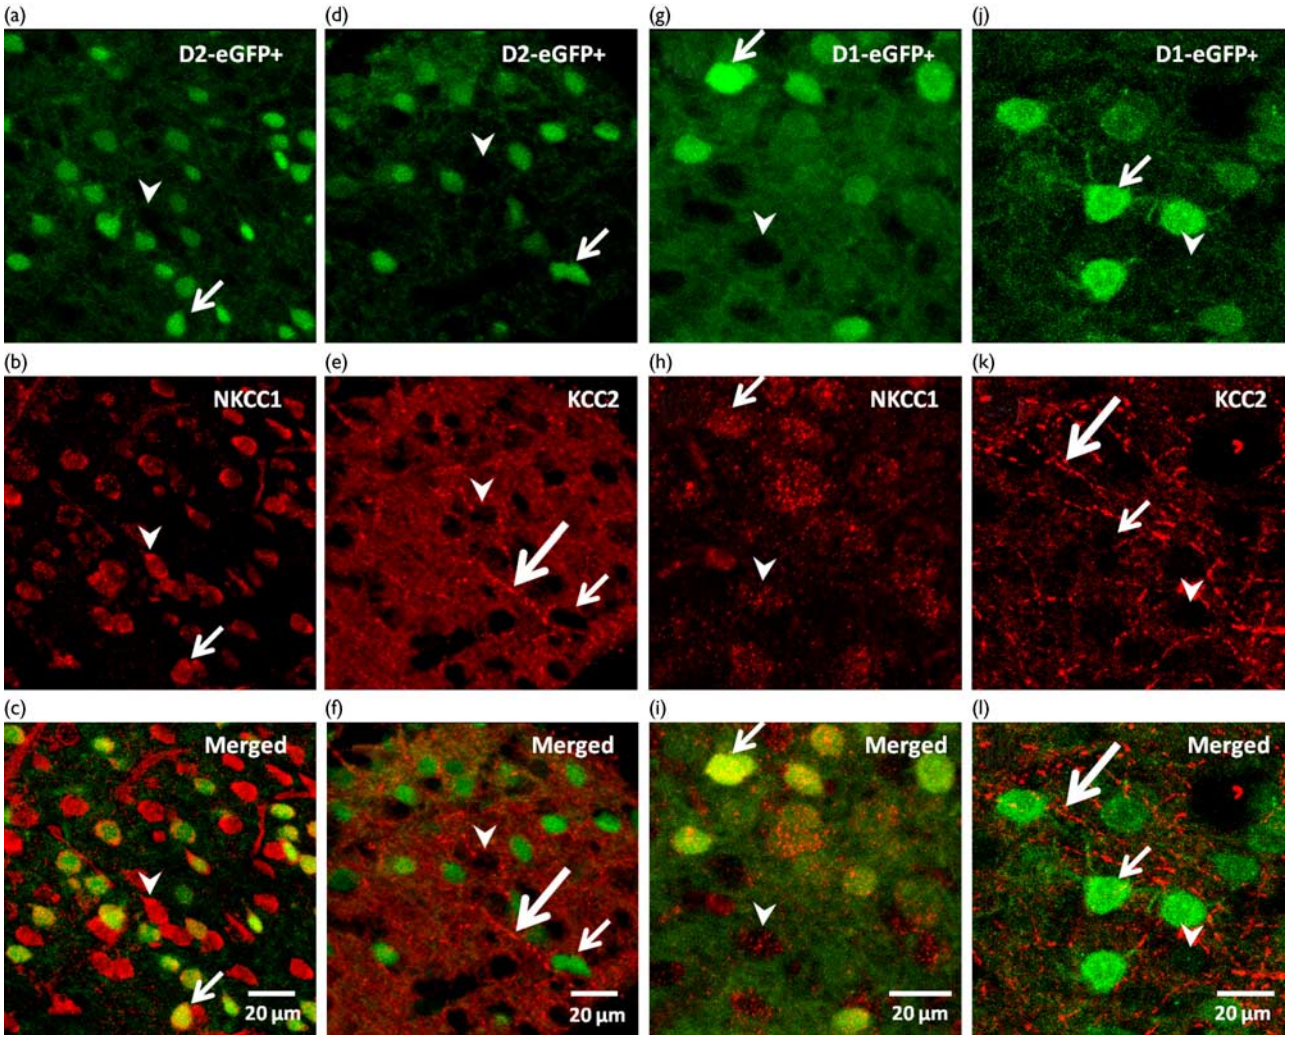

Figure 2a and b shows photomicrographs of intracellular injected projection neurons with biocytin streptavidin-conjugated Cy3. The NKCC1 antibody was only observed within the soma of neuron in Fig. 2c (arrow), not in dendrites of the biocytin-injected neuron (Fig. 2e, arrow). Note the labeled somata of other NKCC1-positive cells (Fig. 2e, arrow head). Figure 2b shows the somato/dendritic morphology of another SPN injected intracellularly with biocytin; in this case, no KCC2 expression was observed in the soma (Fig. 2d, arrow). Some positive KCC2 neuronal perikarya can be observed in the field (Fig. 2d, arrow heads). The KCC2 antibody was not expressed in the dendrites of this SPN (Fig. 2f, red arrow), but some positive dendritic processes were observed in the field (Fig. 2f, green arrow head).

These data show that intracellular labeled dendrites with biocytin (dendrites in red) in SPNs do not express the NKCC1 or the KCC2 (Fig. 2e and f) co-transporters. NKCC1

INFORME DE LABORES 2019

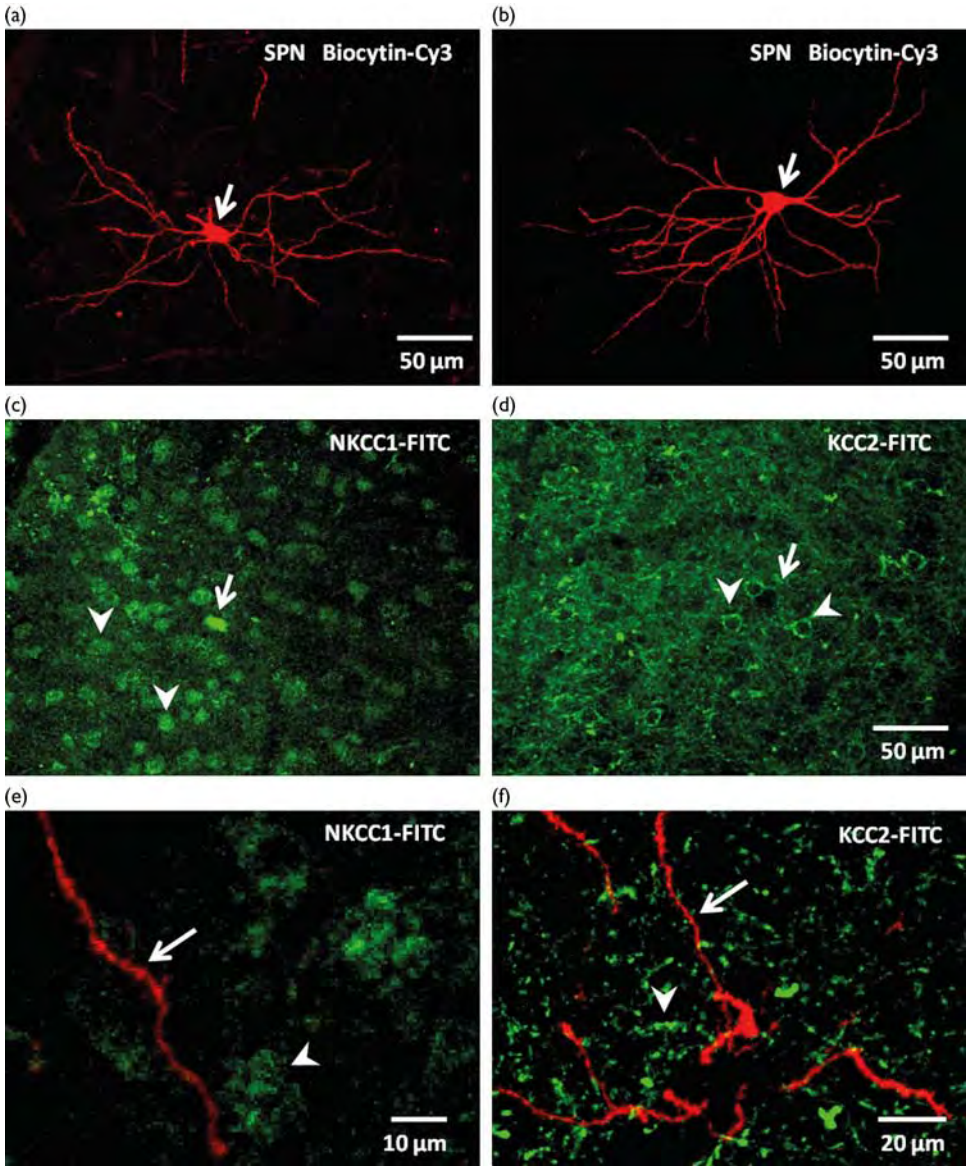
Fig. 1

Striatal projection neurons (SPNs) only express the NKCC1 transporter in the soma. Confocal images of the striatum double stained for D2-eGFP-positive neurons (a, in green), and the anti-NKCC1 antibody (b, c, in red) and for D2-eGFP and KCC2 antibody (d–f). Some neurons seen in the merged images (c, in yellow) co-express the green fluorescence and the NKCC1 transporter (arrows). D2-eGFP-negative neurons also co-express the NKCC1 antibody immunoreactivity (a–c, arrow heads). Note that KCC2 is highly expressed in the neuropile of the striatum (e, big arrow), but the antibody is not expressed in either D2-eGFP-positive (arrows) or D2-eGFP-negative (f, arrow heads) SPNs. D1-eGFP-positive neurons (g, in green), and the anti-NKCC1 antibody (h and I, in red) and for D1-eGFP and KCC2 antibody (j–l). Some neurons seen in the merged images (c, in yellow) co-express the green fluorescence and the NKCC1 transporter (arrows).

was only observed on the soma of SPNs and not in the neuropile, as in the case of KCC2 (arrows in Fig. 2e and f).

The KCC2 chloride transporter is expressed in PV$^+$ interneurons

Figure 3a shows D1-eGFP-positive SPNs (in green). In Fig. 3b, KCC2 immunoreactivity (in red), confirms that D1-eGFP-positive neurons are not immunoreactive (Fig. 3a–c, small arrows). KCC2 immunoreactivity was observed on the somatic periphery of negative D1-eGFP cells (Fig. 3a–c, big arrows) and the thin dendritic profiles in Fig. 3b and c (arrow heads). To identify the KCC2-positive striatal cell population, we utilized PV-Cre transgenic mice transfected with tdTomato. Several PV$^+$ neurons were identified in the striatum (Fig. 3d, in red) and were positively immunoreactive to the KCC2 antibody (Fig. 3e, in green). Double labeling is shown on the right (Fig. 3f, neurons in yellow). As in other brain areas, these experiments show that KCC2 immunoreactivity was distributed in the somatodendritic axis of PV$^+$ interneurons, helping to understand GABAergic inhibition onto PV$^+$ interneurons [16,17].



Discussion

Most striatal neurons are GABAergic. D1-SPNs and D2-SPNs receive inhibitory inputs from axon collaterals of each other, from neurons belonging to the same pathway [16–19], and

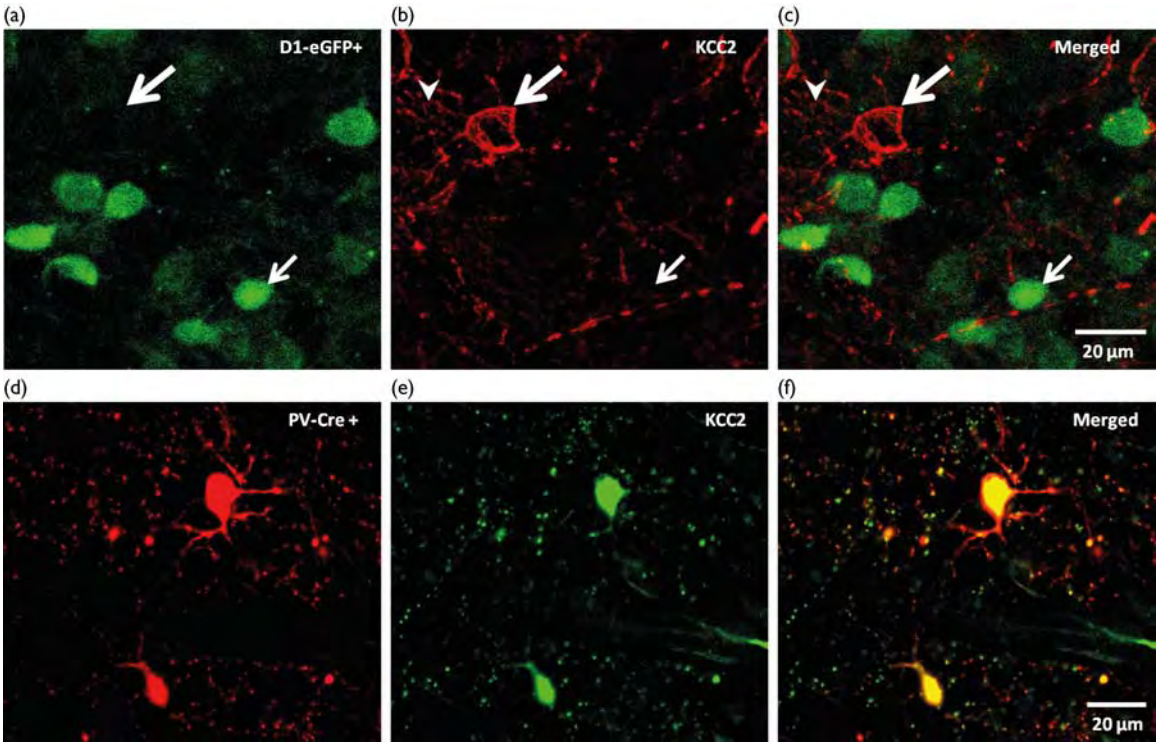
INFORME DE LABORES 2019

Fig. 2



Cellular compartmentalization of co-transporters NKCC1 and KCC2 in the somato/dendritic membrane of striatal projection neurons (SPNs). In (a) and (b) intracellularly recorded SPNs filled with biocytin are in red. The neuron in (a) was positive to the NKCC1 antibody (c, arrow), while the neuron in (b) was negative to the KCC2 antibody (d, arrow). Some positive neurons are shown (arrow heads). Intracellular labeled dendrites of SPNs (e, f, in red) were not associated with the antibodies, instead they were associated with the perikarya of SPNs (e, arrow head) and the neuroplie (f, arrow head).

from several types of GABAergic interneurons including tonic inhibition because of extra synaptic gabaergic receptors [7–9,19]. Feedback and feedforward inhibition have been studied previously in striatal neurons [17,19]. All these inputs contribute toward the synaptic integrated output of SPNs. GABAergic inputs contact the peri-somatic region and distal dendrites interacting with glutamatergic cortical and thalamic inputs [20] and with intrinsic dendritic channels that determine synaptic integration and dynamics [10,14,15]. GABA is generally inhibitory in the adult brain, but it can also mediate depolarizing synaptic responses in immature animals [2,21]. In addition, depolarizing actions of GABA with respect to resting potential have been reported in adult neurons [5–7,22,23] and are important in the adult brain not only to regulate neuronal excitability but also for synaptic integration [9]. However, depolarizing GABA signals may maintain their inhibitory influence because of shunting inhibition [9,23,24]. It has been known for a long time that GABA is depolarizing in adult SPNs [5–9]. Here, we show that somatic depolarizing actions of GABA in adult projection neurons can in part be explained by the expression and somatic localization of the NKCC1 transporters in these cells. However, depolarizing GABA

Fig. 3

Cell-type-specific distribution of KCC2 chloride transporter. Expression of the KCC2 transporter was associated with PV^+ striatal interneurons. (a) Positive striatal projection neurons (SPNs) from a BAC-D1-eGFP mouse in green (small arrow). (b) KCC2 immunoreactivity is observed in some sparse somatic and dendritic processes (big arrow and arrow head). In (c), a and b are merged, showing that the KCC2 chloride transporter is not expressed in D1-eGFP-positive neurons (small arrow). In (d) PV-Cre^+ interneurons interpunct. In (e) KCC2 immunoreactivity was distributed along the somato/dendritic axis of PV-Cre^+ interneurons. In (f), d and e are merged.

signals may maintain their inhibitory influence because of shunting inhibition at threshold potentials, for example, restraining firing at the beginning of a synaptic response, but supporting a prolonged plateau depolarization at later times in D1-SPNs. The inhibitory GABA response can also be revealed by bicuculline application in D2-SPNs in which a larger dendritic calcium contribution is observed [6,8–10,15]. To conclude, depolarizing GABA actions in the striatum are correlated here with specific chloride transporters expression described in this work.

Conclusion

In the presented work, the expression of chloride co-transporters was described in a cell-type-specific manner in SPNs and PV^+ interneurons. The results show for the first time that KCC2 is found in PV^+ striatal interneurons, whereas NKCC1 is expressed within the somatic region of both SPNs classes. The presence of the KCC2 transporter in other striatal interneurons cannot be discarded and remains to be studied. The possible presence of other transporter proteins is not discarded. GABA actions are important to understand the functional integration of microcircuits.

Feed-forward information and zero-lag synchronization in the sensory thalamocortical circuit are modulated during stimulus perception

Contributed by Ranulfo Romo, February 20, 2019 (sent for review November 8, 2018; reviewed by Sonja Grün and Stefano Panzeri)

The direction of functional information flow in the sensory thalamocortical circuit may play a role in stimulus perception, but, surprisingly, this process is poorly understood. We addressed this problem by evaluating a directional information measure between simultaneously recorded neurons from somatosensory thalamus (ventral posterolateral nucleus, VPL) and somatosensory cortex (S1) sharing the same cutaneous receptive field while monkeys judged the presence or absence of a tactile stimulus. During stimulus presence, feed-forward information (VPL → S1) increased as a function of the stimulus amplitude, while pure feed-back information (S1 → VPL) was unaffected. In parallel, zero-lag interaction emerged with increasing stimulus amplitude, reflecting externally driven thalamocortical synchronization during stimulus processing. Furthermore, VPL → S1 information decreased during error trials. Also, VPL → S1 and zero-lag interaction decreased when monkeys were not required to report the stimulus presence. These findings provide evidence that both the direction of information flow and the instant synchronization in the sensory thalamocortical circuit play a role in stimulus perception.

behaving monkeys | somatosensory thalamocortical circuit | tactile detection task | simultaneous single-unit recordings | directed information-theoretic measure

A major challenge in systems neuroscience involves understanding how perceptual experiences arise from coordinated neural activity, and how functional information flows among the interacting neurons (1–5). The sensory thalamus is an essential node within the perceptual circuit, relaying stimulus information from the periphery to cortex (6). Given the connectivity between the thalamus and cortex, feed-back corticothalamic inputs could modulate feed-forward thalamocortical stimulus information transmission during perception (7–10). Thus, the thalamus could act as a processing unit in continuous interaction with the cortex (6, 11, 12). Evidence supporting this view comes from previous studies in anesthetized (13–15) and awake animals (10, 16). However, it is unclear how feed-forward and feed-back information flows coexist within the thalamocortical circuit and whether they correlate with the subject's perception.

To address these questions, we recorded the simultaneous activity of single neurons in the ventral posterolateral nucleus (VPL) of the somatosensory thalamus and in primary somatosensory cortex (S1) sharing the same cutaneous receptive field while monkeys performed a vibrotactile detection task. The animals were trained to report the presence or absence of a tactile stimulus of variable amplitude. In this task, previous work showed that VPL and S1 neurons encode mostly the physical features of the stimulus (17, 18). These findings raise several questions. First, how is sensory information communicated between the VPL and S1 at the level of single neurons? Second, what is the balance between the information flowing in a feed-forward direction (VPL → S1) and in a feed-back (S1 → VPL) direction? Third, does the information flow between VPL and S1 correlate with the subject's perception?

In the current work, we addressed the above questions by detecting time-varying directional couplings between the recorded VPL and S1 neuron pairs across many trials as a measure of the functional thalamocortical information flow needed to perform a vibrotactile detection task. During the stimulus presence, feed-forward (VPL → S1) information largely prevailed over feed-back (S1 → VPL) information. Interestingly, zero-lag interactions emerged with the stimulus amplitude above detection threshold, suggesting the existence of cortical common inputs facilitating the transmission of stimulus information. Critically, at the stimulus onset, feed-forward information correlated with the subject's perception. During a variant of the detection task (passive condition, in which no response was required from the animal), feed-forward information was reduced during the expected stimulation windows of stimulus-present and stimulus-absent trials, while zero-lag interaction was mainly reduced in the first half of the stimulus. Taken together, our results characterize the functional information flow between VPL–S1 neuron pairs during tactile perception. They reveal that besides relaying stimulus information

Significance

The direction of information flow between brain circuits may be key in cognitive functions. We addressed this problem by evaluating a directional correlation measure between simultaneously recorded neurons from somatosensory thalamus (ventral posterolateral nucleus, VPL) and somatosensory cortex (S1) sharing the same cutaneous receptive field while monkeys judged presence or absence of tactile stimuli. During stimulus presence, feed-forward (VPL → S1) information increased as a function of stimulus amplitude, while feed-back (S1 → VPL) information was unaffected. Simultaneously, zero-lag interaction emerged with increasing stimulus amplitude, contributing to thalamocortical synchronization. Furthermore, VPL → S1 information decreased during error trials. Also, both VPL → S1 and zero-lag interactions decreased when monkeys were not required to report stimulus presence. Thus, directional and coordinated information in the thalamocortical circuit is associated with stimulus perception.

feed-forward information conveys task-context information, whereas zero-lag interactions might reflect the cortically driven coordinated activity of VPL and S1 that is required for information transmission during task performance.

Results

Two monkeys *(Macaca mulatta)* were trained to perform a tactile detection task (2, 3). In each trial, the animal had to report whether the tip of a mechanical stimulator vibrated or not (Fig. 1*A*). Stimuli were sinusoidal, had a fixed frequency of 20 Hz, and were delivered to the glabrous skin of one fingertip; crucially, they varied in amplitude across trials. Stimulus-present trials were interleaved with an equal number of stimulus-absent trials in which no mechanical vibrations were delivered (Fig. 1*A*). The presence or absence of the stimulus (0.5 s) was preceded by a variable prestimulus period (1.5 to 3 s), followed by a fixed poststimulus delay period of 3 s before the monkey reported its decision by pressing one of two push buttons (Fig. 1*A*). In stimulus-absent trials, we will refer to the possible window of stimulation (PWS) as the temporal windows when the monkeys may expect the stimulus (19). Stimulus detection thresholds were calculated from the behavioral responses (Fig. 1*B*, *Left*). Importantly, depending on the monkeys' responses, trials could be classified into four types: hits and misses in the stimulus-present trials and correct rejections and false alarms in the stimulus-absent condition (Fig. 1*B*, *Right*). Once the animals performed the task at near detection threshold (8 μm), we recorded the simultaneous activity of spike trains from individual neurons from VPL and S1 (areas 3b or 1; Fig. 1*C*) while monkeys performed the task. Here, it is important to highlight that the recorded neuron pairs (n = 84) from the VPL and S1 shared exactly the same cutaneous receptive fields (Fig. 1*D*). Fig. 1*E* qualitatively shows that the neurons of VPL and S1 modulate their firing rate during the stimulus-present condition (Fig. 1*E*, *Left*), but not during the stimulus-absent condition (Fig. 1*E*, *Right*). Thus, it appears an optimal experimental condition for assessing the functional time-varying information flow between neuron pairs from VPL and S1 during the detection task.

Assessing Directional Information Flow Between VPL and S1. It is well-established that the VPL relays information from the skin mechanoreceptors up to S1 (Fig. 1 *C* and *D*). This knowledge allows us to test the following hypothesis in the detection task: After the stimulus onset, the flow of functional information becomes crucially larger in the VPL → S1 direction than in the S1 → VPL direction. However, given the stronger anatomical connectivity from S1 to VPL than from VPL to S1 (12), the second hypothesis is that the flow of functional information is higher from S1 → VPL than from VPL → S1. Importantly, we also hypothesize that the information flow between VPL and S1 could be affected by task conditions (Fig. 1*B*). We addressed all these hypotheses by using a nonparametric method that measures directional information flows between the simultaneously recorded spike trains of pairs of VPL–S1 neurons in single trials and within slicing time windows of 0.25 ms using a directed information-theoretic measure (5, 20, 21) (*SI Appendix*). The method is illustrated in Fig. 2*A*. To measure single-neuron interactions on a fine temporal scale along each task trial, we estimated delayed versions of the directed information-theoretic measure (*SI Appendix*, Eq. **S1**) in both directions (VPL → S1 and S1 → VPL) for every pair of simultaneous VPL–S1 spike trains at the short time delays [0, 2, 4, . . ., 20 ms] (Fig. 2*A*, *Left*). To infer the significance of each estimation, we defined a maximizing-delay statistic (*SI Appendix*, Eq. **S2**) and built the corresponding null distribution using circular shifts of the target spike-train sequences (Y^T), which preserved the firing rate and the short-range (0 to 50 ms) autocorrelation of both spike trains while destroying their temporal alignment (Fig. 2*A*, *Middle*). For

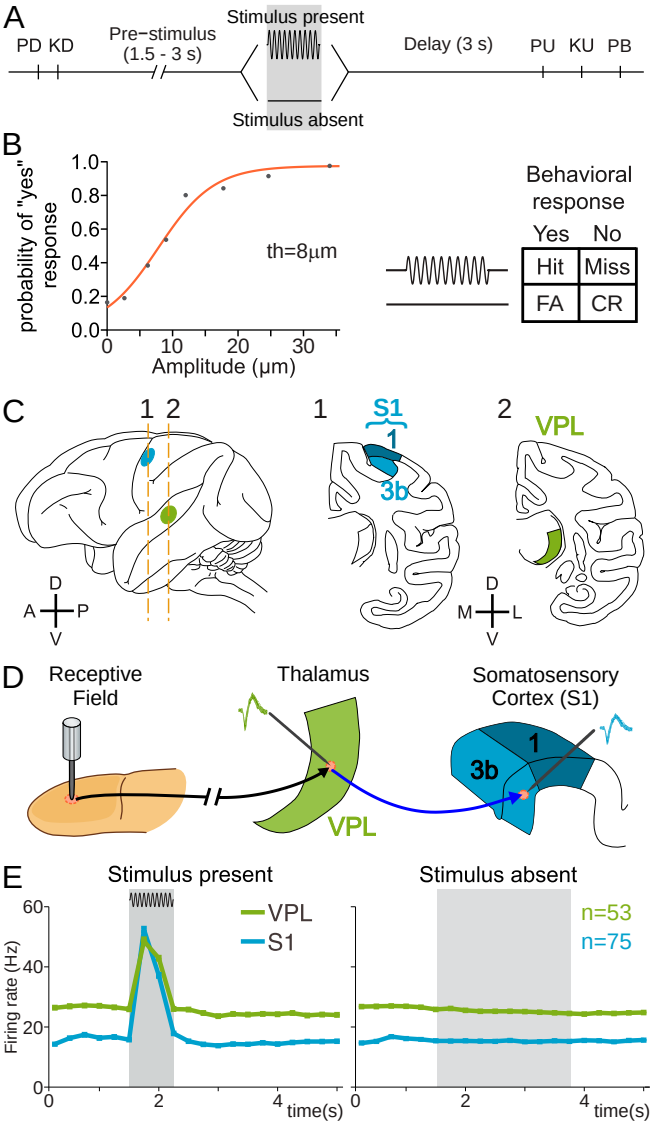

Fig. 1. Detection task, psychophysical performance, recording sites, and neuronal responses during the task. (*A*) Vibrotactile detection task. Trials began when the stimulator probe indented the skin of one fingertip of the monkey's restrained right hand (probe down, PD); the monkey reacted by placing its left, free hand on an immovable key (key down, KD). After a variable prestimulus period (1.5 to 3 s), a vibratory stimulus of variable amplitude (1 to 34 μm, 20 Hz, 0.5-s duration) was presented on one half of the trials; no stimulus was presented on the other half of the trials. Following the stimulus presentation period or a period where no stimulus was delivered, the monkey waited for 3 s until the probe was lifted off from the skin (PU, probe up), then the animal removed its free hand from the key (KU, key up) and pressed one of two push buttons (PBs) to report whether the stimulus was present or absent. Lateral and medial buttons were used for reporting stimulus presence and stimulus absence, respectively. Stimulus-present and stimulus-absent trials were randomly interleaved within a run. (*B*) The button pressed indicated whether the monkey felt the stimulus (henceforth referred as yes and no responses, respectively). (*B*, *Left*) Mean psychometric function depicting the probability of the monkey's reporting yes as a function of the stimulus amplitude (th = 8 μm, detection threshold). (*B*, *Right*) Behavioral responses depending on the stimulus presence (Hit or Miss) or stimulus absence (CR, correct rejection; FA, false alarm). (*C*) Recording sites in the ventral posterior lateral (VPL) nucleus (green) of the thalamus and in areas 1 and 3b of the primary somatosensory cortex (S1, cyan). (*D*) Scheme depicting how the neural activity from single neurons in the VPL and S1 (3b or area 1) sharing the same cutaneous receptive field was simultaneously recorded during the detection task. (*E*) Mean firing rate for the simultaneously recorded VPL (n = 53) and S1 (n = 75) neurons during the stimulus-present and stimulus-absent trials.

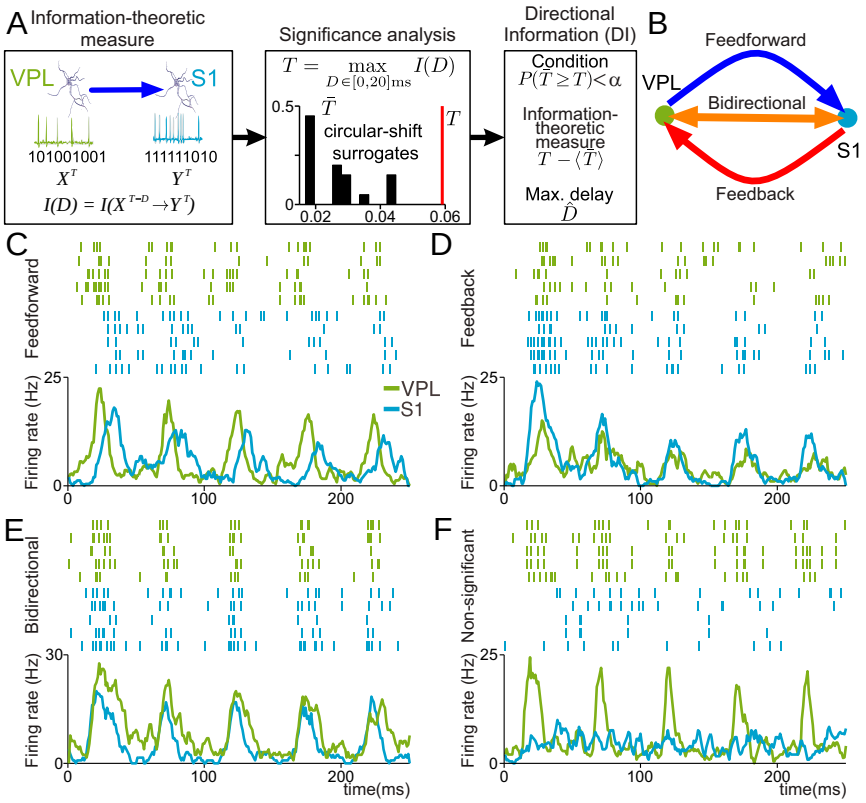

Fig. 2. Assessing DI between pairs of VPL and S1 neurons during the detection task. (*A*) Sequential scheme representing the method to infer DI at single-trial level. (*Left*) Information-theoretic measure is estimated between single-trial spike trains of the simultaneously recorded neurons in VPL and S1 for delays (0, 2, . . ., 20) ms. (*Middle*) Significance is locally determined via nonparametric testing ($\alpha = 0.05$) of a maximizing-delay statistic. (*Right*) Every significant statistic ($P < \alpha$) is associated with an unbiased information-theoretic measure value ($T - \langle T \rangle$) and a maximizing delay ($\hat{D}$). (*B*) Graphical representation for feed-forward (VPL → S1, in blue), feed-back (S1 → VPL, in red), and bidirectional (S1 ↔ VPL, in orange) information between VPL and S1 neurons. (*C–F*) Raster plots and spike density functions depicting the neural activity occurring during the first 250 ms of stimulation (34 μm) for examples of VPL (green) and S1 (cyan) neuron pairs involved in feed-forward (*C*), feed-back (*D*), and bidirectional (*E*) information and nonsignificant (*F*) statistic values.

each directional spike-train pair, (X^T, Y^T), the method assessed the significance of the statistic together with an unbiased estimation of the statistic value and the maximizing delay (Fig. 2*A*, *Right*). Directional spike-train pairs associated with significant estimators ($\alpha = 0.05$) will be referred to as directional information (DI) trials (*SI Appendix*) and will be represented for different experimental conditions as a percentage over the corresponding pairs and trials. Finally, statistical comparisons between percentages were assessed with nonparametric methods (21) and validated via Cohen's *H* (22) effect size (*H*) for proportion differences (*SI Appendix*).

A first characterization of the VPL–S1 simultaneous activity was done by measuring the percentage of DI (*SI Appendix*, Fig. S1*A*) as well as the mean DI value (*SI Appendix*, Fig. S1*B*) for VPL → S1 and S1 → VPL directions during the time course of the detection task for spike trains above a firing rate threshold (35 Hz). Both quantities were calculated separately for the stimulus-present (*SI Appendix*, Fig. S1*B*, *Left*) and stimulus-absent (*SI Appendix*, Fig. S1*B*, *Right*) trials. For the analysis of stimulus-present trials here and in the subsequent figures, we removed the variable-time prestimulus period in every trial and aligned all trials to the stimulus onset time. The analysis showed that for the stimulus-present trials the amount of VPL → S1 DI (trials = 3,216 in neuron pairs = 84, $P < 0.01$, $H > 0.5$, cyan line; *SI Appendix*, Fig. S1*A*, *Left*) was significantly larger than the amount of S1 → VPL DI during the first half (250 ms) of the stimulus period and weaker but still significant during the second half ($H < 0.5$). However, the strongest effect at stimulus onset was not mimicked by the mean DI value ($P < 0.01$, $D < 0.3$; *SI Appendix*, Fig. S1*B*, *Left*). In contrast, for stimulus-absent trials, the greatest differences were manifested by the amount of DI (trials = 4,371 in neuron pairs = 84, $P < 0.01$, $H > 0.3$; *SI Appendix*, Fig. S1*A*, *Right*) during the PWS (1.5 to 3.5 s) with no counterpart evidence from the mean DI value (*SI Appendix*, Fig. S1*B*, *Right*). Despite its moderate statistical effect ($H < 0.5$), *SI Appendix*, Fig. S1 shows a positive gap between VPL → S1 and S1 → VPL directions already during the prestimulus period, which could reflect an underlying directionality imbalance facilitating subsequent sensory information transmission. In conclusion, we restricted our analysis to the percentage of DI (rather than the mean DI value) due to its greater sensitivity to detect directionality differences during the stimulus and possible stimulation windows.

As a first approach, we considered exclusively two directionality cases: VPL → S1 and S1 → VPL (*SI Appendix*, Fig. S1). However, when studying DI flow for two simultaneous spike *T*-length trains X^T and Y^T at a given time interval (e.g., 250 ms) one may instead consider three disjoint cases: The spike trains are coupled in only one direction ($X^T \rightarrow Y^T$), in only the opposite direction ($Y^T \rightarrow X^T$) or simultaneously coupled in both directions ($X^T \leftrightarrow Y^T$). In principle, these three cases correspond to neurons in each pair taking three different roles—driver, target, or both—which may be associated with distinct functional mechanisms (24). According to this notion, we classified DI estimates by pairing the location and role of each neuron per trial. In short, we defined as feed-forward information (VPL → S1) those DI estimates involving pairs where the neuron of VPL was only driver and the neuron of S1 was only target. Similarly, we

Downloaded at instituto de Biotecnologia/UNAM on October 20, 2020

defined as feed-back information (S1 → VPL) where the neuron of S1 was only driver and the VPL neuron was only target. Finally, pairs where the neuron in VPL and the neuron in S1 were simultaneously drivers and targets (at possible different delays) of that interaction were labeled as bidirectional information. Fig. 2*B* shows a schematic representation for the three types of DI and Fig. 2 *C*–*E* shows four example pairs of neurons (five repetitive trials; green for VPL raster plots and cyan for S1 raster plots) responding during the first 250 ms after stimulus onset holding feed-forward (Fig. 2*C*), feed-back (Fig. 2*D*), and bidirectional (Fig. 2*E*) information, together with neuron pairs with nonsignificant statistic values (Fig. 2*F*). Since the significance analysis leading to DI is always single-trial, the choice of five trials in Fig. 2*D* is only for illustrative purposes here.

Stimulus Presence Modulates Feed-Forward and Bidirectional Information. Having set the above definitions, we first examined for each type of DI the average DI delay as a putative intrinsic property of each directionality case (*SI Appendix*, Fig. S2). Bidirectional information occurred at shorter delays than unidirectional information for both stimulus-present (trials = 3,217 in neuron pairs = 84, $D = 0.35$, time-average Cohen's d; *SI Appendix*, Fig. S2*A*, *Left*) and stimulus-absent trials (trials = 4,731 in neuron pairs = 84, $D = 0.37$, time-average Cohen's d; *SI Appendix*, Fig. S2*A*, *Right*). The delay histograms (*SI Appendix*, Fig. S2*B*, *Top*) outside the stimulus period or the PWS revealed that these differences were, in general, due to higher percentage of zero-delay couplings (around 33%) in bidirectional information compared with unidirectional information (around 15%). Further, we examined the DI delay distribution during the stimulus period (*SI Appendix*, Fig. S2*B*). We found that the arrival of the stimulus increased the relative amount of bidirectional information at zero delay (from 33 to 49%). However, the relative amount of feed-forward (from 9 to 19%) and feed-back information (from 9 to 15%) was enhanced at 8 ms.

Second, we investigated two main questions regarding feed-forward, feed-back, and bidirectional information: (*i*) What was the contribution of each DI type to a greater amount of VPL → S1 DI observed during the stimulus presence? and (*ii*) What was the contribution of each neuron pair to this effect? Fig. 3*A* depicts the percentages of DI according to their types (feed-forward, feed-back, and bidirectional) for stimulus-present (Fig. 3*A*, *Left*) and stimulus-absent trials (Fig. 3*A*, *Right*) during the time course of the task. The proposed decomposition highlighted the contribution of each type into the directionality differences illustrated in *SI Appendix*, Fig. S1. The increment in the VPL → S1 DI, especially after the stimulus onset, was mainly contributed by feed-forward information (trials = 3,216 in neuron pairs = 84, $P < 0.05$, $H = 0.23$; blue trace in Fig. 3*A*, *Left*) and lesser by the bidirectional information (trials = 3,216, neuron pairs = 84, $P < 0.05$, $H = 0.1$; orange trace in Fig. 3*A*, *Left*). In contrast, the increase in the S1 → VPL direction (*SI Appendix*, Fig. S1) could only be explained by an increase in bidirectional information. Indeed, genuine feed-back information was not significantly modulated during the stimulus presence ($P > 0.05$; red trace in Fig. 3*A*, *Left*). However, for stimulus-absent trials, no DI type showed a significant modulation (trials = 4,271 in neuron pairs = 84, $P > 0.05$; Fig. 3*A*, *Right*).

We then investigated the contribution of each neuron pair to the increment in feed-forward and bidirectional information during the first half of the stimulus period in the stimulus-present trials. To do so, we repeated the analysis of Fig. 3*A* for every VPL–S1 pair and obtained a stimulus-driven effect size per pair. Fig. 3*B* illustrates these results by sorting the neuron pairs independently for each DI type in a descending effect size order. Consistent with our previous findings, there were more neuron pairs exhibiting large stimulus effects in feed-forward and bidirectional information than in feed-back information. Besides that, ~40% (33/84) and 20% (18/84) of the neuron pairs increased the number

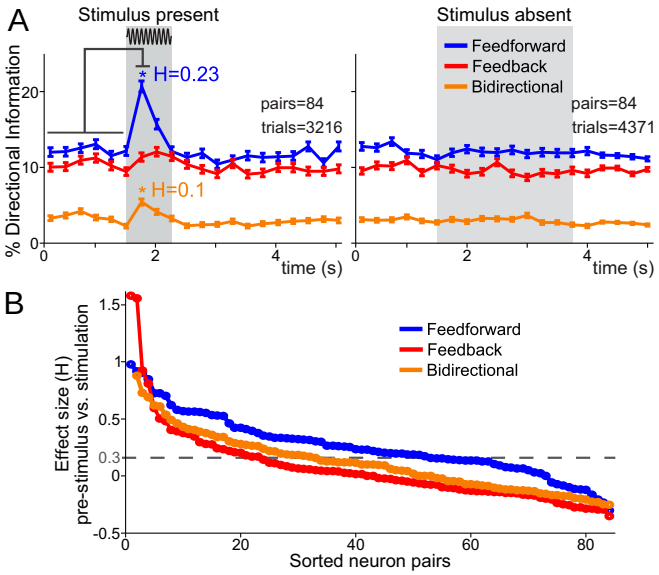

Fig. 3. VPL–S1 feed-forward, feed-back, and bidirectional information during the detection task. We analyzed hit and correct rejection trials across all recorded VPL–S1 neuron pairs. (*A*) Percentage of feed-forward, feed-back, and bidirectional information during the time course of the task during the stimulus-present (*Left*, trials = 3,216 hits; neuron pairs = 84) and stimulus-absent trials (*Right*, trials = 4,371 correct rejections; neuron pairs = 84). Error bars denote the SEM. In all figures, gray boxes depict the stimulus period for the stimulus-present trials and the PWS for the stimulus-absent trials. Asterisks denote significant differences ($P < 0.05$) between the prestimulus (first six task intervals, 1.5 s) and the first half (0 to 0.25 s) of the stimulus period (nonparametric test, $\alpha = 0.05$). H denotes the effect size (Cohen's H) of significant differences. Here and in the next time-varying figures, we removed the variable-time prestimulus period in every stimulus-present trial and aligned all trials to the stimulus onset. In stimulus-absent trials, we aligned the trials to the probe down event (PD). (*B*) Effect size of the difference between the percentage of each DI type during the prestimulus period and during the first stimulus interval as a function of the neuron pairs. Each curve is represented by ordering the neuron pairs in descending order according to the magnitude of the effect size for each particular DI type. The black horizontal dashed line represents the effect size threshold ($H \geq 0.3$).

of feed-forward and bidirectional information, respectively, with moderate and large effect sizes ($H > 0.3$; Fig. 3*B*).

Next, we asked how often a VPL–S1 neuron pair could simultaneously handle both DI modulations during the stimulus period. To address this question, we correlated the stimulus effect sizes associated with each DI type across all of the recorded VPL–S1 neuron pairs. The correlation value between the effect sizes was rather low ($\rho = -0.11$, $P > 0.5$, Spearman's rho), suggesting that feed-forward and bidirectional information might be modulated by a different thalamocortical mechanism. We also analyzed how neuron pairs were differently modulated during stimulus-absent trials (*SI Appendix*, Fig. S3). To this end, we compared the percentage of feed-forward, feed-back, and bidirectional information per neuron pair during the first interval of the stimulus window and during the first interval of the PWS. Each point in *SI Appendix*, Fig. S3 represents a VPL–S1 neuron pair and the histograms of all points' angles with respect to the stimulus-present axis (x axis: stimulus present; y axis: stimulus absent) are shown as insets. Therefore, angular values smaller than 45° indicated a stronger amount of DI during the stimulus period. Thus, mean angular values indicated that the stimulus-present effect ($\theta < 45°$) was more prominently manifested in feed-forward ($\theta = 30.5°$; *SI Appendix*, Fig. S3) and bidirectional information ($\theta = 25.2°$; *SI Appendix*, Fig. S3) than in feed-back information ($\theta = 41.1°$; *SI Appendix*, Fig. S3). In sum, we provided

Downloaded at Instituto de Biotecnologia/UNAM on October 20, 2020

consistent evidence from independent analyses that tactile stimuli mainly modulated feed-forward and bidirectional information in the VPL–S1 neuron pairs.

Correlation Between the Firing Rate and the Type of Directional Information. The statistical method used in this study infers DI measurements by preserving the firing rate of both sequences in the null distribution, thus avoiding to a large extent the bias introduced by fluctuations of the neuronal spikes (25, 26). To empirically corroborate this fact, we examined the influence of the firing rate into the observed VPL–S1 DI. In previous related work (17, 18) we showed that the average firing rate was larger in VPL than in S1 neurons (Fig. 1*E*). Therefore, the reported increase of feed-forward information (compared with feed-back information) occurred while the VPL and S1 neurons exhibited similar firing rates. This initially suggested a low dependence between the firing rate and the existence of DI. We then tested this hypothesis by correlating the firing rate driver and target neurons with the existence of incoming/outgoing DI (*SI Appendix*). The obtained Spearman correlation coefficients were significant but rather low for both driver (intervals = 206,360 in neuron pairs = 84, $\rho = 0.11$, $P < 0.05$; *SI Appendix*, Fig. S4*A*) and target neurons (intervals = 206,360 in neuron pairs = 84, $\rho = 0.07$, $P < 0.05$; *SI Appendix*, Fig. S4*A*). Moreover, these results were stable during stimulus-absent trials (intervals = 206,280 in neuron pairs = 84, $\rho = 0.1$ for driver spike trains, $\rho = 0.07$ for target spike trains, $P < 0.05$; *SI Appendix*, Fig. S4*B*). This shows that the increase in the number of DI estimates during the stimulus period could not be explained merely by an increase in the mean firing rate of either the VPL or S1 neurons.

The results shown above suggested that the firing rate might be poorly correlated with the distinct DI types. To specifically address this question, we first computed the time-varying correlation (Spearman's rho) between the firing rate in VPL and S1 neurons (*SI Appendix*, Fig. S4 *C* and *D*) associated with feed-forward, feed-back, and bidirectional information for stimulus-present (trials = 3,216 in neuron pairs = 84; *SI Appendix*, Fig. S4 *C* and *D*, *Left*) and stimulus-absent (trials = 4,371 in neuron pairs = 84; *SI Appendix*, Fig. S4 *C* and *D*, *Right*). The results show that the correlation values obtained during the entire time course of the task were upper-bounded by 0.1 for VPL neurons and by 0.2 for S1 neurons. For S1 neurons specifically, the correlation values decreased during the stimulus period. This implies that, for a substantial number of S1 neurons, the reported increase in firing rate (Fig. 1*E*) during the stimulus presence was not accompanied by an increase of incoming/outgoing DI with VPL. Besides, during the stimulus presence, the correlation values were larger for bidirectional information (rather than unidirectional) in VPL and S1 neurons, suggesting that neurons holding bidirectional information were particularly prone to have large firing rates. To further study this question, we examined the firing rate of VPL and S1 neurons associated with feed-forward, feed-back, and bidirectional information (Fig. 4 and *SI Appendix*). Our analysis revealed that the firing rate of VPL and S1 neurons was not significantly different ($n = 53$ and $n = 75$, respectively, Wilcoxon rank-sum test, $P > 0.05$; Fig. 4) between feed-forward and feed-back information across all task intervals, including those from the stimulus period. In contrast, neurons holding bidirectional information showed a significant increase in their firing rate with respect to the unidirectional case during the first interval of the stimulus period ($P < 0.05$; Fig. 4), in agreement with the reported larger correlation observed in the bidirectional type (*SI Appendix*, Fig. S4 *C* and *D*). These increases were manifested at suprathreshold stimulus amplitudes for VPL neurons ($n = 53$, $P < 0.001$; Fig. 4) during the entire stimulus period but for S1 neurons ($n = 75$, $P < 0.05$; Fig. 4) only during the first interval of the stimulus period. Interestingly, for stimulus-absent trials, bidirectional neurons showed enhanced firing

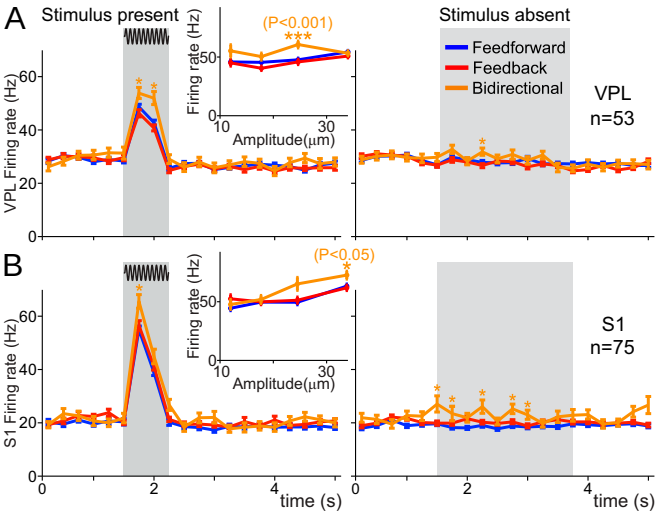

Fig. 4. Mean firing rate of VPL and S1 neurons during the detection task for feed-forward, feed-back, and bidirectional information. We analyzed hit and correct rejection trials across all recorded neurons in VPL and S1. For all panels, gray boxes depict the stimulus period for the stimulus-present trials (*Left*) and the PWS for the stimulus-absent trials (*Right*). Blue, red, and orange traces depict the mean firing rate for neurons holding feed-forward, feed-back, and bidirectional information, respectively, during the time course of the detection task (neuron pairs = 84). Error bars denote the SEM. (*A*) Mean firing rate for VPL neurons ($n = 53$; *Left*, trials = 1,995 hits; *Right*, trials = 2,764 correct rejections). Insets depict the mean firing rate as a function of the stimulus amplitude during the stimulus period. Asterisks denote significant differences (*$P < 0.05$, ***$P < 0.001$, Wilcoxon rank-sum test) among the firing rate of neurons holding distinct DI. (*B*) Similar to *A*, but for S1 neurons ($n = 75$; *Left*, trials = 2,853 hits; *Right*, trials = 3,854 correct rejections).

rates during PWS intervals compared with unidirectional neurons. In sum, these results show that firing rates were not able to discriminate between unidirectional information (feed-forward vs. feed-back) but could be significantly higher for bidirectional information during specific task intervals regardless of the stimulus presence.

Finally, we simulated a stochastic model to evaluate the performance of the DI estimation method as a function of the neuronal firing rate and assess any potential bias in the reported empirical correlations with the firing rate (*SI Appendix*, Fig. S5; details provided in the legend). The results of the model for parameter values that approximated the average firing rate of neurons and the percentage of DI measured in the real data validated that the spurious correlations introduced by the DI estimation method were very low for both unidirectional and bidirectional models (Spearman's rho < 0.08). In the meantime, the DI estimation method was shown to attain large sensitivity values (>90%) even for low firing rates (~35 Hz).

The Amount of VPL–S1 Directional Information Is Modulated by the Stimulus Amplitude. We showed above that both feed-forward and bidirectional VPL–S1 information was enhanced by the stimulus presence, while feed-back information was minimally affected (Fig. 3). Furthermore, each DI type could be modulated by different neuronal populations. This prompted us to hypothesize that feed-forward and bidirectional information could be differently related to the stimulus amplitude. To further investigate this question, we divided the stimulus-present trials into three groups based on the stimulus amplitude. We grouped the 9-μm trials within the near-threshold (Fig. 5*A*, *Top Right*) group and defined the suprathreshold (Fig. 5*A*, *Top Left*) and subthreshold (Fig. 5*A*, *Bottom Left*) groups as those stimulus-present trials above and below 9 μm, respectively. We choose 9 μm as the cutoff amplitude since it is the closer amplitude to the monkey's

Downloaded at Instituto de Biotecnologia/UNAM on October 20, 2020

mean detection threshold (8 μm; Fig. 1*B*). We also considered stimulus-absent trials for comparison (Fig. 5*A*, Bottom Right). First, we quantified the amount of DI within each group (Fig. 5*A*). Notably, we found that the stimulus effect observed for all amplitudes (Fig. 3*B*) was mainly due to the suprathreshold group (>9 μm). At these amplitudes, feed-forward and bidirectional information showed a significant incremental effect (trials = 2,237 in neuron pairs = 84, $P < 0.01$, $H = 0.26$ and $H = 0.14$; Fig. 5*A*, *Top Left*), while feed-back information was not significantly altered ($P > 0.05$). In contrast, for the near-threshold group, the feed-forward increment was preserved (trials = 443 in neuron pairs = 84, $P < 0.01$, $H = 0.2$; Fig. 5*A*, *Top Right*), while bidirectional information dropped dramatically ($P > 0.05$). Finally, the subthreshold amplitudes only showed a weaker significant increase in the amount of feed-forward information (trials = 536 in neuron pairs = 84, $P < 0.01$, $H = 0.13$; Fig. 5*A*, *Bottom Left*). Thus, the results illustrated in Fig. 5*A* demonstrated that the amount of DI was amplitude-dependent. To examine this dependency, we focused on the first 250 ms of the stimulus-present period and plotted the percentage of DI types as a function of the stimulus amplitude (Fig. 5*B*). In addition, we computed single-trial (r) and average-trial (R) Spearman's rho correlations between the amount of DI and amplitude values (*SI Appendix*). During the first 250 ms the amount of each DI type was correlated with the stimulus amplitude values as measured by single-trial types ($P < 0.05$; Fig. 5*B*). However, when considering average-trial correlations, the significance analysis provided different outcomes across DI types. Indeed, Fig. 5*B* shows that feed-forward (trials = 7,587, $r = 0.12$ in neuron pairs = 84, $R = 0.96$, $P < 0.01$; Fig. 5*B*, *Left*) and bidirectional (trials = 7,587, $r = 0.07$ in neuron pairs = 84, $R = 0.87$, $P < 0.05$; Fig. 5*B*, *Right*) information exhibited a significant monotonic modulation, while feed-back information remained approximately constant over the amplitude values (trials = 7,587, $r = 0.03$ in neuron pairs = 84, R = 0.26, $P > 0.05$; Fig. 5*B*, *Middle*). These effects are further illustrated in *SI Appendix*, Fig. S6 by representing feed-back and bidirectional against feed-forward information, which suggested that the bidirectional trend was mainly driven by suprathreshold amplitudes. These results complemented the analysis of Fig. 5*A*, revealing that the amount of feed-forward and bidirectional information was monotonically associated with the stimulus amplitude. Overall, feed-forward and bidirectional information was enhanced by the stimulus presence and they could convey information about the stimulus amplitude.

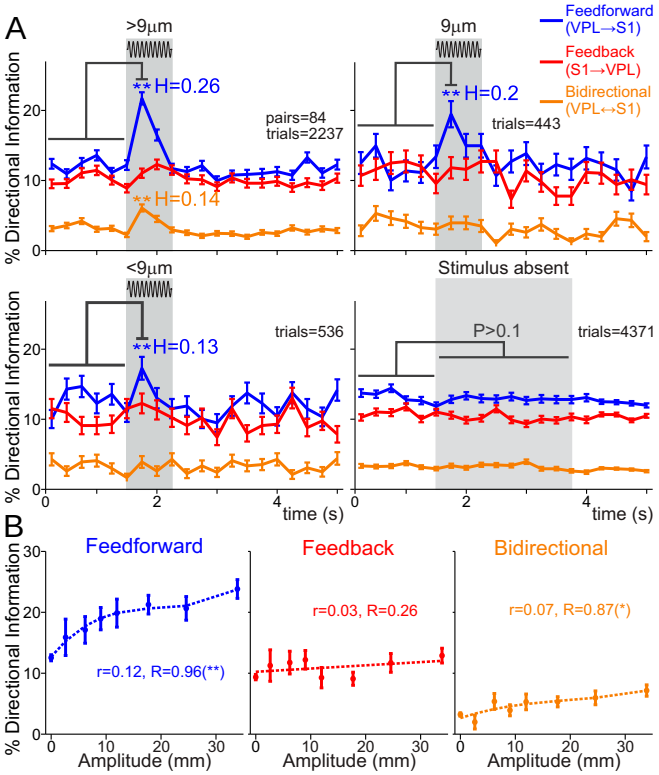

Fig. 5. VPL–S1 feed-forward and bidirectional information is modulated by the stimulus amplitude. We analyzed hit and correct rejection trials across all VPL–S1 neuron pairs. Hit trials were subdivided into three categories (suprathreshold, near threshold, and subthreshold). (*A*) Time course of the percentage of feed-forward (VPL → S1, blue), feed-back (S1 → VPL, red), and bidirectional (S1 ↔ VPL, orange) information between VPL and S1 neurons during stimulus-present and stimulus-absent trials. From left to right and from top to bottom: percentage of DI for suprathreshold (>9 μm, neuron pairs = 84; trials = 2,237 hits; *Top Left*), near threshold (9 μm, neuron pairs = 84; trials = 443 hits; *Top Right*), subthreshold (<9 μm, neuron pairs = 84; trials = 536 hits; *Bottom Left*) stimulus amplitudes, and stimulus-absent trials (neuron pairs = 84; trials = 4,371 correct rejections; *Bottom Right*). Asterisks denote significance levels (**$P < 0.01$; nonparametric test) between the prestimulus (first six task intervals, 1.5 s) and the first half (0 to 0.25 s) of the stimulus period. *H* denotes the effect size (Cohen's *H*) of significant percentage differences. Error bars denote the SEM. (*B*) Mean percentage of feed-forward, feed-back, and bidirectional information as a function of the stimulus amplitude during the first half of the stimulus period (*Left*, 250 ms). The value r is the correlation between the stimulus amplitude and the existence of DI in each type across all trials (no amplitude averages) with Spearman correlation (trials = 7,587). The value R is the analogous correlation considering amplitude-average values (number of stimulus amplitudes = 8). Asterisks depict significance (*$P < 0.05$, **$P < 0.01$, Spearman correlation). Error bars denote the SEM.

Influence of Task Context in Thalamocortical Directional Information. We showed above that for most recorded VPL–S1 neuron pairs there was more feed-forward than feed-back information during the first half (250 ms) of the stimulus-present trials. This differentiated amount of DI was related exclusively to sensory information processing, but whether it was also influenced by the task's context remained unknown. To investigate this question, we applied our directionality analysis to a control task in which the monkey was passively stimulated by the same set of tactile stimuli but no perceptual report was required. Using task-balanced datasets (*SI Appendix*), we repeated some of the previous analyses for stimulus-present trials (neuron pairs = 36, trials = 1,307 hits) and stimulus-absent trials (neuron pairs = 36, trials = 1,364 control rejects) in both task conditions, exploring potential differences in the percentage of DI when the monkey was passively stimulated (Fig. 6). Based on the previous analysis of amplitude modulation (Fig. 5), we restricted our analysis during stimulus-present trials to near-threshold and suprathreshold amplitudes for feed-forward information (neuron pairs = 36, trials = 1,105 hits) and suprathreshold amplitudes for feed-back and bidirectional information (neuron pairs = 36, trials = 932 hits).

We first revisited the firing rate of single neurons in VPL and S1 (17, 18) and found that the average (over neurons) firing rate of each area was not substantially altered during the time course of the passive stimulation task (Fig. 6*A*). Consistent with this quantification, we thereafter analyzed the percentage of DI during the passive condition over all neuron pairs that had been recorded in both task conditions. For these paired samples, we outlined task intervals where the difference was significant and the effect size was larger than 0.3. In general, our analysis revealed task-specific variations at the level of DI, which occurred around the stimulus period for stimulus-present trials (Fig. 6 *B–D*, *Left*). Compared with the vibrotactile task, the arrival of the (suprathreshold) stimulus in passive trials produced a lesser increase of bidirectional information (neuron pairs = 36; Fig. 6*D*, *Left*) during the second half of the stimulus window and a specific increase of feed-back information during the first 250 ms

Downloaded at Instituto de Biotecnología/UNAM on October 20, 2020

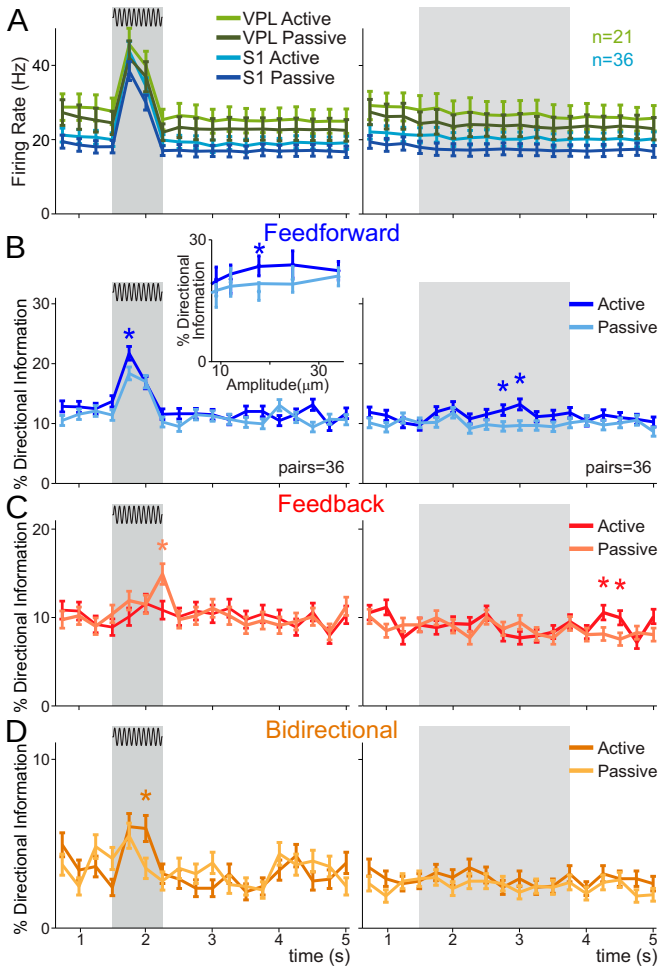

Fig. 6. VPL–S1 DI during passive stimulation. For the comparison between the vibrotactile detection task and the passive stimulation task, we analyzed supra- and near-threshold hit trials for feed-forward information and suprathreshold hit trials for feed-back and bidirectional information in addition to correct rejection trials. The left panels depict stimulus-present trials, whereas the right side depict stimulus-absent trials. Dark and light colors depict DI data belonging to the active and passive conditions, respectively. (*A*) Time course of the mean firing rates for VPL (n = 21) and S1 (n = 36) neurons. The same neuron pairs (pairs = 36) were simultaneously recorded during the detection task and passive stimulation. (*B*) Time course of the percentage of feed-forward information (pairs = 36; trials = 1,105 hits; trials = 1,364 correct rejections). (*Inset*) The percentage of feed-forward information as a function of stimulus amplitude. (*C*) Percentage of feed-back information for the active and passive conditions across time (pairs = 36; trials = 932 hits; trials = 1,364 correct rejections). (*D*) Percentage of bidirectional information across time (pairs = 36; trials = 932 hits; trials = 1,364 correct rejections). Asterisks denote significance levels (*P < 0.05, nonparametric balanced test) associated with effect sizes (Cohen's H) larger than 0.3.

of the poststimulation window (neuron pairs = 36; Fig. 6*C*, *Left*). Notably, feed-forward information was significantly higher in the active than the passive condition, both during the stimulus period (Fig. 6*B*, *Left*) and PWS (Fig. 6*B*, *Right*). Thus, our findings show that DI across VPL–S1 neuron pairs was sensitive to the task context. In particular, passive stimulation mitigated the amount of bidirectional information during stimulus delivery while enhancing feed-back information with a certain delay.

Influence of the Task on Zero-Lag Interactions. A priori, we defined DI types by matching the location of driver or target neurons to either VPL, S1, or both. However, the characterization of each DI type presented in *SI Appendix*, Fig. S2 unraveled features that could give rise to new characterizations. More specifically, the large percentage of bidirectional information occurring at zero delay (≥33%; *SI Appendix*, Fig. S2*B*) suggested that the zero-delay case could partially explain the trends reported for the bidirectional type. To study this question in detail, we decomposed bidirectional information into two subtypes: zero lag, for which both DI statistics (one per direction) were significant at zero delay, and non-zero lag, for which both statistics were simultaneously significant at non-zero delays (*SI Appendix*). We repeated most of the previous analyses on these two subtypes (Fig. 7). To begin with, we represented the time-varying percentage of each DI subtype during the time course of the task (Fig. 7*A*). Crucially, Fig. 7*A* shows that only zero-lag bidirectional information was significantly increased during the first 250 ms of the stimulus period ($P < 0.05$, $H > 0.14$; Fig. 7*A*, *Left*) and hence the reported overall bidirectional increase ($H = 0.1$; Fig. 7*A*, *Left*) was due to the zero-delay subtype. We then related zero-lag and non-zero lag bidirectional information with the firing rate of neurons in VPL and S1 ($n = 53$ and $n = 75$, respectively; Fig. 7 *B* and *C*). The results highlight that the firing rate of neurons holding zero-lag bidirectional information was frequently larger than those with non-zero lag (Wilcoxon rank-sum test, $P < 0.05$). Nonetheless, *SI Appendix*, Fig. S7 *A* and *B* validated that this enhancement of the firing rate did not simply follow from a larger correlation between the firing rate and zero-lag bidirectional information compared with other DI types (Spearman's rho < 0.2). Another reported feature of bidirectional information was its monotonic association with the stimulus amplitude (Fig. 5 and *SI Appendix*, Fig. S7*C*, *Left*). Hence, in light of the new decomposition, we investigated the contribution of the zero-lag sub-type to this trend. Performing the same analysis of Fig. 5*B*, we found that the modulation of bidirectional information by the stimulus amplitude was mostly explained by zero-lag bidirectional information (trials = 7,587, r = 0.06 in neuron pairs = 84, $R = 0.81$, $P < 0.05$; *SI Appendix*, Fig. S7*B*). Finally, we investigated the influence of the task context into zero-lag bidirectional information (Fig. 7*D*). In line with our previous analysis (Fig. 6*D*), we considered suprathreshold amplitudes (neuron pairs = 36, trials = 932 hits) and compared the amount of zero-lag bidirectional information across the same neurons pairs in both tasks. Critically, as compared to the original task ($P < 0.05$), zero-lag bidirectional information was not altered by the stimulus presence during passive stimulation. In contrast, this context effect was not observed in non-zero-lag bidirectional information. Taken together, we concluded that the distinctive features of bidirectional information reported so far were essentially occurring at zero delay. For the sake of interpretability, zero-lag bidirectional information will be referred to hereafter in short as zero-lag interaction.

Feed-Forward Information Correlates with the Animal's Task Performance. An important question is whether the DI across VPL–S1 neuron pairs is modulated by the animal's task performance. To further examine this question, we first analyzed the differences between hit and miss trials during the stimulus-present condition (Fig. 8*A*, *Left*) and between correct rejections and false-alarm trials during stimulus-absent trials (Fig. 8*A*, *Right*) across single neuron firing rates (Fig. 8*A*) and DI types (Fig. 8 *B*–*D*). In stimulus-present trials, we controlled for the effect of stimulus amplitudes by analyzing the difference between hits and misses at the near-threshold amplitude value (9 μm), where the number of samples was the most balanced between hit (trials = 443 hits in neuron pairs = 79) and miss responses (trials = 389 misses in neuron pairs = 79). In both experimental conditions, we controlled for a possible sample bias and experimental sessions effect, by using group-based permutation tests at the level of neuron pairs (*SI Appendix*). We then outlined task

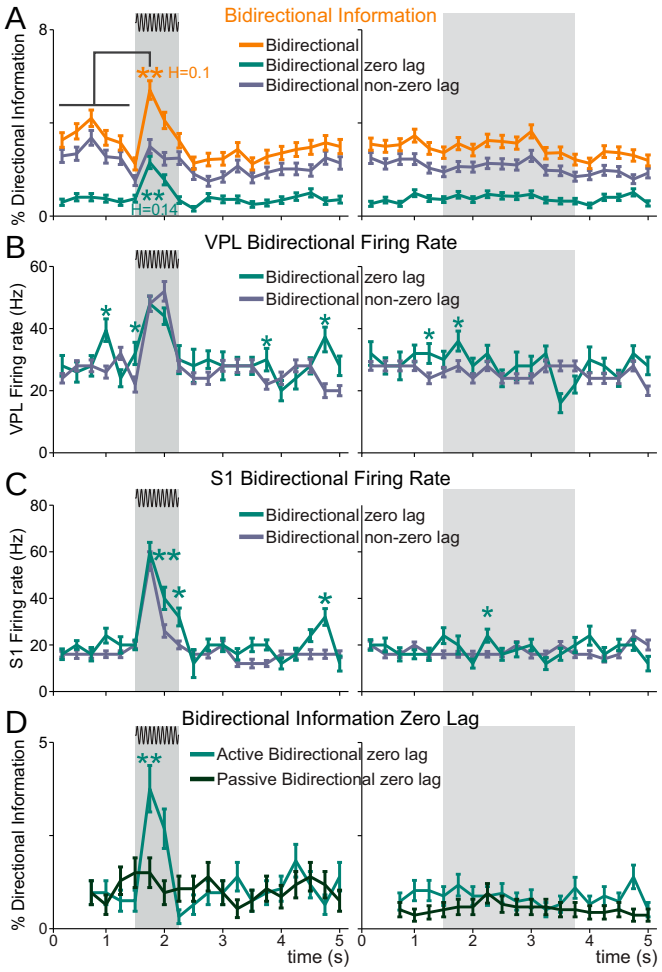

Fig. 7. Bidirectional information across zero-lag and non-zero-lag trials. We analyzed suprathreshold hit and correct rejection (CR) trials across neuron pairs. Error bars denote the SEM. (*A*) Percentage of overall bidirectional information (pairs = 84), zero-lag, and non-zero-lag bidirectional information across the task during stimulus-present (*Left*, trials = 3,216 hits) and stimulus-absent trials (*Right*, trials = 4,371 CR). Asterisks denote significant differences (**$P < 0.01$, nonparametric test) between the prestimulus (first six task intervals, 1.5 s) and the first half (0 to 0.25 s) of the stimulus period. H denotes the effect size (Cohen's *H*) of significant differences. (*B*) Mean firing rate for VPL neurons ($n = 53$; *Left*, trials = 1,995 hits; *Right*, trials = 2,764 CR). Asterisks denote significant differences (*$P < 0.05$; **$P < 0.01$; Wilcoxon rank-sum test) among the firing rate of neurons holding zero-lag and non-zero-lag bidirectional information. (*C*) Similar to *B*, but for S1 neurons ($n = 75$; *Left*, trials = 2,853 hits; *Right*, trials = 3,854 CR). (*D*) Percentage of zero-lag and non-zero-lag bidirectional information during suprathreshold and stimulus-absent trials (n pairs = 36; trials = 932 hits; trials = 1,364 CR) across the detection task and passive stimulation. Asterisks denote significance levels (**$P < 0.01$; nonparametric balanced test) associated with effect sizes (Cohen's *H*) larger than 0.3.

intervals where the difference was significant and the effect size was larger than 0.2. Our analysis primarily revealed that the amount of feed-forward information during the first half of the stimulus period in stimulus-present trials was significantly larger ($P < 0.05$, $H > 0.2$) in hit trials (Fig. 8*A*, *Left*). In contrast, our data did not unravel strong significant differences between correct rejections and false alarms during stimulus-absent trials (trials = 4,188 correct rejections and false alarm trials = 933 in neuron pairs = 82; Fig. 8*A*, *Right*). Overall, our results indicate that the amount of feed-forward information during the first half of the stimulus window was correlated with the monkey's behavior and could potentially predict the monkey's performance in stimulus-present trials (Fig. 8*B*, *Left*).

Discussion

Here, we sought to determine the functional roles of thalamocortical information flows in perception at a fine temporal scale. This was done by estimating a directional information measure (referred to as DI) between simultaneously recorded VPL–S1 neuron pairs sharing the same cutaneous receptive field while monkeys performed a vibrotactile detection task. Notably, the estimated DI could not be merely explained by increases in the firing rates of neurons within VPL or S1 during the stimulus period. We found that the stimulus presence elicited a significant increment on the amount of feed-forward information (VPL → S1) and zero-lag interaction. In

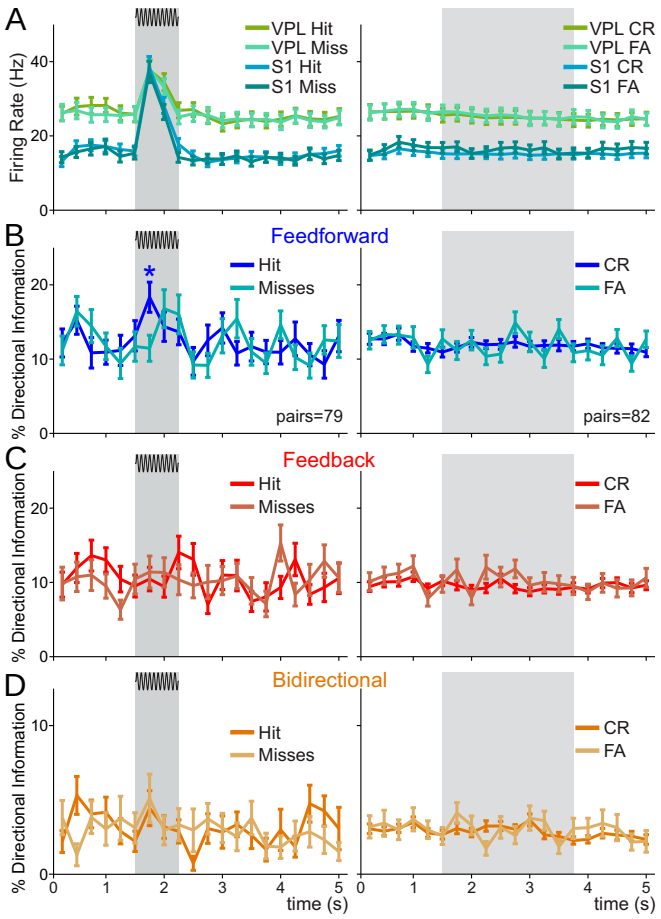

Fig. 8. VPL–S1 DI during correct and error trials. We analyzed hit and miss trials for near-threshold (9 μm) amplitudes as well as correct rejection trials and false alarms across all VPL–S1 neuron pairs. (*A*) Time course of the mean firing rate VPL ($n = 48$) and S1 ($n = 70$) neurons during stimulus-present trials and for VPL ($n = 51$) and S1 ($n = 73$) neurons during stimulus-absent trials. Neuronal responses were separated according to the monkey's behavioral output. (*Left*) Hits and misses for the stimulus-present trials. (*Right*) Correct rejections and false alarms for stimulus-absent trials. Neurons and pairs were selected to have more than two trials at near-threshold amplitude for each condition. (*B*) Time course for the percentage of feed-forward information. (*C*) Time course for the percentage of feed-back information. (*D*) Time course for the percentage of bidirectional information. (*B–D*, *Left*) Hits (dark colors) and misses (light colors) for the stimulus-present trials (neuron pairs = 79; trials = 443 hits; trials = 389 misses). (*B–D*, *Right*) Correct rejections (dark colors) and false alarms (light colors) for the stimulus-absent trials (neuron pairs = 82; trials = 4,188 correct rejections; trials = 933 false alarms). Asterisk denotes significance level (*$P < 0.05$; nonparametric test) associated with effect sizes (Cohen's *H*) larger than 0.2.

contrast, pure feed-back (S1 → VPL) information remained practically unaltered during the stimulus presence. Remarkably, increments in feed-forward and zero-lag interaction were differently modulated as a function of the stimulus amplitude. Specifically, we found a monotonic relationship between both feed-forward and zero-lag interaction and the stimulus amplitude. However, zero-lag interaction only emerged significantly with suprathreshold sensory inputs during task performance. Additionally, we identified that thalamic and cortical neurons involved in bidirectional information exhibited higher firing rates during stimulus presence. Interestingly, the amount of feed-forward information was correlated with the monkeys' performance when they judged the presence at near-threshold stimuli. Also, during a passive stimulation task, when the monkeys were not required to report their percepts, both feed-forward and, more prominently, zero-lag interaction were reduced during the stimulus presence. This suggests that feed-forward information and zero-lag interaction are modulated by the task context. We discuss these findings below.

In the current study, we extended previous spectral and neural population studies on thalamocortical directionality (10, 27–29) to the temporal domain, at the level of single-neuron activity. To achieve this, we analyzed the DI between VPL and S1 neuronal spike trains with a nonlinear measure (5, 20, 21). Indeed, we decomposed single-neuron DI into three types, feed-forward, feed-back, and bidirectional, and explored their temporal evolution from the prestimulus up to the poststimulus intervals of the detection task. In particular, the lack of pure feed-back modulation (i.e., not concurrent to feed-forward information) during the stimulus period suggests that the spike-field coherence increment in the S1 → VPL direction shown in ref. 29 could be associated with increments in zero-lag interaction. Our data analysis approach involved the use of nonparametric significance tests (30) and the choice of the percentage of significant DI estimates as a relevant connectivity metric (5). Both choices were critical to detect nonlinear spike-train temporal correlations in a way that was shown to be weakly dependent on the firing rate in real and simulated data. As a result, we were able to analyze neuronal data in a dimension that was quasi-orthogonal to the firing rates (17, 18), while still showing rich stimulus modulations. It is important to mention the differences between the DI measure used here and the widespread measure of noise correlation (31, 32). Noise correlation averages across trials under the same stimulus condition, correlating fluctuations in firing rate of two neurons. In contrast, DI quantifies, in a single trial and for any given time, the information that the recent past and present spike train of a given neuron has about the present spike train of the other, simultaneously recorded, neuron.

Notably, feed-forward VPL–S1 information was modulated during the stimulus period. Further, the modulation was stronger 250 ms immediately after the stimulus onset. These findings are congruent with the adaptation of feed-forward information over the stimulus period. Indeed, previous studies have shown that thalamic and cortical neurons become adapted to tactile stimuli after several pulses (17, 18, 33). Moreover, it has been reported that this adaptation changes the neural code of cortical neurons and thalamic synchrony from a detection to a discrimination modality (34). As stated above, our directionality measure is poorly correlated with differences in firing rate of VPL and S1 neurons. Therefore, our results are congruent with the adaptive coding paradigm (34), by showing that feed-forward and zero-lag interactions exhibit the strongest modulation during the first part of the stimulus presence. In sum, we hypothesize that feed-forward adaptation reflects an internal mechanism that prioritizes the information contained within the first pulses of the sinusoidal stimulus to further transmit this information to the cortex and, therefore, for stimulus detection during this task.

According to the standard classification of thalamic sensory nuclei (6), VPL is considered a first-order relay nucleus that mainly transmits afferent information to S1 in the presence of cortical feedback (9, 35, 36). Our results support this view by showing that feed-forward information alone was primarily boosted during the first 250 ms immediately after the stimulus onset. The increment in feed-forward information was concentrated at a delay of 8 ms, which is consistent with previous literature (37). Moreover, these increments were reduced during incorrect trials and, to a lesser extent, during the passive control condition. In particular, the relationship between feed-forward information and the monkey's performance during stimulus-present trials is of special novelty. In previous related studies, this correlation did not arise either in spiking activity (18) or in the oscillatory activity (29). This result suggests that perceptual detection might be related to the amount of stimulus information flowing from VPL to S1. In contrast, pure feed-back information did not display substantial task modulations. We hypothesize that pure feed-back information might be relevant for perceptual detection but is generally less frequent than feed-forward information. However, cortical areas and higher-order thalamic nuclei (reviewed in ref. 38) might show more prominent feed-back corticothalamic information, perhaps related not only to facilitating the gating of the stimulus but also to some other cognitive aspects not detected in this task (however, see the discussion below).

Our study revealed that feed-back information could take place concurrently with feed-forward information, suggesting the emergence of a thalamocortical loop, denominated here in sum as bidirectional information. In particular, our analysis identified that bidirectional information showed bimodality between those cases where DI simultaneously occurred at zero delay (zero-lag interaction) and those cases at non-zero delay. Crucially, only zero-lag interaction was modulated by the stimulus presence, involved neurons exhibiting higher firing rates than in the unidirectional case, and was significantly diminished in the passive stimulation task. Hence, zero-lag interaction conveyed both stimulus and contextual information, thus indicating that its mechanism might be different from the non-zero subtype. Unlike the feed-forward type, we suggest that zero-lag interaction may not reflect direct routing of information (39). Instead, it could be established by common inputs from mediating cortical neurons. In particular, it will be interesting in future studies to simultaneously record the activity of higher-order areas like prefrontal cortex to examine how common cortical inputs driving zero-lag interactions (40) are associated with the expectancy caused by different prestimulus period times, a variable that was out of the scope of this study. In light of the existing models of corticothalamic circuitry (ref. 7 and Fig. 1), we hypothesize that the inferred feed-forward thalamocortical information could be related to layer 4 (15) as well as deep cortical layers 5/6 in S1 (41). In fact, future experiments involving multicontact electrodes and inactivation are needed to shed light on the contribution of the distinct cortical layers to the information flow within the thalamocortical circuit. However, we consider that the task-context modulation of zero-lag interaction requires the engagement of downstream cortical areas in this loop. Specifically, in concordance with computational models supporting zero-lag brain interarea synchronization (42–44), we propose that zero-lag interaction could be originated by a top-down modulation of cortical areas, establishing a similarly delayed reciprocal loop with both S1 and the thalamus (9, 45).

Recently, a study in monkeys performing a visual detection task was also able to relate the propagation of neural activity along the visual pathway with the monkey's detection accuracy (46). The authors showed that information about unreported stimuli may be lost at any stage of the pathway (V1–V4–prefrontal cortex) with an overall excursion that depended on the stimulus strength. Despite the methodological differences with the study presented here [the authors recorded cortical areas along the visual

Downloaded at Instituto de Biotecnologia/UNAM on October 20, 2020

pathway, analyzed multiunit activity (MUA) instead of single-unit activity, indirectly measured activity propagation via local MUA, and used microstimulation, among others], their results suggest that stimulus perception of near-threshold stimuli may depend on the feed-forward information flow across the early stages of the sensory pathway. More specifically, they explain their results with a model involving thalamocortical and corticocortical propagation, but no corticothalamic projections. While our main findings may fit in this model (see also ref. 3), the task modulation of zero-lag interaction between VPL and S1 suggests the additional existence of indirect corticothalamic pathways toward VPL in the somatosensory model.

In brief, the present study employed a fine-temporal methodology supporting that the increment of VPL → S1 neuronal DI (as opposed to S1 → VPL) at around 8 ms during the stimulus period reflects the effective transmission of tactile information from thalamus to cortex. Moreover, it suggests that the amount of feed-forward information occurring during the first 250 ms of stimulation correlates with the monkey's stimulus perception and with the behavioral task performance. Meanwhile, zero-lag interaction, which was reduced when monkeys were not required to report stimulus presence, may reflect the top-down modulation of the corticothalamic circuitry needed for stimulus perception. Our results, therefore, contribute to understanding the DI functional flow between the VPL and S1 during the detection of a tactile stimulus. Finally, the minimalistic approach used here, that is, the simultaneous recording of VPL–S1 neuron pairs sharing the same receptive field, together with the estimation of DI flow, could be used not only to investigate the functional role of the thalamocortical DI during perception but also across other brain areas in this and other behavioral tasks.

Materials and Methods

Monkeys were trained to report whether or not they felt the stimulus (*SI Appendix*). Neuronal recordings were obtained in VPL and S1 while the monkeys performed the detection task. Directional information was calculated between neuron pairs simultaneously recorded in VPL and S1 (*SI Appendix*). Animals were handled in accordance with standards of the National Institutes of Health and Society for Neuroscience. All protocols were approved by the Institutional Animal Care and Use Committee of the Instituto de Fisiología Celular, Universidad Nacional Autónoma de México.

ABSTRACT

Interferon-stimulated gene 15 (ISG15) is a ubiquitin-like protein that conjugates to its target proteins to modify them through ISGylation, but the relevance of *ISG15* expression and its effects have been not completely defined. Herein, we examined the interplay between ISG15/ISGylation and the interferon-gamma (IFN-γ) signaling pathway in mammary tumors and compared it with that in normal mammary tissues. Our results indicated that mammary tumors had higher levels of *ISG15* mRNA and ISG15 protein than the adjacent normal mammary tissue. Furthermore, the expression of IFN-γ signaling components was altered in breast cancer. Interestingly, IFN-γ treatment induced morphological changes in MCF-7 and MDA-MB-231 breast cancer cell lines due to cytoskeletal reorganization. This cellular process seems to be related to the increase in ISGylation of cytoplasmic IQ Motif Containing GTPase Activating Protein 1 (IQGAP1). Interactome analysis also indicated that IFN-γ signaling and the ISGylation system are associated with several proteins implicated in cytoskeletal remodeling, including IQGAP1. Thus, ISG15 may present a potential biomarker for breast cancer, and IFN-γ signaling and protein ISGylation may participate in the regulation of the cytoskeleton in breast cancer cells.

1. Introduction

IFN-γ is a unique member of the type II interferon family, and possesses important immunomodulatory and antiviral properties but has ambiguous functions in several cancers. The canonical signaling of IFN-γ requires a specific heterotetrameric receptor complex formed by IFNGR1 and IFNGR2 subunits and the JAK-STAT1 system. In response to the binding of IFN-γ to its receptor complex, activated JAKs1/2 (associated with the receptor complex in the intracellular region) mediates STAT1 phosphorylation. Activated STAT1 homodimers bind to the gamma interferon activated site (GAS) localized in the regulatory sequences of IFN-γ target genes to modulate gene expression [1,2]. Genes induced by IFN-γ include *IRF-1/2* [3–5], *RIG-1* [6–9], *SOCS1/3* [10] *SMAD7* [11], and genes implicated in antigen presentation by major histocompatibility complex (MHC) class I and II [12,13] *IRF-1* mediates IFN-γ-induced expression of late genes, while *IRF-2* represses the transcription of these genes [5]; *RIG-1* has antiviral, immunomodulatory, and suppressor tumor activities and regulates the expression of some genes [6–9]. *SOCS1/3* inhibits IFNs-signaling, and *SMAD7* is a negative regulator of TGFβ signaling [10,11]. Interestingly, in breast cancer, it has been suggested that IFN-γ induces apoptosis and cell cycle arrest, and also that there is autocrine signaling by IFN-γ in these cells [14,15]. Additionally, a gene signature regulated by IFNs may be associated with sensitivity and/or resistance to chemotherapy and endocrine therapy observed in breast cancer cells [16,17].

There is a high rate of heterogeneity observed in breast cancers. Approximately 70% of the cases are estrogen receptor-α positive (ERα+), and the residual cases are ERα-. In both cases, mechanisms that modulate ERα activity and expression appear to be deregulated [18–20]. Previously, we demonstrated that IFN-γ increases ISG15 (Interferon-stimulated gene 15) protein levels in ERα + and ERα- breast cancer cells in addition to type I interferons (IFN-α and IFN-β) that had been previously considered to be the exclusive inducers of ISG15 in other cell types [21–24].

ISG15 is a 15 kDa ubiquitin-like protein that conjugates to its target proteins in a covalent manner through an enzymatic process similar to ubiquitination [25–28]. This process is known as ISGylation and the enzymes involved are the E1-activating (UBE1L), E2-conjugating (UBCH8) [29], and E3 ligase enzymes (HERC5, EFP, and HHARI) [30–33], as well as the de-ISGylase enzyme USP18 that removes

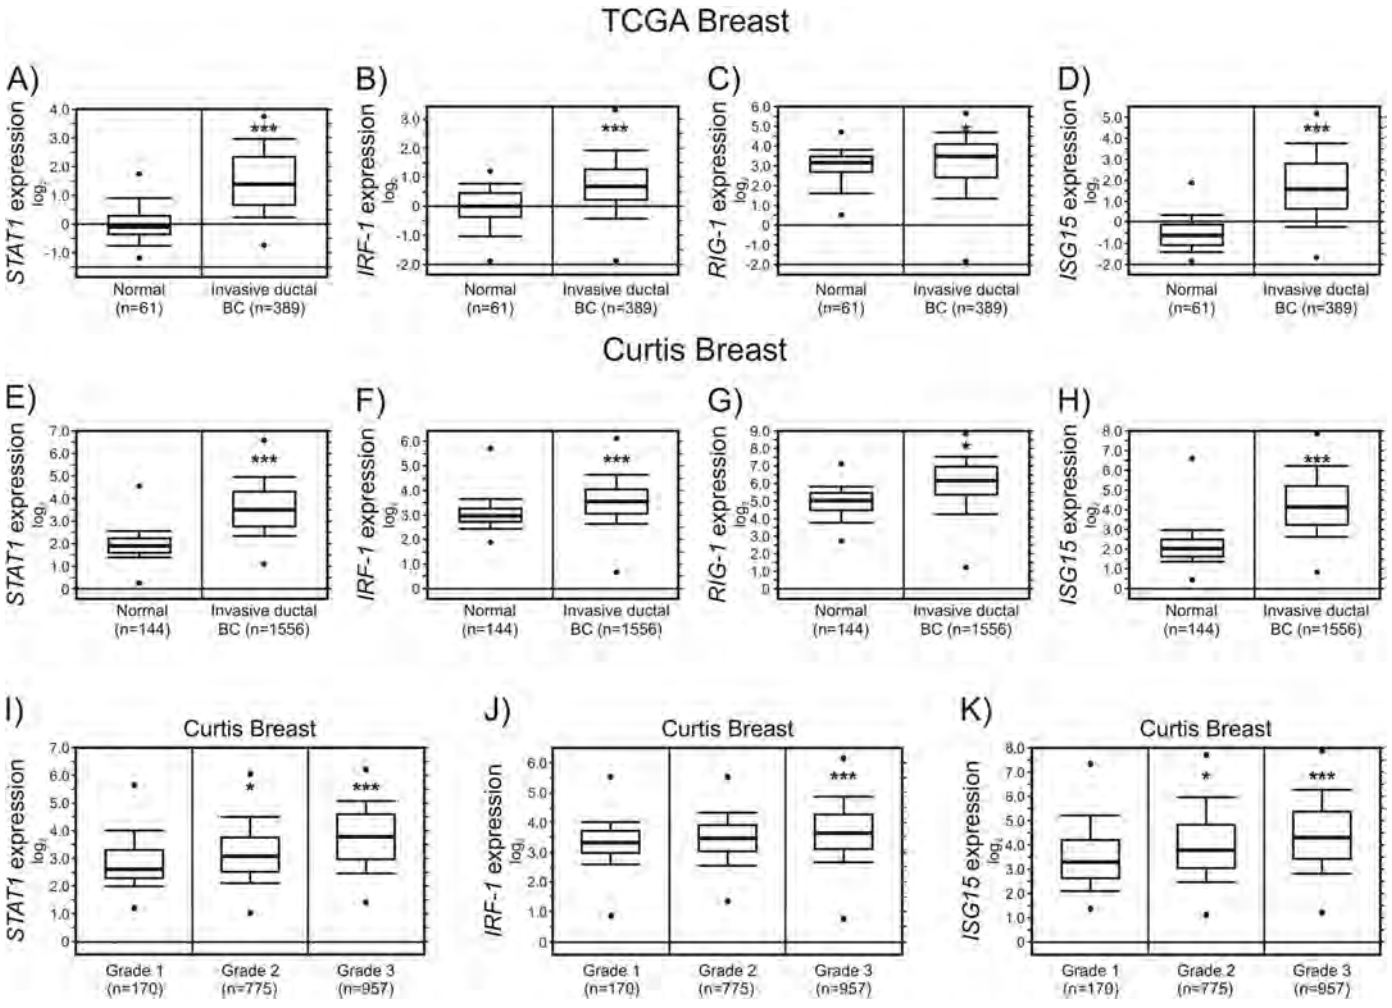

Fig. 1. Increased expression of *STAT1*, *RIG-1*, and *ISG15* in mammary tumors. A-D) TCGA (The Cancer Genome Atlas) and *E*-H) Curtis datasets from Oncomine were analyzed to evaluate *STAT1, IRF-1, RIG1*, and *ISG15* expression in human mammary tumors compared to those in normal tissue. I—K) Curtis dataset was analyzed to determine the *STAT1, IRF-1,* and *ISG15* expression in mammary tumors of grade 1, 2, and 3. Results are considered significant when $p < .05$ (*), $p < .01$ (**) and $p < .001$ (***).

ISGylation of proteins [34]. Additionally, ISG15 can also be detected as free ISG15 when it is not covalently bound to a target protein [35–37]. The function of ISGylated proteins is unclear, as this modification can interfere with and also collaborate with the ubiquitination pathway [38–42].

In breast cancer, it has been shown *in vivo* experiments using athymic mice models demonstrate that depletion of ISG15 enhances tumor development. In contrast, downregulation of ISG15 has been shown to decrease proliferation and migration in breast cancer cell lines *in vitro* [38,43,44]. Although ISGylation functions are yet to be elucidated, since only a limited number of proteins modified by ISG15 are known, it is evident that expression of ISG15 affects the malignancy of breast cancer cells, and many proteins may be modulated by ISGylation under this condition.

In order to explore the significance of ISG15 expression in patients diagnosed with breast cancer, we analyzed the levels of ISG15 and the expression of IFN-γ signaling components in normal and mammary tumor tissues. We probed the effect of IFN-γ on viability, morphology, and protein ISGylation in breast cancer cells. Our data indicate that ISG15 can act as a potential biomarker for breast cancer. Our findings also suggest important implications for IFN-γ induced protein ISGylation in the biology of breast cancer cells.

2. Materials and methods

2.1. Reagents and cell lines

Recombinant human IFN-γ (285-IF-00) was obtained from R&D systems, culture media were obtained from Invitrogen, and reagents were obtained from Sigma, AMRESCO-VWR, and Bio-Rad. The MDA-MB-231 (ERα-, triple negative breast cancer cells), and MCF-7 (ERα + breast cancer cells) cell lines were maintained in Dulbecco's modified Eagle's medium supplemented with 5% fetal bovine serum and penicillin/streptomycin.

2.2. Subcellular fractionation and total extracts

Nuclear and cytoplasmic fractions were obtained by subcellular fractionation as described previously [23,45]. Using homogenization buffer (250 mM sucrose, 3 mM imidazole protease, and phosphatase inhibitors), the cells were homogenized and then passed 15 times through a 22-gauge needle. The homogenized cells were then centrifuged at 700 × *g* for 10 min to separate the supernatant (cytoplasmic fraction) from the pellet (nuclear fraction). Both fractions were lysed with RIPA buffer (50 mM Tris-HCl pH 7.4, 150 mM NaCl, 1 mM EDTA, 0.5% deoxycholic acid, 1% NP-40, and 0.1% SDS) containing protease and phosphatase inhibitors. For total extracts, the cells were directly

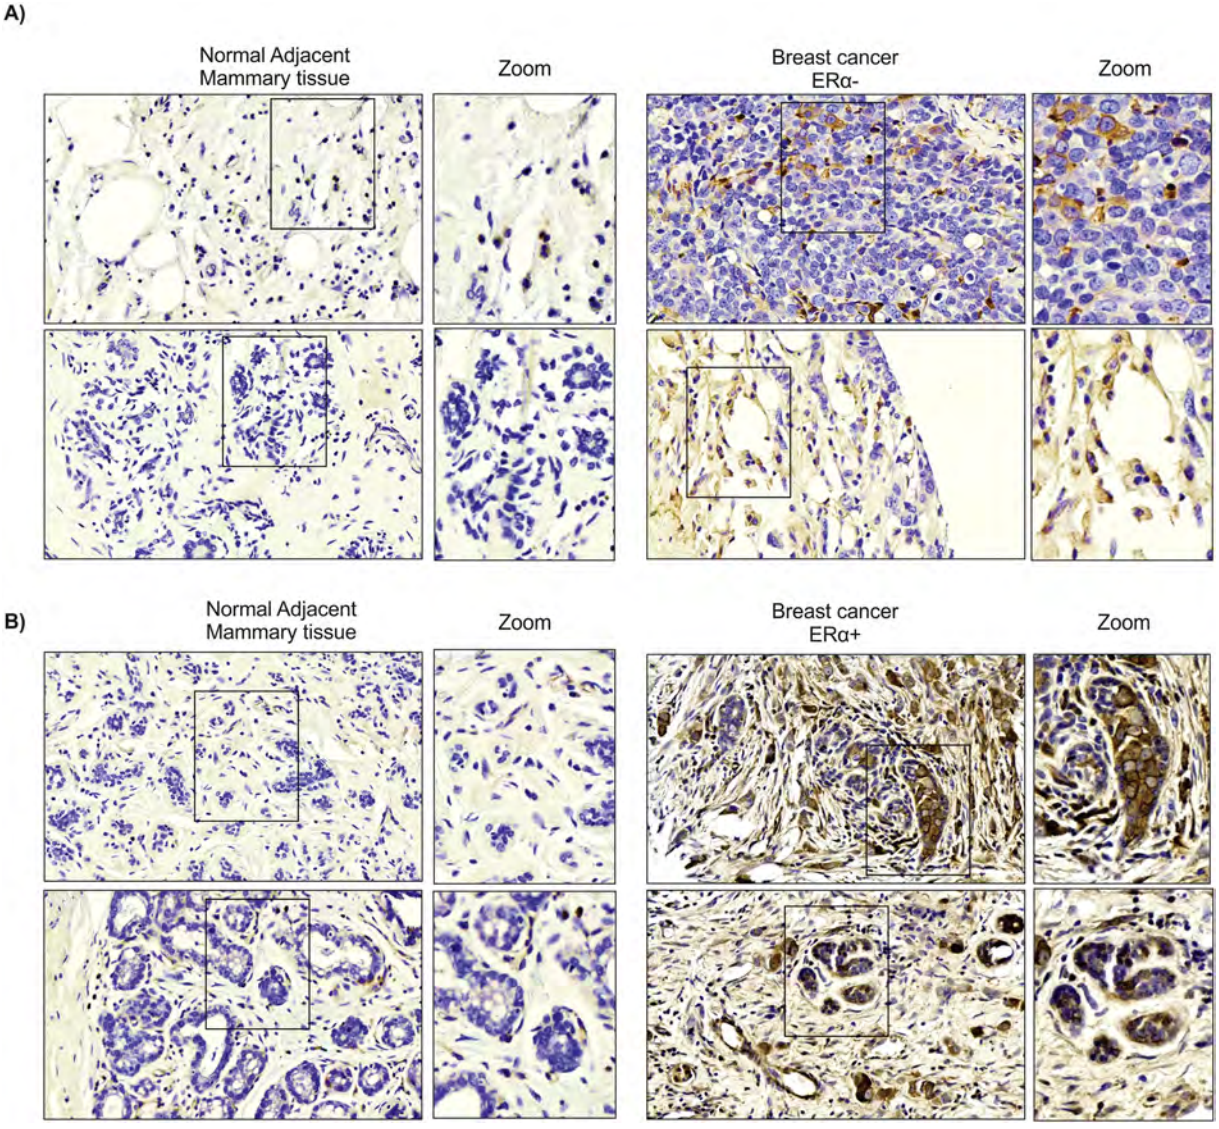

Fig. 2. ISG15 is detected at higher levels in mammary tumors than in adjacent normal mammary tissue.
A, B) Immunohistochemical (IHC) analysis of ISG15 protein expression in invasive ERα + and ERα- breast carcinomas. ISG15 protein expression is predominant in ERα + and ERα- breast cancer tissue in comparison with that in normal adjacent mammary tissue. 20× magnification of representative images. ISG15 protein is mainly detected in the cytoplasm of ERα + and ERα- mammary tumors from patients (A and B, zoom).

lysed with RIPA buffer. Lysis was performed at 4 °C for 1 h, and protein extracts were quantified using the Bradford method for WB and immunoprecipitation assays.

2.3. Cell viability assays

For the determination of cellular viability, calcein-AM (green) and propidium iodide or PI (red) assays were performed. Viable cells

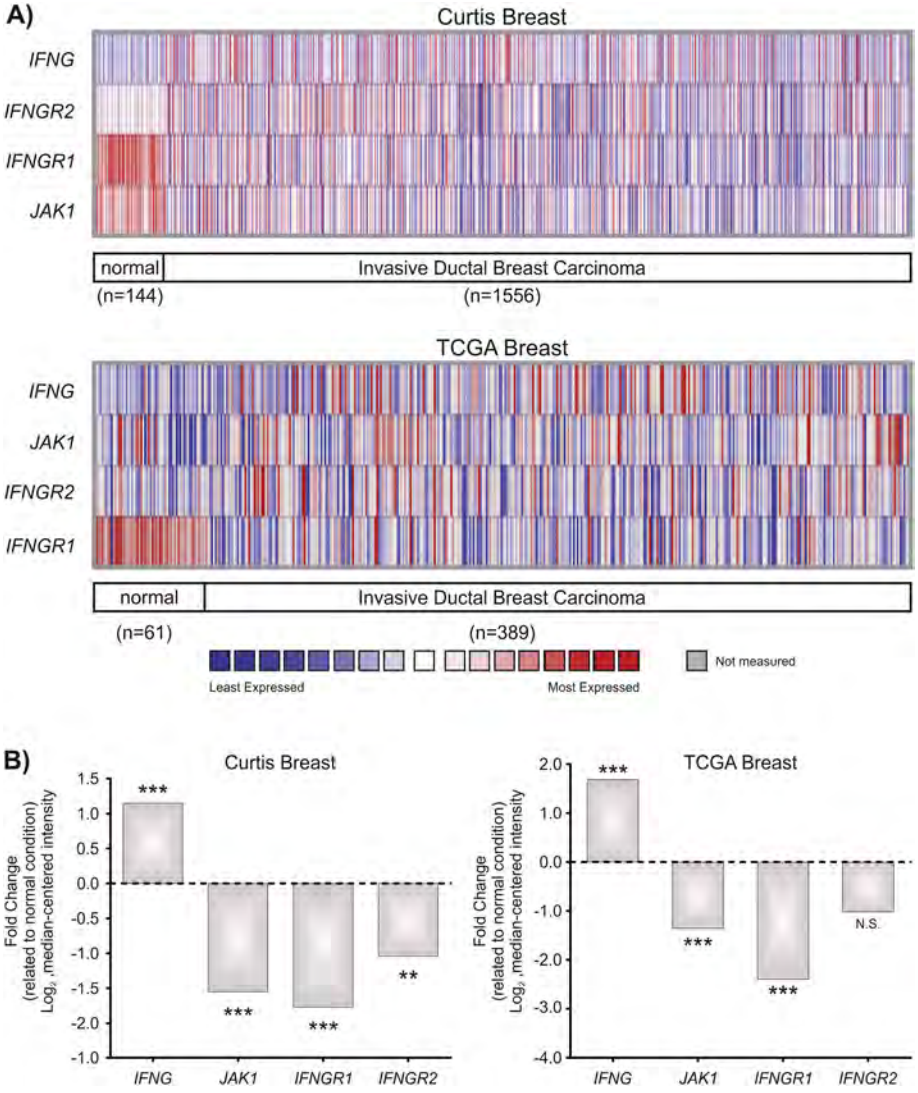

Fig. 4. Expression of IFN-γ signaling components in breast cancer. Heat maps for gene expression of IFN-γ signaling components. A) Curtis and TCGA (The Cancer Genome Atlas) datasets from Oncomine were analyzed to evaluate *IFNG, IFNGR2, IFNGR1* and *JAK1* expression in human mammary tumors and normal tissue. B) Analysis of *IFNG, JAK1*, *IFNGR1* and *IFNGR2* expression in mammary tumors compared to those in normal mammary tissue. Results are expressed as significant when $p < .01$ (**), and $p < .001$ (***). Non-significant differences are indicated by N.S.

possess an active metabolism, allowing intracellular esterases to convert non-fluorescent calcein-AM to green fluorescent calcein. In non-viable cells, a red fluorescence signal is generated when PI binds to DNA indicating that the nuclear membrane is disrupted. Cells treated with or without IFN-γ were incubated with calcein-AM (1 μM) and PI (5 mM) at 37 °C for 30 min, and the cells were then analyzed by fluorescence microscopy.

2.4. Co-immunoprecipitation assays and western blotting

Cytoplasmic and nuclear extracts or total extracts were used for immunoprecipitation assays as described previously [24]. Immunoprecipitation was performed using a specific anti-ISG15 (Santa Cruz Biotechnology) antibody. The immunoprecipitated complexes were separated by SDS-PAGE followed by immunoblotting with specific primary anti-IQGAP1 antibody (H-109, Santa Cruz Biotechnology). As input, cytoplasmic and nuclear extracts (25–100 μg of protein lysates) were used and separated by SDS-PAGE and then immunoblotted with anti-ISG15 (1:1000) (F-9, sc-166,755), anti-α-tubulin (1:3000) (B7, sc-5286) obtained from Santa-Cruz Biotechnology, and anti-lamin B1(1:2000) obtained from Cell Signaling (D4Q4Z). A secondary anti-rabbit IgG antibody was used (1:10000) against anti-lamin B1 (sc-2004; Santa Cruz Biotechnology), and peroxidase Affinipure goat anti-mouse antibody (1:10000) was used for anti-tubulin and anti-ISG15 (115–035-003, Jackson). Protein detection was performed using SuperSignal West Pico chemiluminescent substrates (Thermo Scientific) or Immobilon Western (Millipore) reagents. The experiments were performed in triplicate, and representative images are shown.

2.5. Immunofluorescence assay

The cells were fixed in 4% paraformaldehyde for 10 min, permeabilized with 0.1% Triton X-100 for 10 min, and blocked with 1% albumin for 1 h. Cells were incubated overnight with anti-ISG15 (F-9, sc-166,755; 1:100), and then the cells were washed and incubated with Alexa Fluor 647 anti-mouse IgG secondary antibody (ab150107, Abcam; 1:750) for 1 h in the dark. The slides were prepared with ProLong Diamond Antifade Mountant containing DAPI (Invitrogen). For phalloidin assays, after blocking, the cells were incubated for 1 h with phalloidin (1:40) and mounted with DAPI solution. An Olympus IX2 confocal laser-scanning microscope was used to visualize the cells, and ImageJ software was used for imaging, processing, and analyzing the

results.

2.6. Gene expression analysis

The cancer microarray database Oncomine (www.oncomine.org) was used to analyze gene expression in patient-derived mammary tumors and normal mammary tissue. The datasets used were The Cancer Genome Atlas (TCGA) and Curtis.

2.7. In silico analysis

The analysis of protein–protein interactions was carried out using STRING 10.5 version software (https://string-db.org/cgi/network.pl) [46].

2.8. Human breast cancer tissue microarray

Breast cancer and normal tissue arrays, along with corresponding control tissues derived from the same patient (16 cases/48 cores), were purchased from Biomax (BRC481, U.S. Biomax human breast cancer tissue microarray). This microarray was composed of formalin-fixed, paraffin-embedded tissue.

2.9. Immunohistochemical assay

The microarrays were examined by immunohistochemical (IHC) analysis using a monoclonal antibody specific for ISG15 (F-9, sc-166,755 from Santa-Cruz Biotechnology). Samples were initially deparaffinized in xylene followed by rehydration in graded alcohol. Endogenous peroxide activity was quenched using 3% hydrogen peroxide (5 min) and samples were blocked using horse serum solution. Samples were then incubated with anti-mouse IgG (peroxidase). Results were visualized after incubation using DAB solution. Slides were dehydrated and cleared in xylene baths, and then mounted. A counterstain with Hematoxylin was also performed. Positive and negative controls (negative control: lacking the ISG15 antibody) were used.

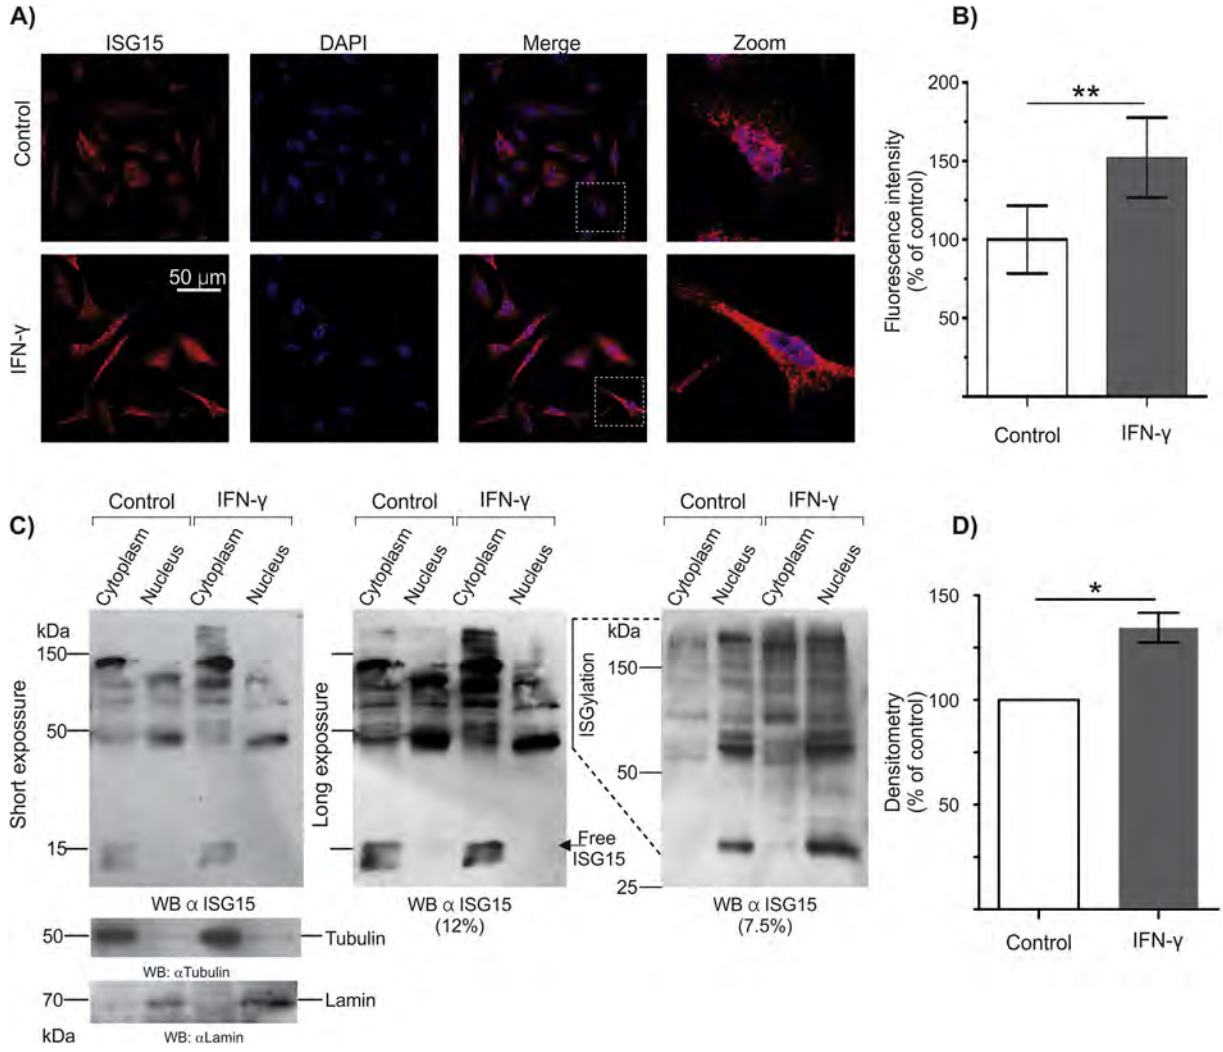

Fig. 6. IFN-γ increases cytoplasmic ISGylation marks in MDA-MB-231 cells. A) Subcellular localization of ISG15 in MDA-MB-231 cells with or without IFN-γ (100 ng/ml) treatment were evaluated by immunofluorescence. Changes in morphology are visible in the zoomed image. B) Quantification of ISG15 fluorescence intensity in MDA-MB-231 cells with or without IFN-γ treatment. C) Cytoplasmic and nuclear extracts taken from MDA-MB-231 cells with or without IFN-γ (100 ng/ml) treatment were used for WB analysis of ISG15 (gels 12%, short and long exposure). Cytoplasmic and nuclear fractions were also separated in 7.5% acrylamide gels for WB against ISG15. Lamin and tubulin were used as controls for the cytoplasmic and nuclear fractions, respectively. D) Densitometry analysis of the cytoplasmatic levels of protein ISGylation. Results are considered significant when $p < .05$ (*), and $p < .01$ (**).

2.10. Immunohistochemical analysis

2.10.1. Image acquisition

IHC photomicrographs were captured using an AxioScan.Z1 microscope (Zeiss, Germany) equipped with an AxioCam MRc5 camera (Zeiss, Germany). Light and camera settings were operated by ZEN2.3 software (blue edition, Carl Zeiss microscopy GmbH, 2011). Images were captured under 20× and 40× objective lenses.

2.10.2. Digital Image Analysis

IHC photomicrographs were used for developing a semi-automated analysis protocol called IHC profiler [47]. Quantitative analysis was performed using photomicrographs of 4 randomly selected fields taken from each representative tumor tissue on the microarray.

2.11. RT-PCR assay

ISG15 and *β-actin* mRNA levels were detected by RT-PCR. TRIzol (Invitrogen) was used to isolate total RNA from MCF-7 and MDA-MB-231 cells treated with or without IFN-γ (100 ng/ml) for 24 h. Total RNA (2 μg) was used for cDNA synthesis, and random hexamers and Moloney murine leukemia virus RT (Invitrogen) were used to promote the reaction. PCR was performed using a *Taq* PCR Master Mix kit (Qiagen) and primers specific for *ISG15* (Sense 5′-3′: GGT GGA CAA ATG CGA CGA AC and antisense 5′-3′: ATG CTG GTG GAG GCC CTT AG) and *β-actin* (Sense 5′-3′: GGG TCA GAA GGA TTC CTA TG and antisense 5′-3′: GGT CTC AAA CAT GAT CTG GG). PCR products were analyzed by agarose gel electrophoresis.

2.12. Statistical analysis

The data presented in our figures are representative of 3 or more independent experiments. Densitometry for WB, quantification of cell viability assays and fluorescence intensity percentages were performed using Fiji-ImageJ. Data were shown as percentages. Unpaired student's *t*-tests were performed using *GraphPad Prism* 5 software (GraphPad). Results were considered significant when $p < .05$ (*), $p < .01$ (**), and $p < .001$ (***). Non-significant differences were by N.S. Mann-Whitney rank sum test, and Kruskal-Wallis One Way Analysis of Variance on Ranks were performed to analyze IHC data.

3. Results

3.1. Expression of STAT1, IRF-1, RIG-1, and ISG15 is increased in breast cancer

Approximately 80% of breast cancers develop in the mammary ducts and are invasive [48]. In order to explore the expression of factors activated by IFN-γ signaling (*STAT1, IRF-1,* and *RIG-1*) and *ISG15*, we evaluated their mRNA levels in tumors of patients diagnosed with invasive ductal breast cancer and compared them with their corresponding levels in normal mammary tissue using TCGA (450 patients) and Curtis (1700 patients) datasets. Our analysis of both datasets showed that the expression of all four genes (*STAT1, IRF-1, RIG-1*, and *ISG15*) were significantly increased in breast cancer (Fig. 1A-1H). Additionally, using the Curtis dataset (1902 patients), we found that the mRNA levels of *STAT1, IRF-1* and *ISG15* increased in a tumor-grade dependent manner. Expression levels were lower in grade 1 tumor tissues (well differentiated, tumor tissues appear similar to normal mammary tissues) and increased in grade 2 tumors (moderately differentiated) that grow and spread slowly. The mRNA levels of *STAT1, IRF-1*, and *ISG15* were highest in grade 3 tumors, which were poorly differentiated with a rapid growth and spread (Fig. 1I-1K). These results indicated that the expression of *STAT1*, *IRF-1*, *RIG-1*, and *ISG15* were increased in mammary tumors, and in particular, *STAT1, IRF-1*, and *ISG15* expression seemed to be critical in the progression of breast cancer.

Interestingly, other IFN-γ target genes were also upregulated in mammary tumors when compared to normal mammary tissue. These included *SOCS1* and *SMAD7*, whereas other IFN-γ regulated genes such as *SOCS3* and *IRF-2* were downregulated in breast cancer when compared to healthy breast tissue (Supplementary fig. 1). Furthermore, genes associated with antigen presentation by MHC class I and II were generally upregulated in breast cancer (Supplementary fig. 2). These results indicate that the IFN-γ-driven transcriptome may be deregulated in breast cancer.

3.2. ISG15 protein levels are enhanced in mammary tumor samples compared to normal adjacent tissue

Because *ISG15* is one the upregulated genes in breast cancer, we first decided to analyze the protein levels of ISG15 in tumors of patients with breast cancer. We evaluated a breast cancer microarray that contained 16 cases of invasive breast cancer in duplicates with adjacent uninvolved tissue from the same patients, and we detected ISG15 protein by immunohistochemistry (IHC). A strong signal was detected for ISG15 protein in different cases of ERα- and ERα + mammary tumors compared to signals detected in normal mammary tissue (Fig. 2A and B). The ISG15 signal was mostly detected in the cytoplasm in all cases. However, in some cells, ISG15 was also detected in the nucleus (Fig. 2A and B, zoom). Our statistical analysis demonstrated that ISG15 protein expression was significantly higher in breast cancer samples than in the normal mammary tissue (Fig. 3A). We performed the same analysis by classifying the tumors as ERα- and ERα + , and our results indicated that these tumors also have higher levels of ISG15 protein than the adjacent normal mammary tissue and was independent of ERα status (Fig. 3B). These results indicate that the ISG15 modifier protein is upregulated in breast cancers, and this upregulation may lead to the ISGylation of target proteins to modulate their activities.

3.3. Expression of the IFN-γ signaling pathway elements IFNGRs, JAK2, and IFNG is also altered in breast cancer

Expression of *STAT1* and *ISG15* is positively associated with tumor grade, and ISG15 protein levels are increased in breast cancer cells. Since STAT1 and ISG15 are linked to IFN-γ signaling, we analyzed the expression of the elements of this pathway including *IFNGR1*, *IFNGR2*, and *JAK1*, as well as the expression of the gene that encodes for IFN-γ cytokine (*IFNG*) in mammary tumors. These analyses were performed using Curtis and TCGA datasets derived from Oncomine. The analysis of these two datasets indicated that the IFN-γ signaling pathway is deregulated in mammary tumors, as the mRNA levels of *JAK1*, *IFNGR2*, and *IFNGR1* were decreased in these tumors in comparison to those found in normal tissue, and the expression of *IFNG* was increased (Fig. 4A, B). Taken together, these results suggest that IFN-γ production and secretion may be enhanced in mammary tumors, and the activation of the IFN-γ pathway and some of its effectors may be altered in comparison with normal mammary tissue.

3.4. IFN-γ affects the morphology of breast cancer cells

Previously, we demonstrated that the protein levels of free ISG15 and protein ISGylation are increased in response to IFN-γ treatment in MCF-7 and MDA-MB-231 breast cancer cells [24]. To examine if *ISG15* is an IFN-γ-induced gene in these breast cancer cells, we performed an

INFORME DE LABORES 2019

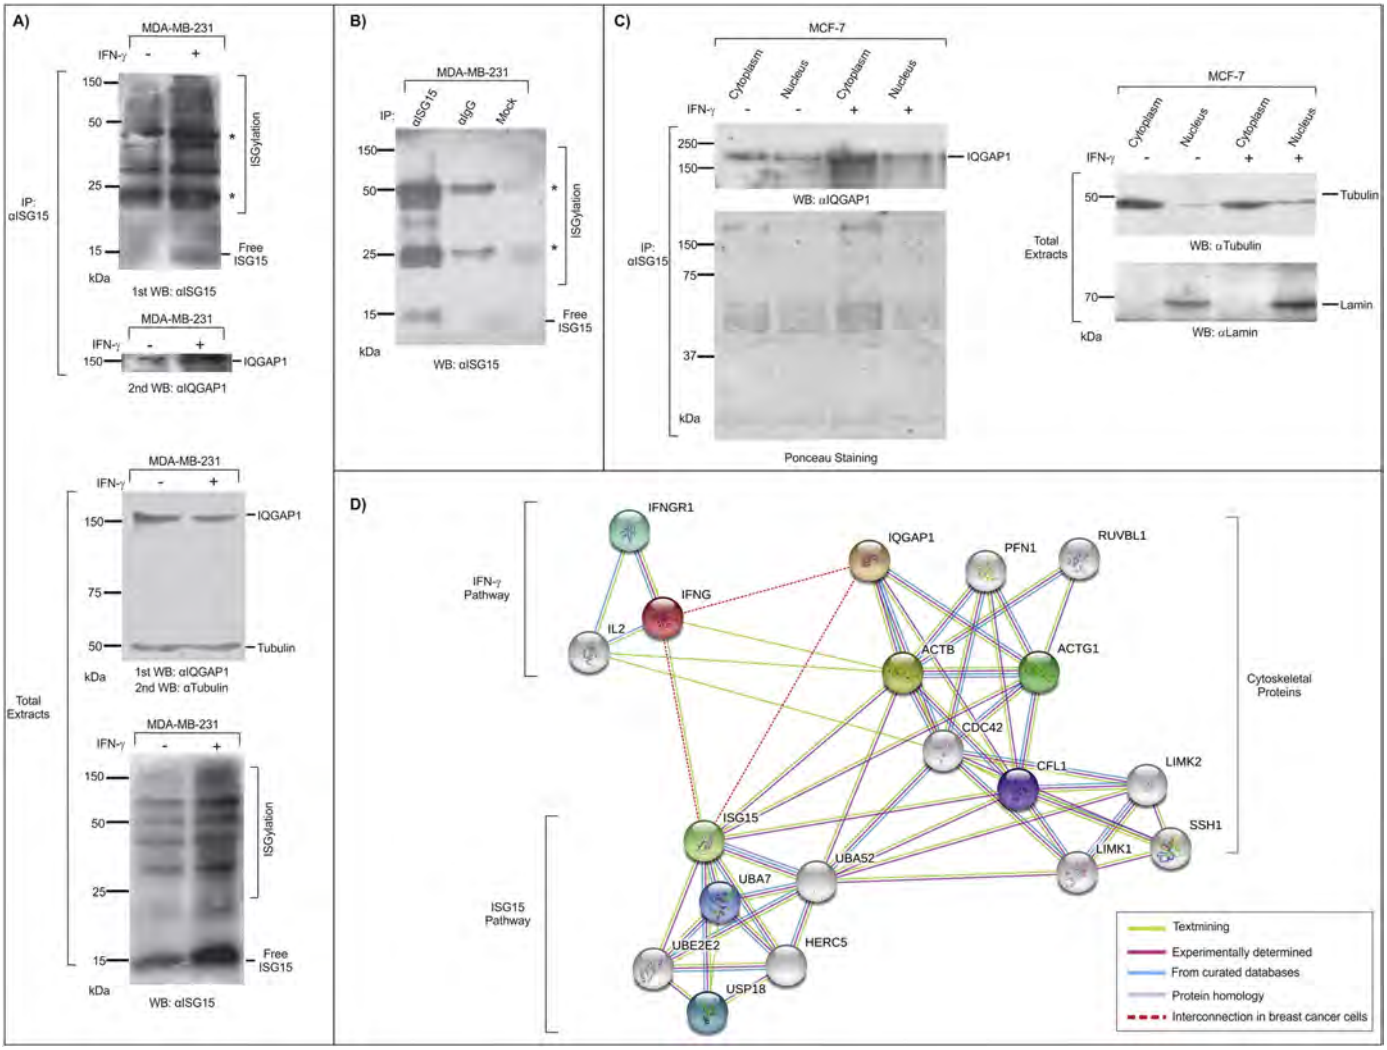

Fig. 8. Association between ISG15 and IQGAP1 is increased by IFN-γ treatment of breast cancer cells. A) Endogenous ISG15 immunoprecipitation (IP) followed by WB for ISG15, and then for IQGAP1, using total extracts from MDA-MB-231 cells with or without IFN-γ (100 ng/ml) treatment. IQGAP1 and ISG15 levels were also evaluated by WB, and tubulin was used as a loading control. B) Mock and IgG were used as controls to evaluate the specificity of ISG15 IP (*IgG). C) Cytoplasmic and nuclear extracts derived from MCF-7 cells with or without IFN-γ (100 ng/ml) treatment were immunoprecipitated using the ISG15 antibody and analyzed by WB for IQGAP1. Lamin and tubulin were used as loading controls for nuclear and cytoplasmic fractions, respectively. Ponceau staining was used on IP membrane. E) Interactome analysis using STRING software for IFN-γ signaling, ISGylation, and cytoskeletal remodeling associated proteins. The association between ISG15, IQGAP1, and IFN-γ is shown as a dashed red line. Known interactions from curated databases, text mining, experimental findings, and protein homology are indicated in blue, green, purple, and dark blue lines, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

RT-PCR assay using RNA obtained from cells treated or untreated with IFN-γ for 24 h. Our results indicated that *ISG15* mRNA levels are up-regulated by IFN-γ (Fig. 5A), suggesting that these cell lines may provide a useful system to study the effects of IFN-γ/ISG15 signaling. Since IFN-γ signaling pathway seems to be deregulated in breast cancer cells, we decided to examine the effect of IFN-γ treatment on the morphology and viability of MCF-7 and MDA-MB-231 human breast cancer cells. Initially, the cells were treated with IFN-γ for 24 h, followed by calcein staining, and as a result we detected morphological changes in MCF-7 and MDA-MB-231 cells, since some of the cells were more elongated in comparison with cells without IFN-γ treatment (Fig. 5B, C, zoom). We then evaluated the viability of these cells after IFN-γ treatment for 48 h using cell viability assays (Calcein-AM/propidium iodide (PI)). Calcein emits a green fluorescence when it is released from Calcein-AM by esterases enzymatic activity of viable cells. PI emits a red fluorescence when it passes the membranes of dead cells to intercalate with nuclear DNA. As a result, Calcein-AM stains viable cells green and PI stains dead cells red. Our results indicated that MDA-MB-293 cells with or without IFN-γ treatment were viable, as the majority stained green for calcein (Fig. 5D and F). Similarly, the viability of MCF-7 cells treated with IFN-γ was not decreased by IFN-γ stimulation (Fig. 5E and G). Our statistical analysis, determined that the percentage of dead cells was not significantly different between the IFN-γ treated and untreated cells (Fig. 5F and G). Thus, our assays revealed that MCF-7 and MDA-MB-231 breast cancer cells undergo morphological changes in response to IFN-γ, and IFN-γ treatment does not appreciably affect the viability of these cells.

3.5. IFN-γ increases the marks of ISGylation in the cytoplasm of MDA-MB-231 breast cancer cells

We have evidenced changes in the morphology of breast cancer cells when they were treated with IFN-γ. For this reason, we performed an immunofluorescence assay to evaluate the subcellular distribution of ISG15 in response to IFN-γ treatment and its possible relation with the changes in morphology of MDA-MB-231 cells in this condition. As a

INFORME DE LABORES 2019

result, ISG15 signal was detected in the cytoplasm and nucleus of breast cancer cells without IFN-γ treatment. After IFN-γ treatment we also detected changes in the morphology of some of these cells (cell shape more elongated) in comparison with untreated cells (Fig. 6A, zoom). We also observed that IFN-γ treatment had no effect on ISG15 subcellular distribution in these cells, but a stronger signal for ISG15 was detected (Fig. 6A). Our analysis demonstrated that fluorescence intensity for ISG15 was significantly higher in MDA-MB-231 cells treated with IFN-γ compared with that detected in untreated cells (Fig. 6B).

Additionally, we performed a western blot (WB) to specifically detect the distribution of ISGylation marks between the cytoplasmic and nuclear compartments in MDA-MB-231 cells treated with or without IFN-γ (Fig. 6C short/long exposure, 12% and 7.5% gels). We detected statistically significant increase in ISGylation marks within the cytoplasm in response to IFN-γ (Fig. 6D). Hence, IFN-γ induces changes in the morphology of breast cancer cells and also increases ISG15 levels, while exerting no effects on subcellular distribution of this protein. ISGylation marks were mainly detected in the cytoplasm, suggesting that this interferon promotes the conjugation of ISG15 to several cytoplasmic proteins to modify them and modulate their functions.

3.6. *IFN-γ induces changes in the actin cytoskeleton and ISGylation of some cytoplasmic proteins could be implicated*

To further explore if IFN-γ could modulate the actin cytoskeleton of breast cancer cells, we performed phalloidin staining of actin filaments (also known as F-actin) in IFN-γ treated and untreated MDA-MB-231 cells. We observed changes in the actin cytoskeleton that were promoted by IFN-γ treatment. F-actin was concentrated in various subcellular areas but was reorganized into stress fibers following 48 h and 72 h of IFN-γ treatment (Fig. 7A and B). A similar effect was observed in MCF-7 cells expressing the ISGylation system (Supplementary Fig. 3). Given these observations, modifications in the morphology of breast cancer cells are clearly linked to cytoskeletal remodeling in response to IFN-γ treatment.

The changes in the cytoskeleton of breast cancer cells promoted by IFN-γ treatment could be linked to ISGylation of cytoplasmic proteins, but few ISGylation-target proteins have been identified to date. IQGAP1 is a protein that participates in the regulation of cytoskeletal dynamics, and interestingly, is one of the few proteins that appears to be ISGylated [49–51]. Based on this, we evaluated the effect of IFN-γ treatment on ISGylation of IQGAP1. Using total extracts obtained from MDA-MB-231 cells that were untreated or treated with IFN-γ, we performed an immunoprecipitation assay to enrich the modifier protein ISG15. A first WB against ISG15 was performed to probe the efficiency of immunoprecipitation, displaying a pattern of ISG15-conjugated proteins that increased in response to IFN-γ treatment (Fig. 8A, 1st WB:αISG15). Then, a second WB against IQGAP1 showed that IFN-γ also increased association between ISG15 and IQGAP1 (Fig. 8A, 2nd WB:αIQGAP1). Furthermore, the detection of tubulin from total extracts was used as a loading control, and it was observed that the IQGAP1 levels were not affected by IFN-γ. In contrast, ISGylation levels increased when the cells were treated with IFN-γ (Fig. 8A, bottom). Additionally, the use of IgG and mock controls were used to evaluate the specificity of ISG15 immunoprecipitation (Fig. 8B). IFN-γ treatment also increased this association between ISG15 and IQGAP1 in the cytoplasm of MCF-7 breast cancer cells (Fig. 8C). This ISG15 immunoprecipitation was probed using Ponceau staining. Therefore, proteins such as IQGAP1 that are involved in cytoskeletal remodeling may associate with ISG15 *via* ISGylation, and be modulated by IFN-γ in breast cancer cells.

To investigate the relationship between the IFN-γ signaling pathway, ISG15, and the ISGylation system in the context of the modulation of cytoskeletal reorganization, we performed an interactome analysis using STRING software. Our analysis showed a connection between these pathways, where the actin proteins (ACTB, ACTG1) are key players along with other proteins that regulate the cytoskeleton. Importantly, we observed a novel association between IFN-γ, ISGylation, and IQGAP1 in the cytoskeletal dynamics of breast cancer cells (Fig. 8D).

4. Discussion

Our study revealed increased expression of *STAT1, IRF-1, RIG-1* (factors that mediate IFN-γ signaling), and *ISG15* genes in breast cancer cells compared to their expression in normal mammary tissues, suggesting a possible interplay between IFN-γ and ISG15-regulated molecular pathways. We also observed increase in the expression of *STAT1, IRF-1*, and *ISG15* in grade 3 mammary tumors in comparison to grade 1 tumors, demonstrating the relevance of the expression of these genes in the progression of breast cancer.

Additionally, the observation that the levels of the modifier ISG15 are elevated in mammary tumors in comparison with those in normal adjacent tissue suggests that protein ISGylation may be a highly active modification in breast cancer cells. Under this condition, the function of several proteins may be affected by ISGylation, and some of them may be linked to proliferation and metastasis. As ISG15 expression and protein levels are increased in breast cancer, this may provide a potential biomarker for this cancer type. It must be noted that ISG15 upregulation has also been reported in other cancer types [52–56], but the mechanism of action is unclear.

Breast cancer cells exhibit a characteristic profile of free ISG15 and ISGylation that is upregulated by IFN-γ [23,24] and not exclusively by IFN-α/β as in some cell types. Given this, IFN-γ signaling may also play a critical role in breast cancer by mediating the modification of proteins by ISGylation and the gene expression characteristic of these cells. For example, it has also been reported that patient-derived mammary tumor xenografts in athymic mice can secrete IFN-γ, and a gene signature regulated by interferons may be associated with the grade of sensitivity to chemotherapy. Additionally, IFN-γ autocrine signaling has been associated with sensitivity to fulvestrant treatment [14–17].

Accordingly, IFN-γ may be a key component of the mammary tumor microenvironment and may function to generate autocrine and paracrine signals to induce protein ISGylation. Here, our results suggest that the *IFNG* gene that encodes for IFN-γ is increased in mammary tumors relative to control tissue, and as a consequence the production and secretion of IFN-γ may be increased in these tumors. Our analysis also indicated, however, that expression of IFN-γ signaling elements such as receptors and JAK1 is decreased in breast cancer. It is unclear if the deregulation of these IFN-γ signaling components is a compensatory mechanism to regulate this signaling, but this deregulation may have serious implications in for intercellular communication within the tumor microenvironment. Additionally, the deregulation of IFN-γ signaling in breast cancer may affect the expression of IFN-γ target genes, including those that allow for recognition of tumor cells by the antitumor immunity system (Supplementary fig. 2), and may also affect the pattern of proteins regulated by ISGylation.

Although there are alterations in the expression IFN-γ signaling elements in mammary tumors from patients, MCF-7 and MDA-MB-231 breast cancer cell lines are responsive to this molecule. Cellular outcomes, however, may be different due to crosstalk with other signaling pathways such as ERα and other nuclear receptor pathways that possess altered regulatory mechanisms that affect signaling in certain cancer types [57]. MCF-7 cells are ERα+, and the viability of these cells is not altered in a statistically significant manner when treated with IFN-γ. Additionally, MDA-MB-231 cells are ERα- and their viability is also unaffected by IFN-γ stimulation. Interestingly, in both cell types, IFN-γ treatment induced changes in cellular morphology, and our results suggest that these changes are linked to cytoskeletal reorganization. A deregulation of the IFN-γ signaling pathways may be associated with breast cancer progression.

The changes in the morphology of breast cancer cells induced by IFN-γ can, in part, be mediated *via* ISGylation of cytoplasmic proteins,

INFORME DE LABORES 2019

as IFN-γ increases ISGylation mark mainly in the cytoplasm. Here, we analyzed IQGAP1, a protein that is associated with cytoskeletal remodeling that has also been identified as an ISGylation target. Our findings suggest that the interaction between ISG15 and IQGAP1 is increased by IFN-γ treatment.

An important challenge is to identify other ISG15-interacting proteins that modulate the cytoskeletal organization and determine the specific function of this modification. To date, protein ISGylation has been determined principally as monoISGylation, regulating the protein stability either by inhibiting or promoting the ubiquitination pathway. Also, functions unrelated to protein stability have been proposed, in which ISGylation appears to modulate protein–protein interactions. For example, filamin B is another protein associated with actin that connects actin filaments to the cell membrane. When filamin B is not ISGylated, it acts as a scaffold for RAC1, MEKK1, and MKK4 proteins allowing IFN-α/β induced JNK signaling for the induction of apoptosis. When filamin B becomes ISGylated, however, its interactions with RAC1, MEKK1, and MKK4 proteins are lost, resulting in the inhibition of JNK signaling. Therefore, filamin B ISGylation blocks IFN-α/β induced JNK signaling [58]. In our study, we observed that IQGAP1 levels were not altered by IFN-γ stimulus (Fig. 8 A (bottom) and Supplementary fig. 4), and it is likely that ISGylation modulates the interaction of IQGAP1 with other proteins. Additionally, our interactome study indicated a close relationship between IFN-γ signaling, the ISGylation system, and proteins, such as IQGAP1, present in the cytoskeleton that may participate in cytoskeletal organization. Many of these proteins may be regulated by IFN-γ-induced ISGylation and/or modulated at the transcriptional level by IFN-γ. Thus, our findings may provide insight between these pathways in breast cancer cells. More studies may help to demonstrate functional and mechanistic implications of these pathways in the growth and progression of mammary tumors, as well as, their potential for the diagnosis, prognosis, and treatment of breast cancer.

5. Conclusion

In conclusion, our results indicate that the expression of elements involved in IFN-γ signaling pathway, IFN-γ target genes, and protein ISGylation are deregulated in mammary tumors. IFN-γ in breast cancer cells increases *ISG15* expression and subsequent protein ISGylation, and induces changes in cellular morphology associated with the cytoskeleton. ISG15 can be a potential biomarker for breast cancer, and the target of ISGylation, as IQGAP1, may present important implications in this context.

Abstract: More than 70% of all breast cancer cases are estrogen receptor alpha-positive (ERα). ERα is a member of the nuclear receptor family, and its activity is implicated in the gene transcription linked to the proliferation of breast cancer cells, as well as in extranuclear signaling pathways related to the development of resistance to endocrine therapy. Protein-protein interactions and posttranslational modifications of ERα underlie critical mechanisms that modulate its activity. In this review, the relationship between ERα and ubiquitin protein (Ub), was investigated in the context of breast cancer cells. Interestingly, Ub can bind covalently or non-covalently to ERα resulting in either a *proteolytic* or *non-proteolytic* fate for this receptor. Thereby, Ub-dependent molecular pathways that modulate ERα signaling may play a central role in breast cancer progression, and consequently, present critical targets for treatment of this disease.

Keywords: Estrogen receptor alpha, breast cancer, monoubiquitination, polyubiquitination, non-covalent ubiquitin binding, endocrine therapy.

1. INTRODUCTION

Over 70% of all breast cancer cases are diagnosed as estrogen receptor-positive (ERα+) [1-5]. ERα is a nuclear receptor having nuclear and extranuclear activities related to gene transcription and signal transduction pathways, respectively. These activities of ERα are possible because of its structural organization into several domains, including the ligand-binding domain (LBD), the DNA-binding domain (DBD), and a hinge region that separates the LBD and the DBD. LBD recognizes estrogenic hormones, mainly 17-beta-estradiol (E2), while DBD binds to specific palindromic sequences in enhancer and promoter regions of its target genes [6-8]. Activation function domain-1 (AF-1), localized in the N-terminus, and activation function domain-2 (AF-2), localized in the C-terminus, recruit several proteins, including transcriptional coregulators. Functions of AF-1 and AF-2 domains are tissue-specific, where AF-1 functions in an E2 hormone-independent manner, and AF-2 in an E2 hormone-dependent manner [9-13].

ERα is a central element in the signal transduction pathways of breast cancer cells, both inside and outside the nucleus (Fig. **1**). Outside the nucleus, ERα is present in the cell membrane due to palmitoylation or association with other transmembrane proteins [14, 15]. ERα is also localized in the cytoplasm, where it interacts with several protein mediators of signaling pathways, such as MNAR, MTA1, MEMO, and RB, related to endocrine resistance in breast cancer [16-20]. Despite these important extranuclear functions, this receptor is well known by its function as a transcription factor, as well as a coregulator of other transcription factors, such as Sp1, AP1, and NF-kappa B [21, 22]. Importantly, ERα activity is promoted in response to the E2 hormone. However, growth factors, such as EGF and IGF, also promote ERα activity in an E2 hormone-independent manner by inducing its phosphorylation [23, 24].

In order to regulate transcription of its target genes in response to E2 hormone in breast cancer cells, ERα is recruited on enhancer and promoter sequences facilitated by pioneer factors, such as FOXA1 and GATA3 [25, 26]. Over 300 coregulators (coactivators and corepressors) have been identified as modulators of ERα activity that are frequently deregulated in breast cancers. For example, in breast cancer, coactivators are commonly upregulated while corepressors are downregulated. Coactivator complexes open chromatin to facilitate transcription and corepressor complexes compact chromatin to inhibit gene expression [27-31]. Although coregulators are central for modulating ERα activity, other mechanisms such as protein-protein interactions and post-translational modifications which regulate the stability and subcellular localization of this receptor, also act as crucial regulatory factors of ERα function [32-34].

Due to the importance of ERα and its signaling pathways in breast cancer cells, detection of ERα is an indicator for the administration of *endocrine therapy,* which includes the use of aromatase inhibitors, selective estrogen receptor degraders or downregulators (SERDs) and selective estrogen receptor modulators (SERMs). Aromatase inhibitors such as anastrozole and letrozole are used to reduce E2 levels by inhibiting

INFORME DE LABORES 2019

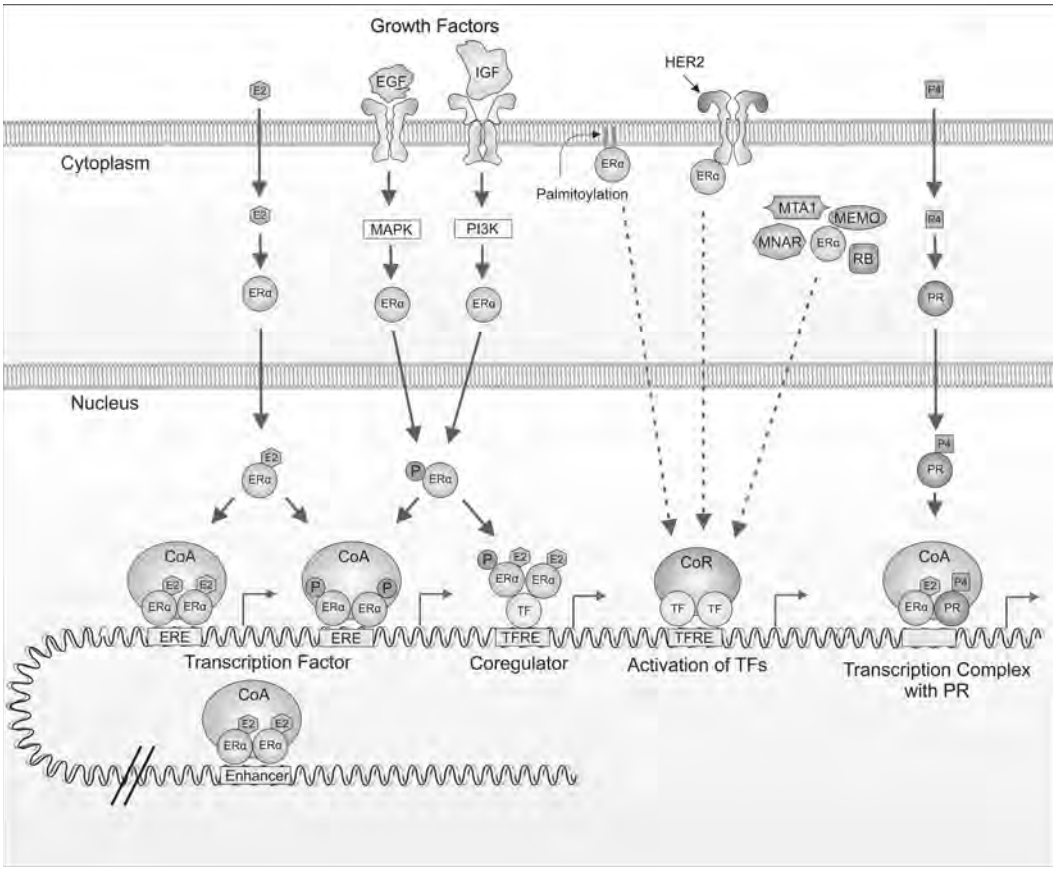

Fig. (1). Pathways of ERα in breast cancer cells. ERα is activated by E2 binding in the cytoplasm and/or nucleus. ERα recognizes AGGTCAnnnTGACCT sequence (estrogen response elements: EREs) in target enhancers and promoters. Coactivators (CoA) promote ERα-dependent gene expression. E2 induces ERα phosphorylation. Growth factors (EGF and IGF) also induce E2-independent ERα phosphorylation. This modification regulates ERα activity as a transcription factor or coregulator for some transcription factors (TFs). ERα is also out of the nucleus, membrane-localized by palmitoylation, with transmembrane receptors such as HER2, and/or associated with proteins such as MEMO, MTA1, MNAR and RB in the cytoplasm. In this manner, ERα is associated with kinase-dependent signaling that may activate other TFs and coregulator (CoR) complexes. Additionally, progesterone receptor (PR) may interact with ERα and re-direct its binding to chromatin regions to modulate gene expression.

the conversion of testosterone into E2 hormone [35-37]. Moreover, SERDs such as fulvestrant, and SERMs such as tamoxifen, are antiestrogens, which compete with E2 hormone for binding to ERα to decrease its abundance and/or activity, respectively. In summation, E2, SERDs and SERMs are ligands that bind to LBD of ERα, inducing a conformational change in the receptor depending on the ligand type. As a result, E2 induces ERα-dependent transcription, fulvestrant promotes the degradation of ERα, and tamoxifen binds to ERα and inhibits the induction of E2 hormone-target genes by recruiting several transcriptional corepressors [37-39]. Some breast cancer patients do not respond to endocrine therapy, presenting a *de novo resistance*, whereas many others develop resistance to these therapies later, presenting an *acquired resistance.* Mechanisms underlying both cases have not been completely defined yet [36, 40].

In this review, we focus on the modulation of ERα actions by Ub-associated pathways, and its potential implications in endocrine resistance to SERMs and SERDs in breast cancers.

1.1. Literature Search

The PubMed database was searched, using terms associated with ERα in relation to Ub, degradation and stability, with particular reference to human breast cancer including the treatment of this disease and implications for endocrine resistance. Articles included several original research such as studies on human breast cancer cell lines, *in vivo* studies on xenotransplantation to athymic mice from patients and analysis of tumor samples from patients. These articles contained data related to gene expression profiles, molecular mechanisms, and functional effects resulting from the interconnection of Ub-ERα pathways. The data were evaluated using several approaches, including clinical, molecular, and novel techniques such as NGS, ddPCR and CRISPR-Cas. Moreover, some critical general reviews were also perused.

2. BASICS OF THE UBIQUITIN PROTEIN AND UBIQUITINATION

Ubiquitin (Ub), a highly conserved protein in organisms ranging from yeast to humans, is composed of 76 amino acids (8-kDa). Ub contains a conjugation motif in its C-terminus, through which it is covalently attached to target proteins. The conjugation motif facilitates the formation of an isopeptide bond between Ub and specific lysine residues of its target protein, mediated by a sequential system of three enzymes: E1-ubiquitin-activating enzyme, E2-ubiquitin-

INFORME DE LABORES 2019

conjugating enzyme and E3-ubiquitin ligase enzyme. The substrate specificity for ubiquitination is determined by the E3 ligases because they attach the Ub to a lysine residue of the target protein [41-43]. In general, there are three main types of E3 ligases: Really Interesting New Gene E3 (*RING* E3) ligases, which contain a RING domain or U-box domain; Homologous to the E6AP Carboxyl Terminus (*HECT* E3) ligases, which are divided into 3 subfamilies (RCC1-like domains, tryptophan-tryptophan domains and ones lacking these domains), and RING-between RING-RING (*RBR* E3) ligases that contain an *in-between-RING domain* (IBR) which separates two predicted *RING domains* (RING1 and RING2). Ub is transferred from the E2-ubiquitin-conjugating enzyme to the substrate protein directly (in one step) by RING E3 ligases, whereas HECT and RBR ligases first transfer Ub from the E2-ubiquitin-conjugating enzyme to themselves and then to the substrate (in two steps). There are more than 600 members of the E3 ligase family, and RING E3 ligases are the most abundant [41, 44-46].

Ub chains are formed by the sequential attachment of Ubs to one another. Ub lysine residues 6, 11, 27, 29, 33, 48, and 63 can be used for polyubiquitin chain extension. Hence, there are homotypic chains *via* the link through one lysine of Ub, and also *via* several lysines of Ub. Moreover, several branched Ub structures can also be generated by other amino acid residues such as cysteine, serine, and threonine, but these have been scarcely studied. On the other hand, more than 100 deubiquitinases (DUBs) which break the isopeptide bond and reverse Ub binding of ubiquitinated proteins have been described in humans so far [47-50].

Covalent attachment of Ub to proteins can occur as monoubiquitination, multiubiquitination (monoubiquitination of several residues), or polyubiquitination, where each of these modifications results in a different cellular outcome. Monoubiquitination is associated with DNA repair, gene expression regulation, endocytosis, and protein stability, whereas polyubiquitination is mostly considered as a signal initiating selection of proteins for degradation by the 26S proteasome, and this coupling is known as the ubiquitin-proteasome system (UPS). Nevertheless, certain non-proteolytic functions have also been suggested for specific polyubiquitination cases [51-55].

3. MONOUBIQUITINATION AND UBIQUITIN-BINDING DOMAINS OF ERα IN BREAST CANCER CELLS

ERα is modified by both mono-and polyubiquitination but there are dissimilarities between these two modifications (Fig. **2**). For example, ERα polyubiquitination is induced by E2, whereas ERα monoubiquitination is negatively regulated by E2 in breast cancer cells [56]. In addition, while polyubiquitination is strongly related with E2-induced degradation of ERα by the UPS, ERα monoubiquitination does not induce its degradation by this system. Instead, monoubiquitination of this receptor modulates its stability, its interactions and DNA-binding activity as a transcriptional regulator [57-59].

Previous studies have indicated that ERα was monoubiquitinated *in vitro* in a BRCA1/BARD1 activity-dependent manner. Endogenous ERα monoubiquitination was observed in breast cancer cells, along with a decrease in monoubiquitinated ERα levels in response to E2 treatment. However, E2-dependent cellular proliferation seems to be promoted by ERα monoubiquitination. In these reports, ERα K302 and K303 residues were proposed as monoubiquitination sites of this receptor [57, 59, 60].

Monoubiquitination confers stability to ERα by inhibiting its polyubiquitination and degradation *via* the proteasome in breast cancer cells. E3-ubiquitin ligase RING finger proteins, such as RNF8 and RNF31 have been identified as modifiers of ERα *via* monoubiquitination. In particular**,** RNF8 associates with ERα to modulate its functions in two interconnected ways: 1) RNF8 induces monoubiquitination of ERα to stabilize it, and 2) RNF8 is a coactivator for ERα, increasing the expression of its target genes, such as pS2 and c-Myc. RNF8 downregulation decreases proliferation of breast cancer cells, whereas its upregulation is common in breast cancer, correlating with ERα levels [61]. Similarly, RNF31 associates with ERα and catalyzes its monoubiquitination to block the polyubiquitination, increasing ERα protein levels and its transcriptional activity. However, RNF31 is not a coactivator of ERα and is not recruited to ERα-dependent DNA regulatory regions [62].

SHARPIN also acts as an E3-ubiquitin ligase that stabilizes ERα by inducing its monoubiquitination to inhibit its polyubiquitination [63]. Thus, monoubiquitination and polyubiquitination compete to modify to ERα in order to modulate its stability and degradation, respectively. The deregulation of these modifications may be a key factor in regulating ERα functions in breast cancer, where ERα monoubiquitination seems to occur predominantly to confer more stability to the receptor and enhance E2 signaling in breast cancer cells.

It has been demonstrated that several proteins with ubiquitin-binding surfaces or domains (UBDs) may bind noncovalently with mono/polyubiquitinated proteins and Ub chains to stimulate signaling pathways, leading to several outcomes [53, 55, 64, 65]. These UBDs apparently lack shared, well-defined features, but it has been proposed that they possess regular secondary structures, such as α-helixes and/or Zn2+-fingers. Proteins modified *via* monoubiquitination also appear to contain one or more UBDs [66-68].

Importantly, UBDs have been reported to be present within the LBD of ERα (Fig. **2**). An interaction between ERα UBDs with ubiquitinated proteins or with recombinant Ub chains was demonstrated *in vitro* studies. Moreover, L429 and A430 residues of ERα were proposed as the key sites in UBDs of this receptor, as mutating these residues affected E2-dependent transcriptional functions of ERα. In addition, it was observed that when L429 and A430 residues in UBDs were mutated, the monoubiquitination of ERα receptor was blocked [69, 70]. These data indicate that these UBDs may have a functional significance for ERα monoubiquitination and for assembly of multiprotein complexes with ERα. Thus, the interactions of ERα *via* its UBDs seem to be critical in the progression of mammary tumors.

4. ERα POLYUBIQUITINATION IN BREAST CANCER CELLS

Certain E3-ubiquitin ligases such as CHIP, E6AP, BRCA1, BARD1, SKP2, and MDM2 are associated with

INFORME DE LABORES 2019

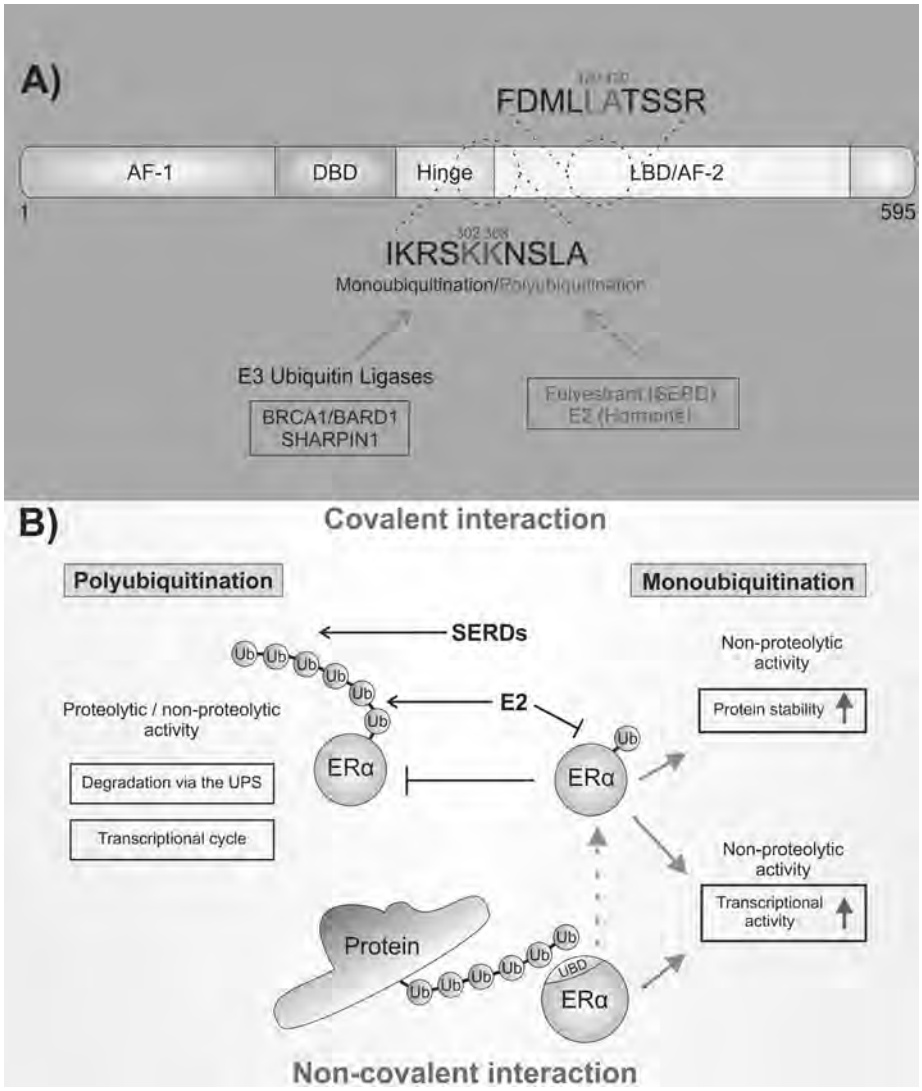

Fig. (2). ERα is modulated by ubiquitin-dependent pathways. A) Residues of ERα for interaction with ubiquitin protein. BRCA1/BARD1 and SHARPIN induces ERα monoubiquitination. E2 hormone and fulvestrant promote ERα polyubiquitination and degradation. ERα contains ubiquitin-binding domains (UBDs) to interact with ubiquitinated proteins. The residues are indicated. **B) Types of interactions between ERα and ubiquitin protein (Ub)**. Covalent (monoubiquitination and polyubiquitination) and non-covalent *via* UBDs. These interactions lead to proteolytic or non-proteolytic pathways for this receptor. ERα monoubiquitination appears to compete with its polyubiquitination in breast cancer cells. SERDs and E2 stimulate ERα polyubiquitination followed by degradation *via* the UPS. E2 decreases ERα monoubiquitination, but some E2-induced actions may require monoubiquitinated ERα.

ERα ubiquitination. Although it is known that polyubiquitination of ERα is followed by its degradation by 26S proteasome, not all ubiquitinated lysine residues of ERα have been identified, and direct interaction between ERα and all E3-ubiquitin ligases has not yet been demonstrated [57, 71-75]. Despite limited mechanistic details, ERα polyubiquitination is a regulatory factor, which controls its abundance or levels, as well as its functions.

In the absence of E2 hormone, the half-life of ERα protein oscillates between 3-5 h depending on cell type, whereas when the cells were exposed to E2, its half-life decreased to 1 h after treatment [76, 77]. Initially, the UPS system was suggested to be crucial to maintain the balance of ERα protein levels and E2 signaling [78]. However, studies performed by Leonard *et al.*, suggested that the interaction between ERα and its coactivators may be important for E2-induced downregulation of this receptor. This study highlighted the strong relationship between the process of degradation and transcriptional activity of ERα [79] (Fig. **2**).

Later, Reid G *et al.* proposed that, in the absence of ligand, ERα may bind to estrogen response elements (ERE) and recruit E3-ubiquitin ligases, promoting polyubiquitination and degradation of ERα, in order to restart the cycle with new receptors. In the presence of E2, ERα binds to ERE and recruits coactivators and E3-ubiquitin ligases. These coactivators facilitate the expression of ERα target genes, while E3-ubiquitin ligases mediate polyubiquitination and degradation of this receptor. Consequently, the cycle frequency, without or with ligand bound ERα, is estimated to be 20 and 45 min, respectively. This study elucidated that when ERα degradation is inhibited, Pol II is not recruited to EREs [80]. Moreover, intranuclear dynamics of unliganded and liganded

INFORME DE LABORES 2019

ERα is nullified when cells are treated with transcription or proteasome inhibitors [81]. A dynamic turnover of ERα protein is associated with its binding to DNA regulatory sequences for an active, cooperative, functional, and cyclical expression of its target genes [80, 82]. Thus, there is a complex relationship between ERα polyubiquitination and proteasomal degradation with the cycling of its transcriptional activity.

Several coactivators of ERα may also function as E3-ubiquitin ligases such as E6AP, RNF8, and SKP2, which may account for the link between polyubiquitination and the transcriptional cycle of ERα [48, 61, 75, 83]. One interesting E3 ligase/coactivator for ERα is SKP2, which functions as an E3-ubiquitin ligase for ERα degradation with a short E2 stimulation time. By contrast, with a longer stimulation time, SKP2 acts as a coactivator of ERα to induce transcription of late E2 target genes linked to cell cycle progression [83]. Similar to SKP2, several E3 ligases/coactivators of ERα may dynamically participate in the processes of degradation and transcription in an E2 hormone stimulation time-dependent manner.

In addition, the phosphorylation of ERα by certain kinases such as ERK7 [84], CDK11 [85], p38 [71], PKC [32], cyclin E-CDK2 [83], and Src [75] is required for its polyubiquitination and degradation [32]. ERα residues S118, S294, S341, and Y537 are phosphorylated in response to E2 stimulation, inducing ERα polyubiquitination [71, 83, 86]. A fine case in point is the phosphorylation of ERα at Y537 by Src following E2 treatment, which induces ERα polyubiquitination by E6AP (an E3-ubiquitin ligase/coactivator) [75]. Interestingly, mutations in this ERα residue, which affect its phosphorylation and degradation, have been detected in the mammary tumors of breast cancer patients resistant to endocrine therapy. Such coupling of phosphorylation and polyubiquitination of ERα may be central to recruiting E3-ubiquitin ligases with dual roles as coactivators to modulate ERα.

5. INHIBITION OF ERα POLYUBIQUITINATION IN BREAST CANCER CELLS

The complex relationship between ERα polyubiquitination with its degradation and transcriptional function may be affected in mammary tumors. Several studies indicate that many proteins directly or indirectly inhibit ERα polyubiquitination in breast cancer cells (Table **1**).

5.1. ERα Polyubiquitination Inhibitor Proteins (EPIPs) in Breast Cancer Cells

MUC1, PIN1, GSK3, LMTK3, cABL, RB, RNF31, RNF8, SMURF1 and SHARPIN proteins interact with ERα to protect it from polyubiquitination and degradation [87]. These ERα-interacting proteins act as ERα polyubiquitination inhibitor proteins (EPIPs). However, the mechanisms underlying the inhibition of ERα polyubiquitination by EPIPs are known to differ (Fig. **3** and Table **1**).

ERα polyubiquitination inhibition appears to be critical for ERα+ breast cancer cells. Polyubiquitinated ERα levels are increased when any EPIP is downregulated, and under this condition, ERα is degraded *via* the UPS, decreasing its abundance. In consequence, an inhibition of survival, proliferation, and migration of breast cancer cells is promoted. However, knockdown cells for each EPIP that are treated with MG132 (proteasome inhibitor) result in a partial restoration of ERα levels and its pro-tumor effects (Fig. **3**). Furthermore, EPIPs seem to be expressed mainly in breast cancer tissue compared to normal mammary tissue. For instance, RNF31 levels in mammary tumors were higher compared to those in adjacent normal mammary tissue [62]. Furthermore, a direct correlation between ERα protein levels and RNF8 or SHARPIN was observed in biopsies of patients with breast cancer [61, 63]. Interestingly, RB is decreased or lost in ERα– breast cancer [17].

5.2. Other Mechanisms Underlying Inhibition of ERα Polyubiquitination in Breast Cancer Cells

Other ERα polyubiquitination inhibitors include phosphatidylethanolamine-binding protein 4 (PEBP4), REG gamma (REG) protein and posttranslational modification processes such as acetylation and palmitoylation of ERα. PEBP4 interacts with Src kinase to block its interaction with ERα, leading to decreased phosphorylation of this receptor which inhibits its subsequent polyubiquitination and degradation [88, 89]. Moreover, REG expression, which correlates to high ERα levels, is increased in breast cancer and results in a poor clinical prognosis. REG-knockdown cells exhibited low ERα levels, probably due to its polyubiquitination and degradation, which recovered when treated with MG132 proteasome inhibitor [88].

Additionally, it has been reported that p300 protein may acetylate ERα at K266, K268, K299, K302, and K303 residues; and acetylation of ERα at K266 and K268 residues has been shown to increase its DNA-binding and transcriptional activities [90-93]. In addition to acetylation, methylation at K302 residue by SET7 has also been associated with ERα stability [94]. On the other hand, human ERα is also modified by palmitoylation at C447 by DHHC7 and DHHC21 palmitoyl acyltransferases to promote its association with the cell membrane [95]. Importantly, each of these modifications can also inhibit polyubiquitination and degradation of ERα in breast cancer cells (Table **1**).

Thus, several mechanisms protect ERα from polyubiquitination (Fig. **3**). Inhibition of ERα polyubiquitination leads to a decrease in the degradation of this receptor, and consequently, to an altered transcriptional activity, which seems to enhance the gene expression profile linked to breast cancer cell proliferation and resistance to endocrine therapy.

5.3. Effects Associated with ERα Polyubiquitination Inhibition in Breast Cancer Cells

When ERα levels are increased due to inhibition of its polyubiquitination and degradation, other changes may occur. For instance, high ERα protein levels may affect the induction of proteolysis and efficiency of ERα degradation [77, 96, 97]. Consequently, when ERα concentration is high, its transactivation function is activated by non-classical mechanisms, in which E2, growth factors or phosphorylation at S104, S106, and S118 are not involved. Therefore, the transcriptional activity of ERα as a result of its high levels is called *concentration-inducible ERα function*, which includes

INFORME DE LABORES 2019

Table 1. Molecular mechanisms associated with ERα stability in breast cancer cells.

	Mechanisms Associated to ERα Stability		References
EPIPs	MUC1	MUC1 interacts with ERα on the DNA and recruits SRC1/GRIP1 coactivators, preventing the degradation of ERα and stimulating the expression of target genes.	[149]
	PIN1	PIN1 interacts with phosphorylated ERα at the S118 residue to block association of the receptor with E6AP, thus inhibiting its degradation. In addition, PIN1 mediates ERα isomerization increasing its binding to DNA and transcriptional activity.	[86]
	LMTK3	LMTK3 interacts with and phosphorylates ERα to avoid its degradation, stabilizing it. Moreover, LMTK3 increases FOXO3-induced ERα expression by decreasing the enzymatic activity of PKC and AKT.	[105]
	GSK3	GSK3 interacts with and phosphorylates ERα (at S102, S104, and S106) to stabilize it in E2 absence. In E2 stimulated cells, GSK3 phosphorylates ERα S118, enhancing its transcriptional activity.	[150]
	cABL	cABL interacts with and phosphorylates ERα at Y52 and Y219 stabilizing it by inhibiting its polyubiquitination and degradation *via* the UPS.	[108]
	RB	RB forms a complex with ERα and HSP90 chaperone proteins, thus avoiding polyubiquitination of the receptor, enhancing its stability.	[17]
	RNF8	RNF8 monoubiquitinates ERα and functions as a coactivator modulating its activity	[61]
	RNF31	RNF31 and SHARPIN postranslationally modify ERα *via* its monoubiquitination	[62]
	SHARPIN		[63]
	SMURF1	SMURF1 also blocks ERα polyubiquitination and increases its stability, however, the molecular mechanism is not yet known.	[151]
Other ERα polyubiquitination inhibitors	Other modifications for ERα stability	Palmitoylation at C447 residue by DHHC7/DHHC21 Acetylations probably at K302/303 by p300 Methylation at K302 residue by SET7.	[95] [92] [94]
	PEBP4	PEBP4 interrupts the interaction between ERα and Src because PEBP4 competes with ERα for the Src protein, increasing ERα stability and its transcriptional activity.	[89]
	REG	ERα protein levels are decreased in REG-knockdown cells. Treatment with MG132 recovers ERα protein levels in these cells. Correlation between high levels of REG with high levels of ERα in breast tumors and poor clinical prognosis.	[88]

an unusual ERα recruitment to EREs, and thereby alters gene expression, such as changes in the magnitude of gene induction or expansion of new E2 target genes. Moreover, p160 coactivators are not required for gene transcription induced by high concentrations of ERα [98, 99].

INFORME DE LABORES 2019

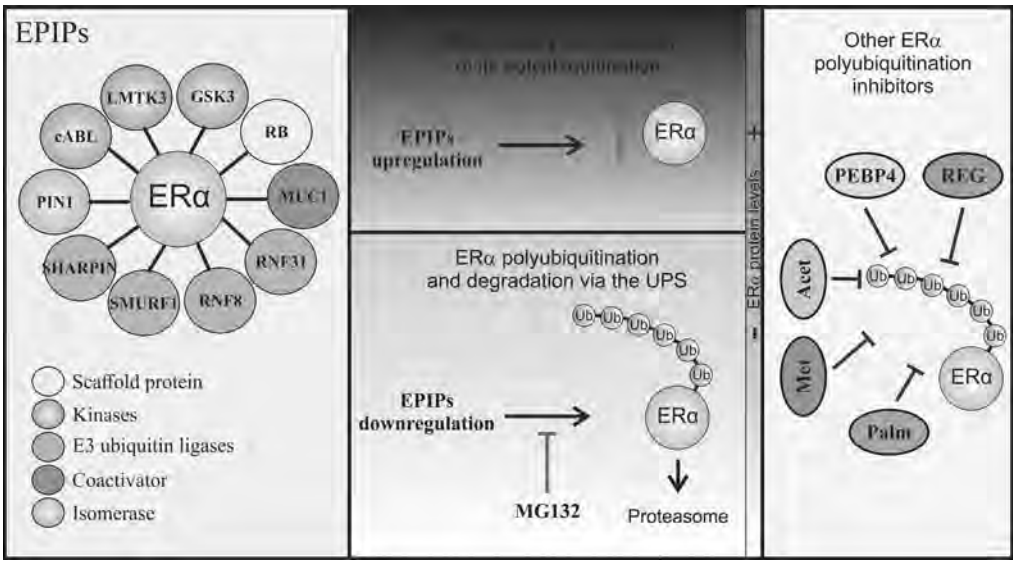

Fig. (3). ERα polyubiquitination inhibitor proteins in breast cancer cells. ERα polyubiquitination inhibitor proteins (EPIPs)**.** EPIPs interact with ERα in breast cancer cells. The upregulation of EPIPs increases ERα stability by inhibiting its polyubiquitination. In knockdown cells for each EPIP (by specific RNA interference), ERα protein levels are decreased by degradation *via* the UPS (Ubiquitin proteasome system). However, treatment with MG132 (proteasome inhibitor) restores ERα protein levels in knockdown cells. ERα modifications such as acetylation (Acet), methylation (Met) and palmitoylation (Palm), and PEBP4 and REG protein have also been associated with ERα stability in breast cancer cells.

6. ERα UBIQUITINATION PATHWAY IN ENDOCRINE RESISTANCE

Because ERα is the target for endocrine therapies using SERMs and SERDs, loss or reduction of ERα in breast cancer cells is the first critical factor in resistance to endocrine therapy. A study indicated that CUEDC2 protein promotes ERα polyubiquitination and degradation *via* the proteasome. Interestingly, CUEDC2 levels were inversely correlated with ERα levels in tumors of breast cancer patients. Moreover, high expression levels of CUEDC2 resulted in resistance to tamoxifen [100, 101]. In addition, the dysfunction or loss of RB in breast cancer has been also linked with resistance to tamoxifen. Likewise, RB tumor suppressor is reported to be lost in ERα– mammary tumors [102, 103]. In RB knockdown breast cancer cell lines, polyubiquitination and degradation of ERα are increased, compared to that in breast cancer cell line controls, but ERα downregulation in these cells is rescued by MG132 treatment [17].

Controversially, cellular processes that protect ERα from polyubiquitination and degradation have also been associated with endocrine resistance. For example, MUC1 forms a transcription complex with ERα inhibiting its polyubiquitination and thereby inducing the expression of genes linked to endocrine resistance, such as *Rab31* [104]. Moreover, ERα phosphorylation by LMTK3 inhibits its polyubiquitination. It has been reported that downregulation of LMTK3 restores the response to tamoxifen [105-107]. Similarly, the upregulation of other EPIPs such as cABL, PIN1, RNF8, and SHARPIN has been associated with the progression of breast cancer and endocrine resistance [61, 63, 108, 109]. In addition, inhibition of ERα polyubiquitination *via* several mechanisms may also facilitate resistance to SERDs used in breast cancer treatments.

7. SELECTIVE ESTROGEN RECEPTOR DEGRADERS (SERDS) IN BREAST CANCER

It is important to note that resistance to tamoxifen is a common phenomenon in the treatment of breast cancer. For this reason, the use of SERDs appears to be a potential therapy alternative for this cancer. ERα polyubiquitination is an essential step for its downregulation *via* the UPS, and this forms the basis for the mode of action of endocrine therapies with SERDs such as fulvestrant. When breast cancer cells are treated for 1 h with fulvestrant, ERα protein levels decrease due to its polyubiquitination and degradation *via* the UPS [35, 38, 39, 90, 110, 111].

Novel drugs based on SERDs other than fulvestrant have been discovered and are being studied to control ERα abundance in breast cancer cells. These include AZD9496 [112], bazedoxifene [113], RAD1901 [114], GDC-0810 [115], ZB716 [116] and LSZ102 [117]. However, fulvestrant is the only clinically approved SERD, with a known tumor growth reduction effect. Fulvestrant has been approved for first-line endocrine therapy, as well as for breast cancers for which tamoxifen or aromatase inhibitor treatment failed [118].

Residues targeted for polyubiquitination induced by fulvestrant and E2 appear to be K302 and K303 of ERα [90]. These same residues are involved in ERα SHARPIN-induced monoubiquitination, which inhibits polyubiquitination and degradation of ERα [63]. Apparently, these sites could be also monoubiquitinated by the BRCA1/BARD1 complex. In addition, these residues are also linked with the stability of the receptor under basal conditions in breast cancer [56, 57, 59, 60, 90]. In this context, ERα monoubiquitination by E3 ligases such as RNF31, RNF8, and SHARPIN may compete with the polyubiquitination of this receptor [34].

INFORME DE LABORES 2019

Remarkably, breast cancer cells may become insensitive to treatment with SERDs, if ERα is protected from polyubiquitination and degradation. Thereby, proteins and modifications that inhibit ERα polyubiquitination may play a crucial role in resistance to SERD, where ERα seems to be stabilized by losing its capacity to be degraded by the UPS (Fig. **3**).

In addition, elements of the Hippo pathway, large tumor suppressor kinases 1 and 2 (LATS1 and 2) promote ERα ubiquitination. LATS downregulation inhibits polyubiquitination and degradation of ERα, increasing the protein levels of this receptor and the expression of its target genes, thereby decreasing sensitivity to fulvestrant and its anti-tumor effects in breast cancer cells. Patients with breast cancer lacking ERα have higher levels of LATS1/2 and shorter relapse-free survival. Thus, LATS and its molecular relationship with ERα and the Hippo signaling pathway may be affected in breast cancer, leading to alterations in sensitivity to fulvestrant treatment [119].

8. *ESR1* MUTATIONS AND SERDs IN BREAST CANCER

8.1. Generalities Related to *ESR1* Mutations in Breast Cancer

ESR1 mutations, Y537S, Y537N, Y537C, D538G, and E380Q, have been discovered *via* large-scale next-generation sequencing (NGS) in mammary tumors from patients. Generally, these mutations are detected in metastatic breast cancer than in early stage breast cancer, facilitating their detection in circulating tumor DNA using droplet digital PCR [120, 121]. Interestingly, *ESR1* mutations have been identified mainly in the LBD of ERα generating conformational changes and E2-independent activity. Moreover, these mutations are associated with an acquired resistance to endocrine therapy [122].

Some of these mutations have been experimentally generated in breast cancer cell lines using CRISPR/Cas genome editing techniques, whereas their activities have been evaluated *via* NGS technologies such as whole-genome sequencing (WGS), ChIP-sequencing (ChIP-seq), whole-exome sequencing (WES) and RNA sequencing (RNA-Seq). These breast cancer cell lines with *ESR1* mutations also display E2-independent ERα activity and resistance to endocrine therapy. Surprisingly, a specific gene profile is altered by each of these *ESR1* mutations with a limited number of target genes in common, suggesting the molecular complexity of the endocrine resistance [123]. Moreover, a cistrome study of these mutants showed that cis-acting targets on genomes of breast cancer cells are different for each *ESR1* mutation, and may be linked to several genes involved in metastasis and endocrine resistance, compared to the E2-bound wild-type ERα protein [124].

ERα mutations detected in breast cancer (including Y537S/N/C, D538G, E380Q or S463P) are associated with resistance to aromatase inhibitors and SERMs, but appeared to have no effect on the response to SERDs (fulvestrant and AZD9496), with the exception of *ESR1* mutations in Y537 residue [121, 123, 125]. Moreover, in breast cancer cell lines with acquired endocrine resistance due to long-term E2 deprivation, *ESR1* mutations Y537C and Y537S were detected after acquiring resistance. These *ESR1* mutants display an alteration in genome binding, target gene transcription, and interactions with other proteins [126].

8.2. *ESR1* Mutations Involved in ERα Ubiquitination in Breast Cancer

As mentioned above, *ESR1* mutations in Y537 residue are commonly detected in mammary tumors of patients. This residue is associated with ERα polyubiquitination. In response to E2, ERα is phosphorylated at its Y537 residue by Src kinase, and then polyubiquitinated by E6AP E3 ubiquitin ligase and degraded *via* the UPS. Because E6AP is an E3-ubiquitin ligase and coactivator for ERα, the interaction with E6AP can also promote ERα binding to chromatin and ERα-mediated gene expression. Accordingly, a laboratory-generated mutant of this residue prevented ERα degradation, thereby affecting its activity and ability to respond to endocrine therapies [75, 127]. Therefore, mutations of the Y537 residue are involved in ERα stability and play an important role in SERD resistance.

In addition, K303 residue has been suggested as the target of polyubiquitination/monoubiquitination and acetylation [57, 59, 90, 92, 94]. Mutations in this residue have been detected in premalignant breast lesions and may be important in breast cancer progression [128, 129].

9. DISCUSSION

Approximately 70% of human breast cancers are ERα+. This nuclear receptor regulates the transcription of certain pro-tumor genes and mediates extranuclear signaling in breast cancer cells. High ERα levels have been detected in ERα+ mammary tumors [130-132], and ERα-dependent gene signatures are differentially expressed in breast cancer cells and mammary tumors of patients with varying clinical outcomes [133-135]. Additionally, nucleocytoplasmic transport seems to be differentially modulated in ERα– and ERα+ breast cancer cells [136]. Thus, ERα expression has important implications for breast cancer biology. More importantly, ERα is the target for endocrine therapies using SERDs and SERMs, but some ERα+ breast cancers are non-responsive or develop resistance to these treatments. Therefore, ERα and its modulatory mechanisms are central to the progression of this cancer. In this context, Ub-dependent pathways have emerged as important regulators of ERα levels and functions in breast cancer.

Ubiquitination system elements (E1, E2, E3 enzymes and DUBs) seem to be altered in mammary tumors compared to normal mammary tissue [137-142]. Furthermore, ERα regulation by Ub is complex since Ub is able to interact either covalently (mono or polyubiquitination) or non-covalently with ERα.

Monoubiquitination increases ERα stability and transcriptional activity. In contrast, ERα polyubiquitination signals ERα degradation *via* the UPS but also acts as a marker, which in combination with proteasome activity, is associated with the transcriptional cycle of ERα. E2 hormone positively regulates polyubiquitination of ERα, but negatively modulates its monoubiquitination, suggesting that a balance between these processes control ERα activity.

INFORME DE LABORES 2019

9.1. Molecular Mechanisms for ERα Ubiquitination

E2 hormone signaling induces several phosphorylations in ERα, one of which is catalyzed by Src kinase at the Y537 residue, which is a prerequisite for recruiting the E6AP E3 ligase/coactivator that mediates polyubiquitination and degradation of ERα in breast cancer cells (Fig. **4**). This is important because metastatic mammary tumors presenting endocrine resistance display mutations in this residue. Moreover, phosphorylation of Y537 can be interrupted by PIN1 that interacts with ERα to block its interaction with E6AP, thereby protecting it from degradation. Also, PEBP4 interacts with Src kinase to inhibit its association with ERα and its subsequent phosphorylation-dependent degradation [75, 86, 89]. Furthermore, the interaction between ERα and EPIPs, alterations in the interactome for its degradation, and its posttranslational modifications such as acetylation, palmitoylation and methylation can increase ERα stability affecting its levels and functions in breast cancer cells (Table **1**, Fig. **3**).

Monoubiquitination is a posttranslational modification that confers ERα stability by inhibiting its polyubiquitination [87]. Interestingly, as the sites for monoubiquitination and polyubiquitination appear to be the same, competition between these modifications may exist. E3 ligases that participate in these processes are different. Ligases, BRCA1, RNF31, and SHARPIN, have been associated with ERα monoubiquitination, whereas RNF8 which acts as a coactivator also induces monoubiquitination of ERα [59, 61-63]. Instead, polyubiquitination of ERα is mediated by different enzymes with dual roles, as E3 ligases and transcriptional coactivators, such as E6AP [75]. Lysine residues responsible for mono/polyubiquitination may also be implicated in acetylation and methylation of ERα which may affect its stability [90, 92-94]. Additionally, ERα has UBDs that interact with ubiquitinated proteins, which apparently are also required for transcriptional activity of the receptor and its monoubiquitination.

Thus, molecular mechanisms that modulate ERα by Ub-mediated pathways are multifaceted and regulate not only the degradation (polyubiquitination), and stability (monoubiquitination) of ERα, but also the transcriptional cycle and ERα-driven gene transcription. Therefore, many posttranslational modifications and interactions appear to be involved in Ub-dependent ERα modulation. Notably, ERα UBDs may also enable interactions with other ubiquitinated modulators of ERα, which remain to be identified.

Mechanisms that underlie ERα stability may also induce serious changes in nuclear and extranuclear activities as well as in ERα crosstalk, thus affecting the response to SERMs. Furthermore, SERDs are drugs that mediate the downregulation of ERα *via* polyubiquitination and degradation by the proteasome. Then, mechanisms that stabilize ERα in breast cancer may be critical in the development of resistance to SERDs.

9.2. ERα Ubiquitination in Endocrine Resistance

Conflicting data exist concerning the effects of inducing or inhibiting polyubiquitination and degradation of ERα, on endocrine resistance in breast cancer. Based on these data, it may be concluded that both induction and inhibition may influence endocrine resistance, but in a different manner. In ERα– breast cancer, polyubiquitination and degradation of ERα may be a factor in the negativity of this receptor [143]. In fact, proteins that promote ERα degradation by the UPS (as CUEDC2 and LATS1/2) are increased in ERα– mammary tumors. Hence, high levels of CUEDC2 and LATS1/2 are correlated with low ERα levels, whereas proteins that protect it from degradation, like RB, seem to be downregulated in ERα– breast cancer [101, 119]. Thus, polyubiquitination of ERα is important in ERα– mammary tumors. The absence of ERα precludes the use of endocrine therapy, these cells being resistant to such therapies.

The exact opposite of the above process may occur in ERα+ breast cancer, where ERα expression is considered as an indicator for the initiation of endocrine therapy. However, these breast cancer cells can present *de novo* or acquired resistance to endocrine therapy even in the presence of ERα, *via* mechanisms that are not completely understood. Based on some data, it is hypothesized that ERα stability may promote endocrine resistance in ERα+ breast cancer. When ERα stability is enhanced, its turnover is affected and levels of ERα+ are sustained. Sustained levels of ERα may stimulate persistent extranuclear and nuclear signaling associated with endocrine resistance and alter crosstalk between pathways, generating new signaling routes that promote the progression of this cancer.

9.3. Future Challenges

Endocrine resistance develops mainly against aromatase inhibitors and tamoxifen than against fulvestrant, indicating its potential as a drug central to breast cancer treatment. Currently, the ERα degrader, fulvestrant, is the first-in-class SERD member used in breast cancer patients. However, this drug has certain setbacks such as poor biodisponibility and the need for intramuscular administration. Therefore, development of new SERDs that can be administered *via* the oral route, with enhanced biodisponibility is being mulled. Currently, several newer SERDs are in the clinical investigation phase and may be nearing release pending approval [37, 40]. In this context, a better understanding of mechanisms that promote as well as inhibit polyubiquitination and degradation of ERα may be important for preventing resistance to SERDs. Hence, mechanisms underlying ERα stability may be targeted in the development of new therapeutic strategies as well as indicators of endocrine therapy selection.

Additionally, ERα LBD mutations linked to endocrine therapy resistance have been identified in metastatic breast cancer patients [121]. Interestingly, the use of Selective Estrogen Receptor Covalent Antagonists (SERCAs), which inactivate both wild-type and mutated ERα has been suggested, but these drugs may require further screening [144]. The need to develop novel drugs, such as E2 antagonists, as well as drugs that target domains other than ERα LBDs, has been recognized. Proteolysis targeting chimeric molecules known as PROTACs that target ERα proteolysis, are being designed [145]. PROTACs show promise as part of a therapeutic strategy involving downregulation of ERα *via* the UPS. Moreover, PROTACs may be useful in regulating proteins that modulate ERα stability. Therefore, modulation of

INFORME DE LABORES 2019

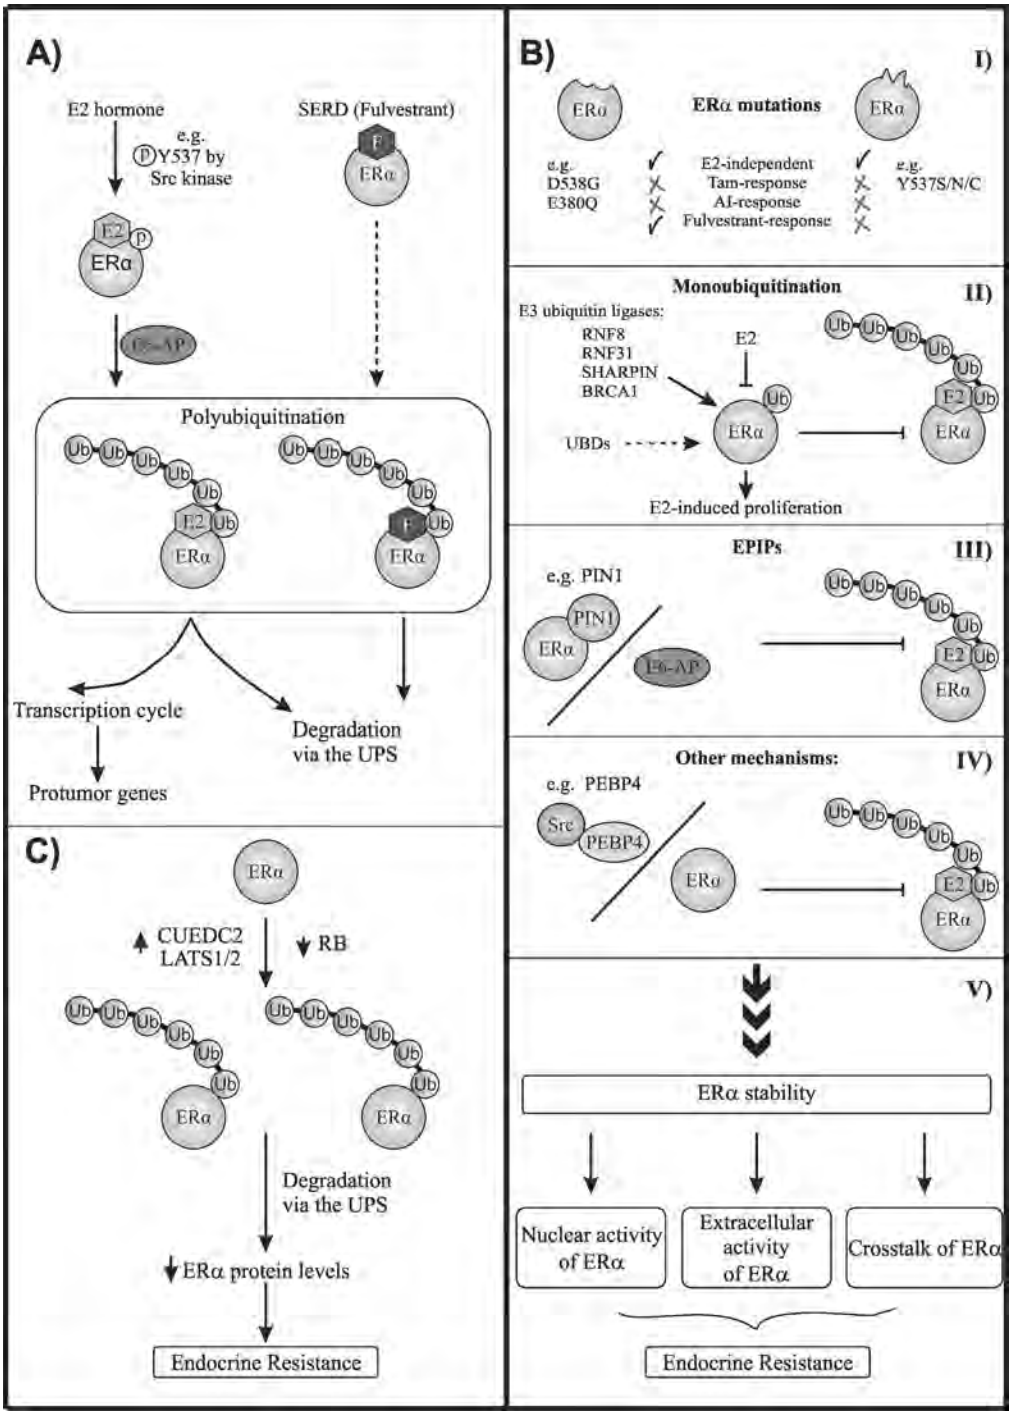

Fig. (4). Molecular pathways in the regulation of ERα by Ub in breast cancer cells. A) E2 activates ERα *via* binding to LBD to induce the expression of pro-tumor genes. E2 also induces phosphorylation in ERα *e.g.* in the Y537 residue by Src kinase. This modification allows the recruitment of E6AP E3 ligase/coactivator to induce its polyubiquitination (polyUb). The polyUb of ERα is required for its transcriptional cycle and its degradation *via* the UPS. SERDs as fulvestrant also induce the polyUb and degradation of ERα but without its transcription activation. **B**) I) In ERα+ advanced breast cancer with endocrine resistance, mutations in ERα were found to be associated with E2-independent activity and insensitivity to endocrine therapy, some of which occur at Y537 residue, also affecting the response to SERDs. II) Moreover, in ERα+ breast cancer cells, monoubiquitination by some E3 ligases inhibit polyUb and degradation of ERα to stabilize it. III) The interaction with EPIPs also confers ERα stability, *e.g.*, PIN1 interacts with ERα to inhibit its interaction with E6AP. IV) Other modifications and proteins can also stabilize ERα, *e.g.* PEBP4 interacts with Src kinase blocking its interaction with ERα avoiding its polyUb and degradation. V) ERα stability can lead to its sustained signaling, and the expression related to endocrine resistance and alterations in its crosstalk with other pathways. **C**) A decrease in ERα stability may be a factor in the negativity of ERα in breast cancer cells. Proteins that promote (CUEDC2 and LATS1/2) the polyUb and degradation are upregulated in ERα– breast cancer cells, whereas proteins (*e.g.* RB) that protect it from degradation seem to be downregulated. As a result, ERα is degraded *via* the UPS, contributing to the reduction of ERα levels. Tam= tamoxifen, AI= aromatase inhibitors.

INFORME DE LABORES 2019

ERα *via* Ub related pathways appear to be key to the development of novel therapeutic strategies for breast cancer control.

Finally, some Ub-like proteins are deregulated in breast cancer. ISG15 is upregulated in mammary tumors in comparison with normal tissue [146, 147]. Similarly, SUMO which modifies ERα is upregulated in breast cancer cells [148]. This indicates that ERα functions may be regulated by other Ub-like proteins. An understanding of these mechanisms may also enable the detection of novel molecular targets for this disease.

CONCLUSION

Ub is a small protein with enormous implications in the regulation of ERα in breast cancer cells. A better understanding of the relationship between ERα and Ub may reveal mechanisms underlying the modulation of ERα signaling by Ub-dependent processes in breast cancer cells, which, in turn, may be useful in determining novel strategies for treatment of this cancer.

LIST OF ABBREVIATIONS

AF = Activation Function
AP1 = Activator Protein 1
BARD1 = BRCA1-associated RING domain protein 1
BRCA1 = Breast Cancer Type 1 susceptibility protein
cABL = Abelson tyrosine-protein kinase
CDK11p58 = Cyclin-dependent kinase 11B
CDK2 = Cyclin-dependent kinase 2
CHIP = Carboxyl terminus of HSC70-interacting protein
CUED2 = CUE domain-containing protein 2
DBD = DNA Binding Domain
ddPCR = droplet digital PCR
DUB = Deubiquitinase
E2 = 17-Beta Estradiol
E6AP = E6-associated protein
EGF = Epidermal Growth Factor
EPIIPs = ER polyubiquitination inhibitor proteins
EREs = Estrogen Response Elements
ERK7 = Extracellular signal-regulated kinase 7
ERα = Estrogen Receptor Alpha
ESR1 = Estrogen Receptor 1
FOXA1 = Forkhead box protein A1
GSK3 = Glycogen Synthase Kinase 3
HECT = Homologous to the E6AP Carboxyl Terminus
HSP90 = Heat Shock Protein 90
IGF = Insulin-like Growth Factor
LATS1 = Large Tumor Suppressor kinase 1
LATS2 = Large Tumor Suppressor kinase 2
LBD = Ligand Binding Domain
LMTK3 = Lemur Tyrosine Kinase 3
MDM2 = Murine Double Minute 2
MEMO = Mediator of ERBB2-driven cell Motility
MNAR = Modulator of Non-genomic Actions of the Estrogen Receptor
MTA1 = Metastasis-Associated Protein 1
MUC1 = Mucin 1
NF-kappaB = Nuclear Factor kappa-light-chain-enhancer of activated B cells
NGS = Next Generation Sequencing
p38MAPK = p38 Mitogen-activated protein kinase
PEBP4 = Phosphatidyl ethanolamine-binding protein 4
PIN1 = Peptidyl-propyl cis-trans isomerase NIMA-interacting 1
PKC = Protein Kinase C
RB = Retinoblastoma
REG = REGgamma
RING = Really Interesting New Gene
RNF31 = RING finger protein 31
RNF8 = RING finger protein 8
SERD = Selective Estrogen Receptor Degraders
SERM = Selective Estrogen Receptor Modulator
SHARPIN1 = Shack-associated RH domain-interacting protein
SKP2 = S-phase kinase-associated protein 2
SMURF1 = SMAD ubiquitination regulatory factor
Ub = Ubiquitin
UBD = Ubiquitin-binding Domain
UPS = Ubiquitin-Proteasome System

CONSENT FOR PUBLICATION

Not applicable.

CONFLICT OF INTEREST

The authors declare no conflict of interest, financial or otherwise.

ACKNOWLEDGEMENTS

A.C.T.-C. designed the research, discussed and integrated the information for all sections, and wrote the manuscript. J.O.R.-J helped in the discussion and integration of information, modified the figures, and improved the manuscript. E.C.-R. helped in the integration of some papers and figures, and prepared the abbreviations list. This work was supported by the DGAPA-UNAM (grants number PAPIIT–IA200916).

Abstract

Estrogens demonstrate biological activity in numerous organ systems, including the immune system, and exert their effects through estrogen receptors (ER) of two types: intracellular ERα and ERβ that activate transcriptional factors and membrane G protein-coupled ER GPER. The latter is capable to mediate fast activation of cytosolic signaling pathways, influencing transcriptional events in response to estrogens. Tamoxifen (TAM), widely used in chemotherapy of ERα-positive breast cancer, is considered as an ERα antagonist and GPER agonist. TAM was shown to possess "off-target" cytotoxicity, not related to ER in various tumor types. The present work was designed to study biological effects of TAM on the glucocorticoid (GC)-resistant cell line Jurkat, derived from acute lymphoblastic leukemia of T lineage (T-ALL). We have shown that T-ALL cell lines, in contrast to healthy T cells, express only GPER, but not ERα or ERβ. TAM compromised mitochondrial function and reduced the viability and proliferation of Jurkat cells. Additionally, TAM induced autophagy in a GPER-dependent manner. Gene expression profiling revealed the up-regulation of autophagy-related gene *ATG5*. Interestingly, TAM sensitized Jurkat cells to dexamethasone (DEX) treatment, which may be related to its capacity to cause autophagy. We suggest that TAM-based adjuvant therapy may represent a novel strategy in T-ALL patients handling.

KEYWORDS

tamoxifen, Jurkat cells, estrogen receptors, GPER, autophagy, apoptosis, cell cycle, proliferation, glucocorticoid resistance

1 | INTRODUCTION

Estrogens are known to have an important biological function in both female and male physiology and pathology in various organ and systems, including the immune system.[1–3] Their effects are mediated through binding ER to two types of ER: first, intracellular or intranuclear ERα and ERβ that activate transcription[4]; and second, membrane G protein-coupled ER, GPER or GPR30, that were identified later.[5] The latter mediate rapid triggering of signaling pathways by estrogens and antiestrogens, through MAPK activation, and early gene expression. Although ERα and ERβ are known to be expressed in immune cells and some lymphomas,[6] the information available on GPER expression in lymphoid cells is limited. Recently, it was reported that GPER contribute to the proliferation and survival of mantle cell lymphoma cells.[7] It has also been proposed that GPER regulates CXCR4 signaling in pre-B cell ALL.[8] Remarkably, GPER mediates the proliferative

effect of estrogen in numerous cancer types.[9,10] Accordingly, GPER agonist G-1 was shown to inhibit tumor growth in triple-negative breast cancer cells,[11] adrenocortical carcinoma,[12] lung cancer,[13] and ovarian cancer.[14]

TAM is considered as an ERα antagonist and GPER agonist,[15,16] which has been the first-line targeted therapy for the management of ERα positive breast cancers for almost 60 years.[17] However, several recent reports have pointed out some novel, "off-target" or non-ER-related anticancer effects of TAM, independent of nuclear ER.[18,19] Among these are target proteins involved in the regulation of proliferation, cell cycle progression, autophagy, and chemoresistance. In this regard, TAM-induced apoptosis of breast cancer MCF-7 cells via GPER/PI3K/MAPK pathway has also been reported.[20]

At doses significantly higher than those used for breast cancer treatment, but still in the therapeutic range, TAM caused an inhibitory effect on PKC, which is overexpressed in different malignancies, particularly in gliomas, glioblastoma, and anaplastic astrocytomas, resulting in cell toxicity.[21–25] Using TAM as a coadjuvant therapy, a significant improvement in the outcome of pancreatic cancer patients was archived.[26–28] Besides, there is evidence that TAM is a potent inducer of autophagy, and that its cytotoxic effect is related to the induction of autophagy previous to cell death.[29] On the other hand, autophagy may also have a protective effect in tumor cells and induce chemoresistance in cancer.[30] Then, the activation or inhibition of autophagy in every type of cancer should be studied in detail, to find the best strategy for targeting this process for cancer treatment. TAM-based coadjuvant therapy may represent an attractive approach in anticancer treatment, and TAM-mediated activation of autophagy may have an important relevance in this process. In this regard, we would like to mention the study published by Laane and colleagues[31] who demonstrated that GC, the first choice drugs used for the treatment of lymphoid malignancies, induced autophagy upstream of apoptosis in acute lymphoblastic leukemia cells of B lineage (B-ALL). The crucial role of autophagy in DEX-induced cell death was confirmed by the fact that autophagy inhibition precluded apoptosis in these cells. Because GC are administered to leukemic patients during all phases of therapy, GC resistance represents an essential challenge to improve the outcome of these patients.[32] At the same time, the referenced work represents the only study relating GC resistance with the autophagic process. Since there is no previously published evidence on the biological effects of TAM-induced autophagy in T-ALL, the present work was designed to study the antileukemic effect of TAM, its capability to induce autophagy and reverse GC-resistance in the Jurkat cell line derived from a T-ALL sample in relapse.

2 | MATERIALS AND METHODS

2.1 | Cell lines and culture conditions

Cell lines established from peripheral blood of a T-ALL patient in relapse were purchased from ATCC: Jurkat, clone E6-1, from a 14-year-old male (ATCC TIB); MOLT-3 from a 19-year-old male (ATCC CRL-1552); CCRF-CEM, from a 4-year-old girl (ATCC CCL-119). The cells were cultured in suspension in Advanced RPMI 1640 Medium supplemented with 5% (v/v) heat-inactivated fetal bovine serum (FBS), 2 mM GlutaMAX, 10 mM HEPES, and 100 U/ml penicillin, 100 μg/ml streptomycin (all from Gibco, Thermo Fisher Scientific). In some experiments, to count the number of autophagosomes and autolysosomes, tandem-labeled mCherry-GFP-LC3 Jurkat cells (gift from Dr. A. Thorburn, Colorado, USA) were used. These cells were maintained in complete growth medium (as for wild type Jurkat cells) additionally supplemented with 400 μg/ml of hygromycin B (Sigma, H3274) for selection. Cell lines were cultured in a humidified incubator in 5% CO_2 atmosphere at 37 °C. Cells were maintained in the logarithmic growth phase by daily medium refreshment.

2.2 | Chemicals

TAM (Sigma, T5648), G-36 (Cayman Chemical, 14397), and Chloroquine (CQ) (Sigma, C6628) were used. Stock solutions of TAM (in ethanol), G-36 (in DMSO), and CQ (in PBS) were prepared at 20 mM and stored at −20°C. DEX was acquired as solution for intravenous injections at 4 mg/ml (Chinoin Pharmaceutical Products, Aguascalientes, Mexico) and stored at 4 °C. All working solutions were prepared from stock solutions in growth medium immediately before experiments. Ethanol and DMSO used as vehicles in concentrations up to 1% did not demonstrate any effect in the protocols used in this study.

2.3 | Purification and activation of CD4$^+$ lymphocytes

Mature CD4$^+$ lymphocytes were obtained from peripheral blood of healthy donors. Peripheral blood was taken by trained personnel under aseptic condition with sterile material for each donor. The protocol was approved by Bioethics and Biosecurity Committee of the Biomedical Research Centre according to Federal (Artículo 100, Ley General de Salud), State, and local laws. Informed consent was obtained from each participant. Blood samples were diluted 1 : 1 with PBS. The mononuclear cells (MNC) were separated by Ficoll gradient (Ficoll-Paque PLUS, GE Healthcare). MNC were subjected to negative selection (to avoid activation) with CD4$^+$ T cell isolation kit, following Miltenyi Biotec specifications. The CD4$^+$ T cells were cultured in complete RPMI 1640 medium, in 24-well plates (no more than 1.5×10^6 cells per ml), for 24 h. For polyclonal activation, resting lymphocytes were pretreated in 96-well plates with anti-CD3 monoclonal antibodies (5 μg/ml) (BD, 555336) for 2 h at 37 °C; medium excess was removed and 1×10^5 cells were incubated with (2 μg/ml) anti-CD28 monoclonal antibodies (BD, 555725) for 4 days. Ligation of CD3/CD28 provides a powerful antigen-independent stimulus by cross-linking T cell receptor (TCR) resulting in transit from quiescent to proliferation state.

2.4 | Cell viability

Jurkat cells or activated CD4$^+$ lymphocytes (1×10^5 per well) were seeded in 96-well plates, treated with corresponding concentrations of TAM alone, or with vehicle, and incubated during 24–96 h. Every 24 h, cell count was performed using a hemocytometer and trypan blue dye.

Additionally, cell viability was determined using metabolic resazurin-based in vitro Toxicology Assay Kit (Sigma-Aldrich, TOX-8) according to manufacturer's recommendations. Kit mix, 10% (v/v) of the final volume, was added to each well and incubated during 4–6 h at 37°C. Resazurin (non-fluorescent) to resorufin (fluorescent) conversion was measured fluorometrically (Ex/Em = 560/590 nm) using GloMax Discover Multimode Microplate reader (Cat. GM3000, Promega). Three or more replicates were prepared for each concentration in all experiments to decrease variability.

2.5 | CFSE cell proliferation assay

CFSE cell proliferation assay was carried out as described earlier[33] with some modifications. Cells were washed, resuspended in PBS at a concentration of 1×10^6/ml and stained with carboxy-fluorescein succinimidyl ester (CFSE, ThermoFisher, C34554) to a final concentration of 0.5 μM or 1 μM for Jurkat cells and $CD4^+$ lymphocytes, respectively. Cells were incubated for 30 min at room temperature, with agitation every 5 min. Labeled Jurkat cells were washed with PBS, seeded in fresh culture medium into 24-well plates (5×10^5 cells/well) in the presence of increasing TAM concentrations, harvested every 24 h, and CFSE fluorescence intensity was measured by flow cytometry (FACSCanto II, BD Biosciences). $CD4^+$ lymphocytes were activated as described previously and TAM was added after 24 h. Lymphocytes were harvested after 72 h of culture for cytometric analysis. Data analysis was performed using FlowJo 10.2 Software.

2.6 | Western blot analysis

For LC3 immunoblotting, cells treated with CQ alone or in combination with TAM were harvested and lysed with RIPA buffer supplemented with protease inhibitors (Complete, Roche, 11697498001). Protein was quantitated using BCA Protein Assay Kit (Sigma, BCA1); 10 μg (for LC3-II) of protein were loaded in a 15% SDS-PAGE, transferred onto PVDF membrane, blocked for 1 h with 5% BSA in TBS Tween-20 buffer (TBS-T) and incubated overnight at 4 °C with anti-human LC3 rabbit antibody (Novus-Biologicals, NB100-2220, dilution 1:3000). For estrogen receptor evaluation, 20 μg of protein were loaded in a 10% SDS-PAGE; primary antibodies were: anti-human ERα (Novus-Biologicals, NBP2-84827, dilution 1:500), anti-human ERβ (Novus-Biologicals, NBP2-16379, dilution 1:1000) and GPER (Novus-Biologicals, NBP1-31239, dilution 1:1000), all produced in rabbit. Rabbit anti-human GAPDH antibodies (abcam, ab9485, dilution 1:2000) were used as a loading control. HRP-conjugated goat anti-rabbit IgG (Novus-Biologicals, NBP2-30348H, 1:3000) was used as secondary antibody and incubated 1 h at room temperature. The membranes were incubated with ECL detection reagent (Bio-Rad, 170–5061), protein bands were visualized with a Bio-Rad Universal Hood II system and analyzed with Image Lab 5.0 software.

2.7 | Mitochondrial membrane potential measurement

To evaluate changes in mitochondrial membrane potential ($\Delta\Psi$m), the fluorescent dye rhodamine-123 (Rhod-123) (Sigma, R8004) was used, which stains mitochondria directly proportional to $\Delta\Psi$m. After treatment with TAM, or carbonyl cyanide 4-(trifluoromethoxy) phenylhydrazone (FCCP) (Sigma, C2920) as a positive control of mitochondrial membrane depolarization, Jurkat cells were harvested, counted (trypan blue exclusion test), washed with PBS and stained with Rhod-123 (100 μl Rhod-123 2 μM for each 2.5×10^5 cells) for 30 min at room temperature. Changes in $\Delta\Psi$m before cell death were observed through flow cytometry (FACSCanto II, BD Biosciences) by selecting live population (PI exclusion) and Rhod-123 fluorescence measurement (Ex/Em = 507/530). Data analysis was performed with FlowJo 10.2 Software.

2.8 | DNA content/cell cycle progression

Samples of untreated or TAM-treated cells were counted (trypan blue exclusion test), harvested, washed with cold PBS and fixed with ice-cold 70% ethanol overnight. Next day, after two washes with PBS, cells were treated for 15 min with 0.1% Triton X-100 in PBS for permeabilization. Finally, 500 μl of PBS working solution containing 0.15 μM of Propidium Iodide (Invitrogen, PNN1011), 10 μg/ml RNase (Sigma, R4875), and 0.1% BSA (Research Organics, 1336A) were added to every sample of 1×10^6 cells. Due to more condensed DNA, PI penetration and staining is less efficient in G2 than G1 cells. Then, to insure PI DNA staining saturation, the samples were incubated in working solution at least 24 h at 4 °C, giving good delineation of G1 versus G2 peaks (G2/G1 ratio usually more than 1.95). For data acquisition, FACSCanto II cytometer (BD Biosciences) was used, equipped by 488 laser, 556 LP mirror, and 585/42 filter, to detect PI (Ex/Em max = 538/617 nm) fluorescence intensity. Cell cycle phase distribution was evaluated after appropriate gating of cell population in FSC versus SSC plot to exclude debris, following by gating in PI-FL (area) versus PI-FL (weight) plot to exclude doublets. Events (50,000) were analyzed in each sample. Data analysis was performed using ModFit 5.0 Software in Trial Version.

2.9 | Immunofluorescence assays for cell death and autophagy

After TAM treatment, cells were stained with cell death kit (Invitrogen, V13245) for 15 min, according to manufacturer's instructions with some modifications. It is well known that externalization of phosphatidylserine on the outer leaflet of the plasma membrane is a feature of apoptotic cells. Annexin V specifically binds to phosphatidylserine, and apoptotic cells are positively stained with Annexin V-Alexa Fluor 488 conjugate (Ex/Em max = 495/519), whereas PI (Ex/Em max = 538/617nm) binds to nucleic acids, permeating only into the necrotic/late apoptotic cells with disintegrated plasma membrane. The double positive fraction then represented late apoptosis and necrosis. For the assay, 3 μl of Annexin V-Alexa Fluor 488 and 0.2 μl PI were added for each 1×10^6 cells. For autophagolysosome accumulation monitoring, cells were incubated with monodansylcadaverine at 60 μM (MDC, Ex/Em max = 335/518 nm; Sigma, 30432). Fluorescence was measured either by flow cytometry (FACSCanto II, BD Biosciences) or confocal microscopy (ZEISS LSM 700) with a ×40 objective. For excitation, 405 nm laser was used for MDC, and 488 nm laser for Alexa

Fluor 488 and PI. In cytometry, data were collected using 510/50 nm, 530/30 nm; 585/42 nm filters. Annexin V-Alexa Fluor 488 and PI negative populations were classified as viable, Annexin V-Alexa Fluor 488 positive, PI negative as apoptotic, Annexin V-Alexa Fluor 488 negative, PI positive as necrotic, and Annexin V-Alexa Fluor 488 and PI positive as late apoptotic or necrotic. Data analysis was performed with FlowJo 10.2 and ZEN 2.3 software.

2.10 | Autophagic flux measurement with mCherry-GFP-LC3

We used stably expressing tandem mCherry-GFP-LC3 Jurkat cells to measure autophagic flux. Upon autophagy induction, microtubule-associated protein light chain 3-I (LC3I) is conjugated to phosphatidylethanolamine (LC3II) and localized to the autophagosomes. However, LC3II is also degraded inside the lysosomes or de-conjugated by Atg4, decreasing its intracellular content. One approach to measure autophagic flux is the use of a tandem/tagged LC3 construct. Thus, LC3II positive autophagosomes would be double mCherry and GFP positive. On the other hand, since GFP signal is more sensitive to the acidic conditions in the lysosomal lumen, after autophagosome fusion with the lysosome, acidic lysosomal pH quenches the pH-sensitive GFP fluorescence and autophagolysosomes would be mCherry+GFP−. Thus, a ratio of mCherry+/GFP+ cells is an indication of autophagosome formation and degradation within the lysosome or autophagic flux as previously described.[34]

After TAM and/or G-36 treatment, LC3 accumulation was observed with ×40 objective using confocal microscopy. Images were acquired using Carl Zeiss LSM 700 system coupled to an inverted Observer Z1 microscope equipped with 488 and 555 nm lasers, or custom made confocal microscope (Solamere Technology Group, Salt Lake city, USA) based on a Yakogawa spindisk confocal scan head (CSUX1M1, Yokogawa Electronic Co., Tokyo, Japan), equipped with solid state Coherent Obis lasers (405, 488, 561, and 640 nm). Autophagy evaluation was assessed by counting red (mCherry+) and green (GFP+) dots in the cell. Cells were treated with TAM ± autophagy blocker CQ which neutralizes lysosomal pH and avoids GFP quenching produced by lysosomal acidic pH. Based on the GFP+ or mCherry+ average dots observed in control conditions, a cell was considered as GFP+ when it had more than two green dots and mCherry+ with six or more red dots. Data analysis was performed with ZEN 2.3 software. Three fields by sample were considered and the mean of mCherry/GFP relation of three independent experiments was graphed.[35]

2.11 | Changes in genetic transcription patterns

Jurkat cells were treated with 7.5 μM TAM for 24 h. In controls, the corresponding concentration of vehicle (ethanol) was used. TRizol reagent (ThermoFisher, 15596018) was used for RNA isolation according manufacturer's instructions. RNA concentration was measured with QuantiFluor RNA System (Promega, E3310), RNA purity and integrity were observed through gel electrophoresis.

Total RNA extracted from 1.5×10^6 cells was used to generate microarray expression data at the microarray facility in the Cell Physiology Institute (UNAM, Mexico). House double channel platform was used and microarrays were printed with a human 50-mer oligo library set "A" from MWG BiotechOligo Sets. The microarray contains approximately 10,000 specific gene oligonucleotide probes representing the best-annotated human genes. Chips were opposite stained with Alexa 555 and Alexa 647 as experimental and SWAP repetitions. The analysis was carried out using Genarise software and the lists of up- and down-regulated genes were obtained (Z-Score cuts 1.5). The data of microarrays were deposited in a public functional genomics data repository Gene Expression Omnibus (GEO) with a reference number GSE122852. Ten genes of interest were selected to confirm their expression level using qRT-PCR.

To quantify the expression of genes of interest in Jurkat cells, or to verify the expression of various estrogen receptors in different cell lines, the qRT-PCR was performed as follows: 500 ng of total RNA was reverse transcribed using QIAGEN Quantitec Reverse Transcription Kit (cat no. 205313), following the manufacturer's instructions, in a final volume of 20 μl; cDNA was diluted 1 : 3 in nuclease-free water. Samples were processed in triplicates. The primers nucleotide sequences are summarized in Table 1.

Quantitative PCR was performed using Maxima SYBR Green qPCR Master Mix (2X) and PikoReal Real-Time PCR System (Thermo

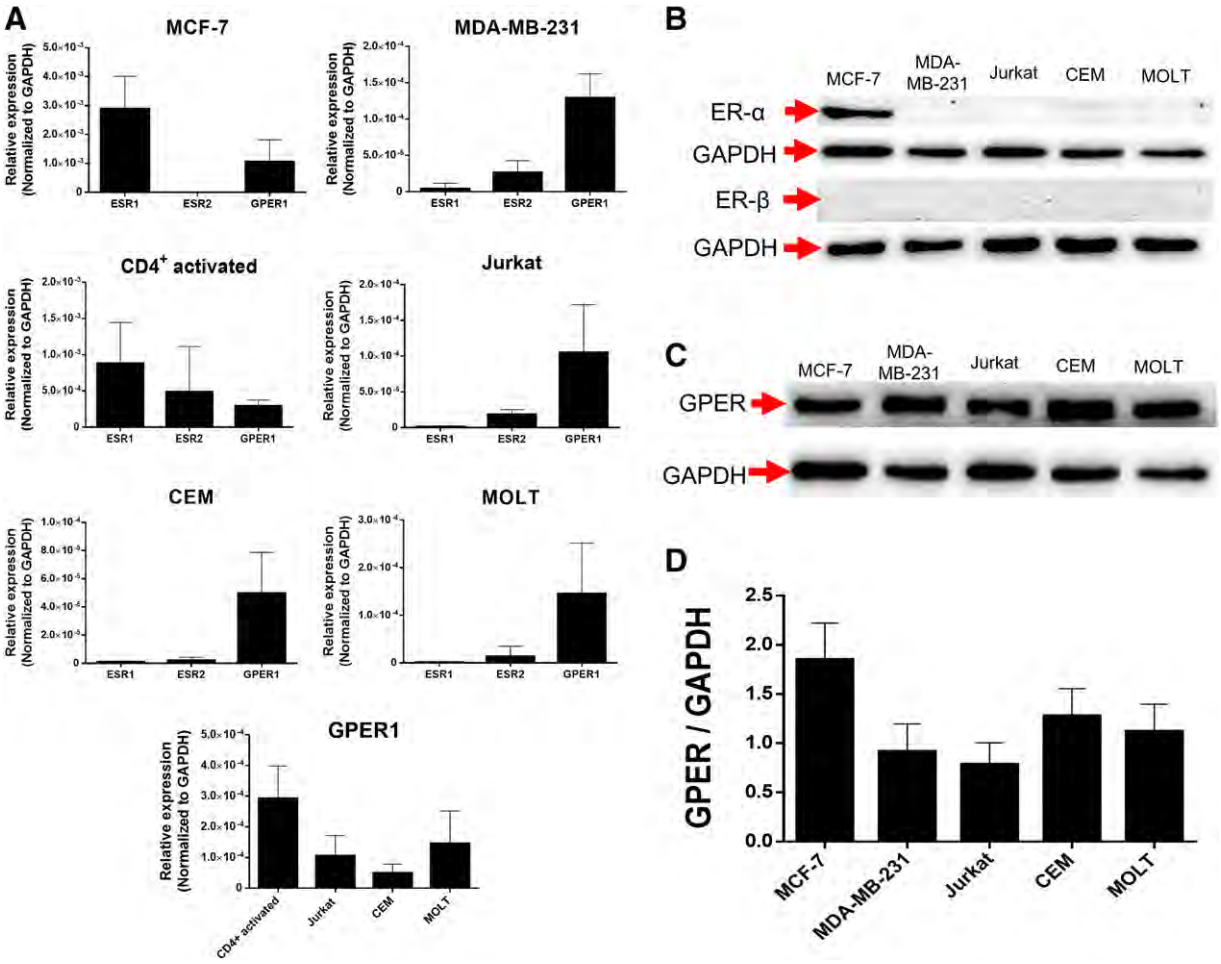

FIGURE 1 **RNA and protein expression of estrogen receptors in leukemic cell lines.** MCF-7, MDA-MB-231, and nonleukemic CD4+ T lymphocytes were used as reference. (**A**) mRNA expression of all ER: *ESR1* (ERα), *ESR2* (ERβ), and *GPER1* (GPER/GPR30). Expression was normalized to GAPDH as housekeeping gene ($2^{\wedge(-\Delta CT)}$). Data are mean ± SEM; $N \geq 4$. (**B**) Representative Western blot of ERα (~69 kDa) and ERβ (~55 kDa) in different cell lines. Data are mean ± SEM; $N \geq 5$

Scientific). The reaction was performed as follows: 10 min at 95 °C, and 38 cycles (denaturing at 95 °C for 15 s, annealing at 60 °C for 30 s, and extension at 72 °C for 30 s). Data collection was made after annealing step. The melt curve protocol was performed from 60 to 95 °C. Each gene was normalized to *GAPDH* and the relative gene expression levels were normalized to Jurkat cells with vehicle, using the comparative $2^{\wedge(-\Delta\Delta Ct)}$ method. The expression level of ER genes relative to *GAPDH* in different cell lines and healthy lymphocytes was evaluated by $2^{\wedge(-\Delta Ct)}$ method.

2.12 | Data analysis and statistics

All experiments were performed at least three times in independent form. Data were analyzed using GraphPad Prism 6.0 software and were expressed as mean values ± standard error. A comparison of individual treatments was performed, statistical significance was calculated and compared between control (without treatment) and treated samples using the analysis of variance (ANOVA) with Dunnett post hoc testing; also, comparison between every mean with every other mean was performed and statistical significance was calculated using ANOVA with Tukey post hoc testing. Comparisons in levels of gene expression between two groups of data (treated vs. untreated Jurkat cells) was made with unpaired *t*-test. Significance was defined as $P < 0.05$.

3 | RESULTS/DISCUSSION

3.1 | T-ALL cell lines express G protein-coupled estrogen receptor

First of all, our goal was to determine the pattern of estrogen receptors (ER) expression in T-ALL cell lines (Jurkat, CEM, and MOLT), both at mRNA as well as at protein level. MCF-7 and MDA-MB-231 breast cancer cell lines, and activated $CD4^+$ T cells isolated from peripheral blood of nonleukemic volunteers were used for reference. As shown in Fig. 1A, of the tree receptors analyzed, *ESR1* (ERα) displayed the highest expression level in MCF-7 (*ESR1* > *GPER1* > *ESR2*), whereas in nonleukemic $CD4^+$ T cells its expression level was the lowest (*GPER1* > *ESR2* > *ESR1*). *ESR1* (ERα) mRNA was not detected in any leukemic T cell line. *ESR2* (ERβ) mRNA was detected in MDA-MB-231 and activated healthy T cells, but in leukemic T cells, it showed a

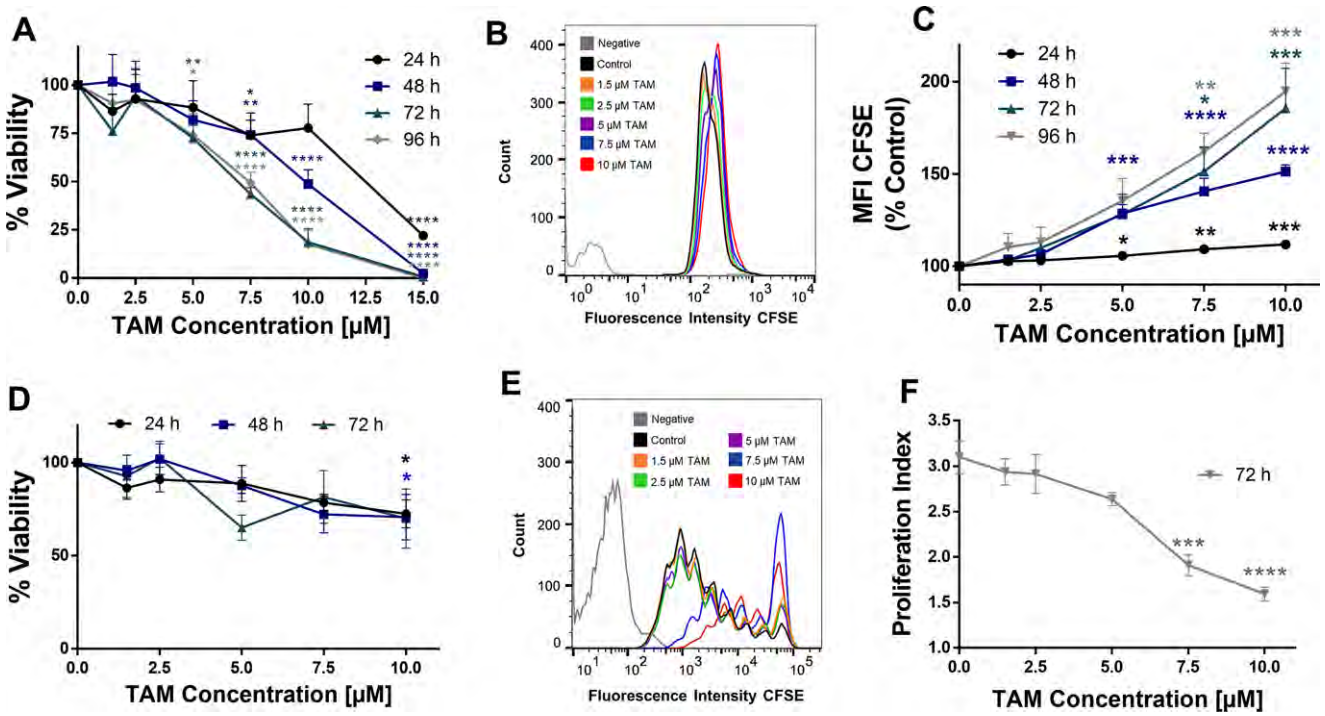

FIGURE 2 **TAM demonstrates cytotoxic and antiproliferative effects in leukemic cells.** Jurkat cells (**A–C**) and CD4$^+$ nonleukemic T lymphocytes (**D–F**) were incubated in presence of growing TAM concentrations during indicated time periods. (**A** and **D**). Cell viability evaluated by cell count (trypan blue exclusion test) after indicated time periods. Data are mean ± SEM; $N \geq 3$; $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, $^{****}P < 0.0001$. For each time point, comparison between control (without treatment) and treated samples was made by one-way ANOVA with Dunnett post hoc testing. (**B**) A representative histogram of changes in CFSE fluorescence intensity of Jurkat cells in presence of increasing concentrations of TAM after 48 h of treatment, where the shift of the mean fluorescence peak (MFI) to the left reflects Jurkat cell proliferation. (**C**) MFI of CFSE normalized to control (without treatment) as a function of TAM concentration. Cell proliferation decreased as TAM concentration increased. Data are mean ± SEM; $N = 3$; $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, $^{****}P < 0.0001$. For each time point, comparison between control and treated samples was made by one-way ANOVA with Dunnett post hoc testing. (**E**) Representative histograms of CFSE fluorescence intensity measured in CD4$^+$ activated (24 h) lymphocytes treated with different TAM concentrations for 72 h. (**F**) Proliferation index calculated for each TAM concentration with FlowJo Software (proliferation tool). Data are mean ± SEM; $N = 3$; $^{***}P < 0.001$, $^{****}P < 0.0001$. For each TAM concentration, comparison between control and treated samples was made by one-way ANOVA with Dunnett post hoc testing

very low expression level. Neither ERα nor ERβ proteins were detected in T-ALL cells (Fig. 1B), being in line with an earlier report where it was described that Jurkat cells do not express nuclear ER.[36] In contrast, *GPER1* mRNA expression was detected in all leukemic cell lines (Fig. 1A), which was also confirmed at protein level showing a high expression similar to GAPDH (Fig. 1C and D). To our knowledge, the present study is the first one to detect high expression levels of GPER at both mRNA and protein level in cell lines derived from T-ALL samples. Remarkably, the pattern of ER expression in T-ALL cell lines is quite different when compared to activated T cells. Whether this pattern is related to T cell maturation or T leukemogenesis, should be revealed in the future studies.

3.2 | TAM reduced viability and proliferation of ER-negative Jurkat cells

Cytotoxic "off-target" effect of TAM has been demonstrated in different types of cells that do not express nuclear ERα or ERβ.[18,19] To reveal whether TAM is toxic for leukemic cells, we performed viability assays in Jurkat cells, where healthy CD4$^+$ T cells were tested for reference. Effect of TAM on cell viability was evaluated by cell count using cell-impermeable dye trypan blue. As shown in Fig. 2A, significant cytotoxic effect was observed in Jurkat cells at TAM concentrations 5 μM and higher.

To evaluate the antiproliferative effect of TAM, fluorescence intensity of cells loaded with nontoxic concentrations of cell permeable cell tracker (CFSE) was measured using flow cytometry. In this assay, every division resulted in dye distribution between daughter cells and decrease of fluorescence intensity. Accordingly, median fluorescence intensity (MFI) evaluated in cell population is shifted to a lower fluorescence intensity as the cells divide. Starting at the concentration of 5 μM, TAM inhibited cell proliferation, as evidenced by decreased MFI shift in relation to the control population (Fig. 2B and C).

Remarkably, TAM was less toxic for activated CD4$^+$ T cells than for Jurkat cells (Fig. 2D), but reduced their proliferation, as clearly seen by the decrease in proliferation index at concentrations higher than 5 μM (Fig. 2E and F).

3.3 | TAM-induced cell cycle arrest in G1 phase

To further reveal whether TAM-induced toxicity is related to an arrest in the cell cycle progression, flow cytometric cell cycle profiling was performed every 24 h of incubation, during 48 h. DNA content, corresponding to G1, S, and G2 phases in living cells was evaluated

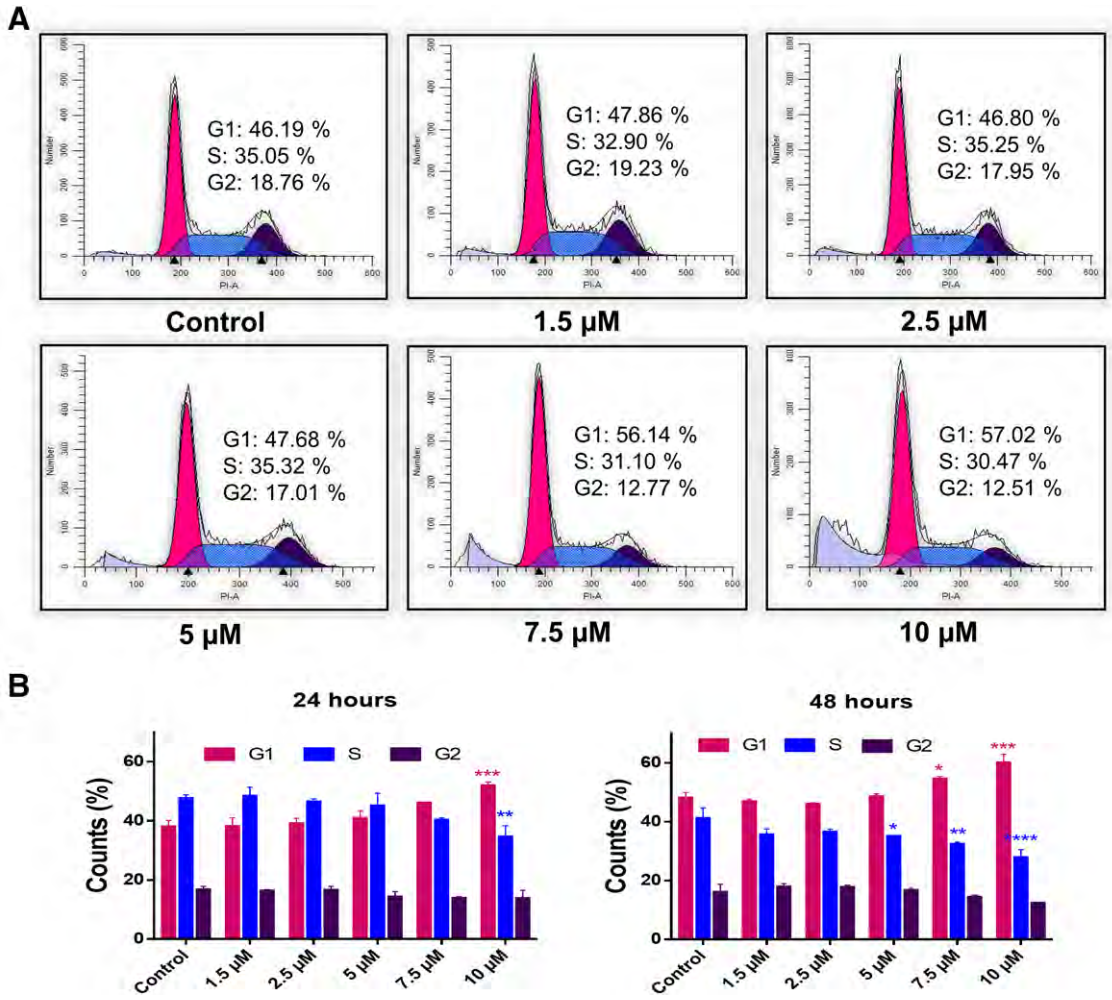

FIGURE 3 **TAM-induced arrest in G1 phase of cell cycle.** Jurkat cells were incubated in presence of growing TAM concentrations (1.5–10 μM) during 48 h. Cell cycle phase profiling was performed every 24 h by flow cytometry. (**A**) As an example of typical experiment, ModFit histograms of cell samples at 48 h of incubation with different TAM concentration are shown. G0/G1 peak is pink, G2/M peak is purple, S phase between G0/G1 and G2/M is blue, and subG1 damaged population is light-purple. (**B**) Cell count of cell subpopulations corresponding to G1, S, and G2 cell cycle phases were graphed at different times of TAM treatment. Data are mean ± SEM; $N = 3$; $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, $^{****}P < 0.0001$. For each cell cycle phase, comparison between control (without treatment) and different TAM concentrations was made by two-way ANOVA with Dunnett post hoc testing

using PI staining. Sub-G1 population, corresponding to dead cells with degraded DNA, was excluded from this analysis. In the Fig. 3A, representative cell cycle histograms of Jurkat cells after 48 h of treatment with different TAM concentrations are shown. After 24–48 h of treatment, statistical analysis revealed that TAM in the 5–10 μM range caused cell cycle arrest in G1 phase (Fig. 3B).

3.4 | TAM treatment caused mitochondrial dysfunction

Mitochondria are multifunctional organelles that link bioenergetics, biosynthesis and many signaling pathways in cancer.[37] Anabolic metabolism of rapidly proliferating T-ALL cells is highly dependent on both aerobic glycolysis and oxidative phosphorylation, and mitochondria are indispensable for fulfillment, fine regulation, and plasticity of these processes.[38] Therefore, mitochondria have been proposed as targets for cancer chemotherapy.[39] Mitochondria were suggested recently as the "gateway" for TAM-induced injury in liver. It was shown that TAM can bind directly to mitochondrial proteins. In particular, it was shown that TAM disrupted mitochondrial functions by mechanism related to alteration of inner mitochondrial membrane fluidity, which in turn affected lipid environment and function of membrane integral proteins, with suppression of 1–5 membrane complexes and impairment of oxidative phosphorylation.[40]

We evaluated whether mitochondria were involved in TAM-induced toxicity in leukemic cells. Reduced $\Delta\Psi$m is a classic indicator of mitochondrial damage, and thus we evaluated this parameter in TAM-treated Jurkat cells using mitochondria specific fluorescent probe Rhod-123 and flow cytometry. The assay was performed after 4 and 8 h of treatment, independently for populations of live and dead cells since cell death is closely linked to loss of $\Delta\Psi$m. Cell-impermeable fluorescent dye PI was used to detect dead cells that have lost plasma membrane integrity (Fig. 4A), and MFI of Rhod-123 was determined separately in dead PI-positive and live PI-negative

INFORME DE LABORES 2019

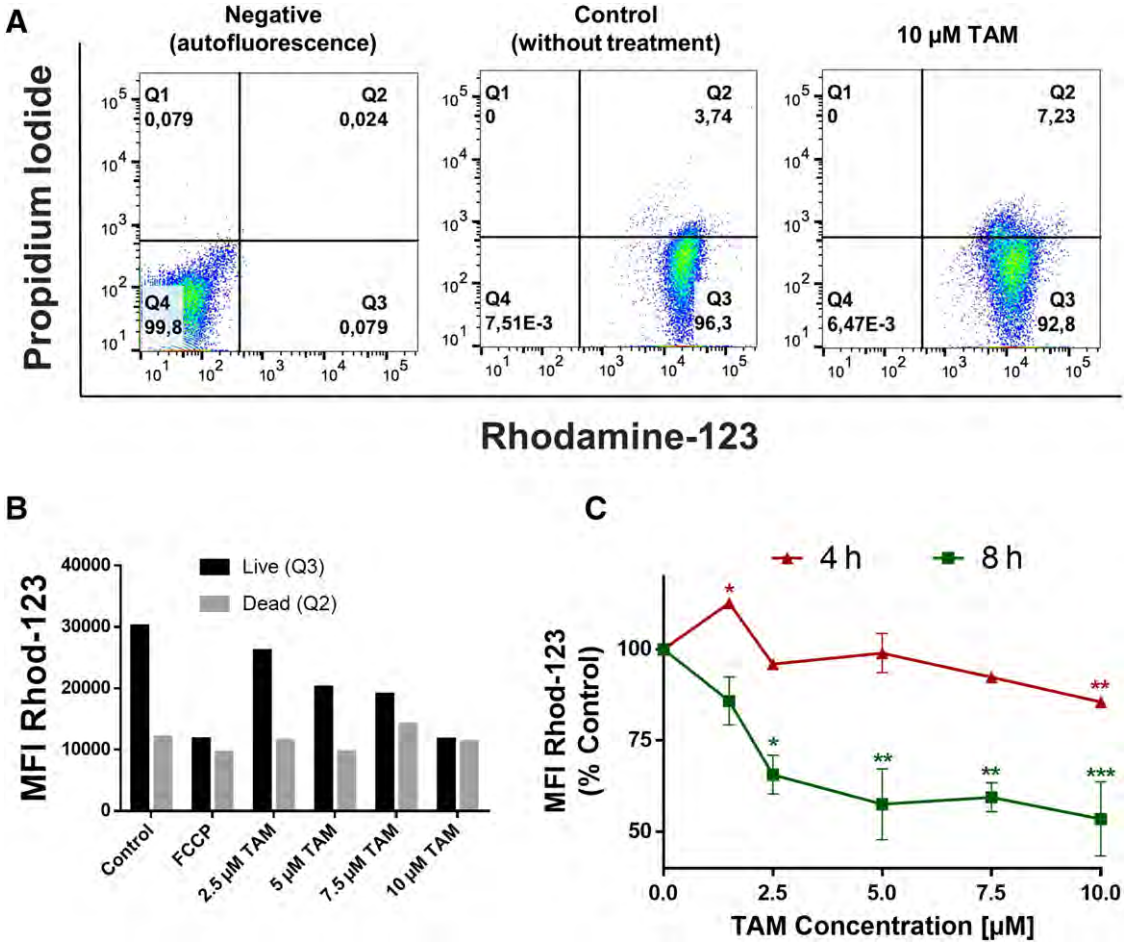

FIGURE 4 **Jurkat cells lost mitochondrial membrane potential after treatment with TAM.** (**A**) Representative dot plots obtained by flow cytometry analysis of Jurkat cells treated with TAM (48 h) and costained with Rhod-123 and PI. (**B**) For each treatment, MFI of Rhod-123 was graphed separately for live PI-negative population (Q3, black bars) and dead PI-positive population (Q2, in gray bars). Data of representative experiment corresponding to 48 h of incubation are present. (**C**) Only populations of PI-negative live cells (Q3) were analyzed: MFI of Rhod-123 was normalized to control (without treatment) and graphed as function of TAM concentration at 4 and 8 h of treatment. Statistical significance is expressed with respect to control. Data are mean ± SEM; $N \geq 3$. For each time, comparison between control and treated samples was made by one-way ANOVA with Dunnett post hoc testing

populations (Fig. 4B). A potent mitochondrial oxidative phosphorylation uncoupler FCCP (20 μM) was used as positive control. It was demonstrated that $\Delta\Psi$m was gradually decreased in live TAM-treated cells (Fig. 4C), indicating that TAM cytotoxicity in leukemic Jurkat cells is linked to mitochondrial damage.

Intrinsic apoptosis pathway is well known to be tightly related to mitochondrial damage.[41] Damaged mitochondria are subjected to degradation by mitophagic/autophagic process as an evolutionally designed mechanism to control mitochondrial number and health.[42] Therefore we decided to monitor apoptosis and autophagy in TAM-treated Jurkat cells.

3.5 | High TAM concentrations induced apoptotic cell death in Jurkat cells

Taking into the account that in our experiments, TAM compromised mitochondria and that mitochondria is an important regulator of the intrinsic apoptotic pathway, apoptotic and necrotic cell death caused by TAM (2.5–15 μM) were monitored at 8, 24, 48 h by confocal microscopy and flow cytometry (Fig. 5). Only high TAM concentrations caused apoptosis evaluated by externalization of phosphatidylserine, in a small part of the cell population. In relation to this result, it should be mentioned here that, in addition to the intrinsic apoptotic pathway, there are some other types of programmed cell death, related to mitochondria. In particular, mitochondrial permeability transition-driven cell death may be initiated by some perturbation of intracellular microenvironment such as oxidative stress and cytosolic Ca^{2+} overload, resulting in rapid $\Delta\Psi$m dissipation. The mechanism of this form of cell death is under intense research and debates.[41] In this regard, TAM was demonstrated to interact directly with mitochondrial membrane proteins,[40] as well as with nonclassical TAM targets including PKC, mTOR, cannabinoid receptors, and multidrug resistance proteins.[18,19] One can suggest also that the same drug may produce multitarget effects, with a complex cross-talk between underlying mechanisms.

3.6 | TAM treatment-induced autophagy in Jurkat cells

Autophagy is a catabolic cellular process highly conserved in evolution and characterized by lysosomal self-digestion of cytoplasmic

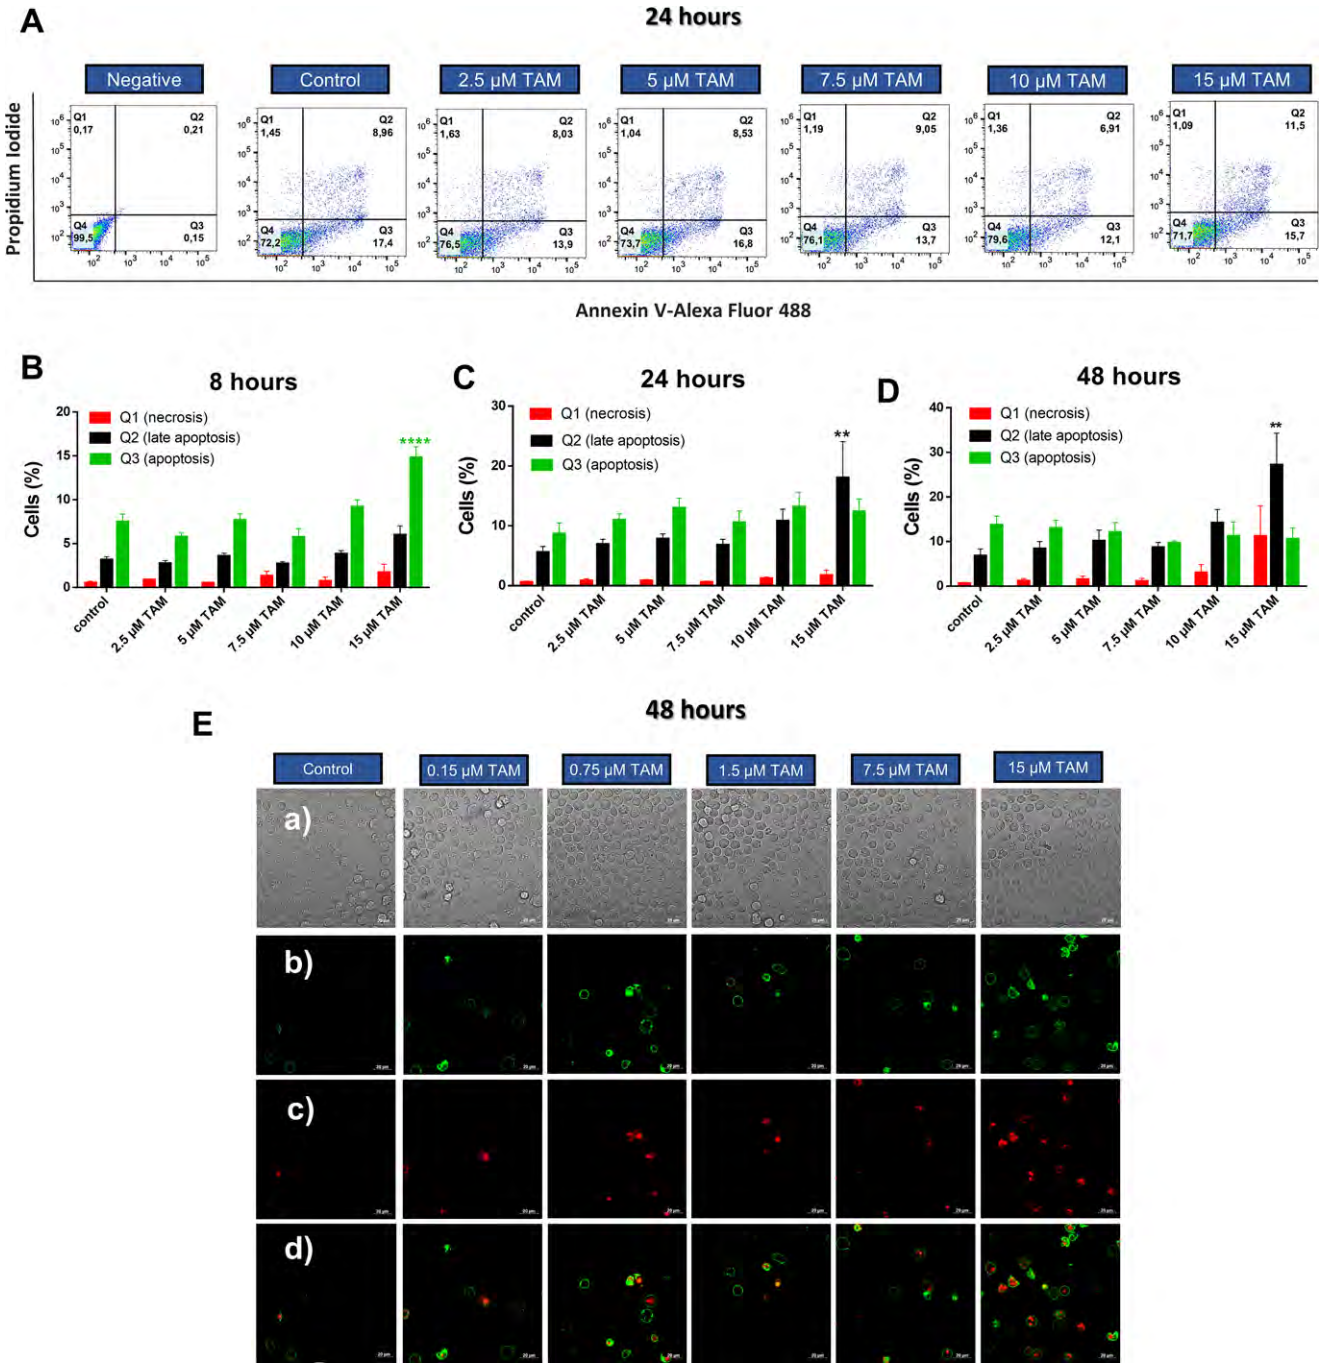

FIGURE 5 **High TAM concentrations produced apoptosis.** (**A**) Representative dot plots obtained by flow cytometry analysis of Jurkat cells treated with different TAM concentrations during 24 h. Q1: necrotic PI-positive population; Q2: late apoptosis/necrosis (double positive) population; Q3: apoptotic Annexin V/AlexaFluor488-positive population; Q4: viable double negative cells. (**B–D**) Bar charts show percentage of viable, necrotic, and apoptotic cells after treatment with TAM for 8 h (**B**); 24 h (**C**) and 48 h (**D**). Data are mean ± SEM; $N \geq 4$; $^{**}P < 0.01$, $^{****}P < 0.0001$. For each time and for each population (Q1–Q4), comparison between control (without treatment) and different TAM concentrations was made by two-way ANOVA with Dunnett post hoc testing. (**E**) Microscopic visualization of apoptosis and necrosis caused by TAM, after 48 h of incubation with indicated TAM concentrations: a) bright field, b) Annexin V-Alexa Fluor 488 (phosphatidylserine externalization), c) PI (plasma membrane integrity), and d) merge Alexa Fluor 488 and PI. Confocal microscopy (×40). Scale bar: 20 μm

material. This process has a multifunctional role in cell physiology. Basal autophagy is responsible for normal turnover of macromolecules and organelles, and during nutrient starvation cells resort to autophagy as a survival strategy. Autophagy is also in charge of removing damaged organelles and unfolded proteins from the cell. In cancer, autophagy has been shown to be involved in the chemoresistance of some types of tumors.[43–48] On the other hand, it has also been suggested that an excessive activation of this self-degradation process may also lead to nonapoptotic autophagic programmed cell death.[41,49] So, some studies suggest that the autophagic process could be a potential chemotherapeutic target for apoptosis-resistant malignancies.[50] In particular, many compounds have been proposed to

induce autophagic cell death instead of cell survival in hematologic malignancies.[51] So, understanding of the precise role of autophagy and its contribution either to cell survival or cell death will facilitate the future design of optimized protocols for treatments for T-ALL and other types of cancers.

TAM is known as a potent inducer of autophagy in different cell types, with different outcomes. In breast cancer, autophagy induced by TAM was considered as cause of chemoresistance, although the underlying mechanisms have not been completely clarified yet.[52,53] In contrast, TAM was shown to induce cytotoxic autophagy in glioblastoma.[54] Remarkably, cell death induced by DEX in B-ALL was shown to be mediated through induction of autophagy upstream of apoptosis.[31] Thus, we tested whether TAM is able to induce autophagy in the GC-resistant T-ALL cell line Jurkat.

In our initial experiments, we used the fluorescent acidophilic compound MDC to evaluate if TAM is able to cause formation and accumulation of autophagolysosomes in Jurkat cells.[55] Confocal microscopy and flow cytometry revealed accumulation of autophagolysosomes as the TAM concentration increased, after 48 h of treatment (Fig. 6A and B). An increased number of autophagolysosomes could result either from an enhanced formation of autophagosomes (increased autophagic flux) or, in contrast, a decreased degradation of autophagolysosomes (decreased autophagic flux). To address this issue, in the next experiments, we used more specific LC3-I-based strategies.

Cytosolic microtubule-associated protein LC3-I translocates to the autophagosomes after conjugation with phosphatidylethanolamine (LC3-II formation) during autophagy. It is known that LC3-II is essential for phagophore elongation and autophagosomes formation. This two forms can be easily distinguished in an SDS-PAGE due to the fact that LC3-II migrates faster than LC3-I. However, LC3-II itself is known to be degraded by autophagy after autophagosome–lysosome fusion, and therefore it is recommended to evaluate LC3-II levels both in the presence and in the absence of lysosomal protease inhibitors.[56] In our experiments, CQ was used to avoid LC3-II degradation. Western blot analysis of LC3 demonstrated that 5 μM TAM-induced autophagic flux in Jurkat cells since LC3II levels were higher in 5 μM TAM + 20 μM CQ when compared to either 20 μM CQ or 5 μM TAM treatment alone (Fig. 6C and D). We also used a more precise method to measure autophagic flux induction by the use of tandem mCherry-GFP-LC3 expressing Jurkat cells.[57] GFP is known to be sensitive to an acidic pH like the one found in the autophagolysosomes (structures produced by autophagosome fusion with the lysosomes). On the other hand, mCherry is stable in this acidic environment. Then, colocalization of GFP and mCherry indicates LC3 positive nonacidic compartments (autophagosomes), whereas mCherry+GFP- puncta correspond to autophagosomes which have fused with acidic endosomes or lysosomes (amphisomes or autophagolysosomes). Figure 6E shows a representative experiment in which Jurkat GFP-mCherry-LC3 cells were incubated with different TAM concentrations. Yellow puncta (GFP+mCherry+) correspond to autophagosomes, while red spots (GFP-mCherry+) correspond to autophagolysosomes, mCherry/GFP ratio was used as a measurement of autophagic flux (autophagosome degradation/formation) and was calculated at 24 and 48 h of treatment (Fig. 6F). High mCherry/GFP ratio effectively blocked by 10 and 20 μM CQ was observed at 5 μM TAM indicating effective TAM concentration to induce autophagy.

Finally, we tested whether TAM-induced autophagy functioned as a cell survival or a cell death mechanism in leukemic cells and if its blocking would produce a change in cell viability. For this purpose, cells were incubated 24 and 48 h with TAM alone, or in combination with CQ. Cell death was evaluated by staining with Annexin V-Alexa Fluor 488 and PI (Fig. 6G–H), where a decrease in cell viability was observed with the combined treatment with CQ.

3.7 | The specific GPER receptor antagonist G-36 efficiently prevented TAM-induced autophagy but not cytotoxicity

Several reports argued that membrane ER GPR30/GPER are able to mediate some estrogenic nongenomic actions.[58–60] Since Jurkat cells express GPER receptors (Fig. 1), we decided to examine whether the observed TAM-induced effects were triggered through GPER activation. G-36 was reported as a highly selective antagonist of GPER.[61] In our experiments, a 30 min pre-incubation of Jurkat cells with G-36 almost completely prevented TAM-induced autophagy (Fig. 7A).

To test if TAM-induced cytotoxicity is also related to GPER, concentration–response curves for different conditions were constructed, namely for TAM alone and TAM after a pre-incubation with different nontoxic doses of G-36 (Fig. 7B and C). If cytotoxicity is associated with GPER, under conditions of pre-incubation with the GPER antagonist, the curve would be expected to shift to the right, which was not actually observed. Instead, G-36 potentiated the cytotoxic effect of TAM, because cell viability in samples pre-treated with G-36 decreased, in a manner dependent on the G-36 concentration. It would be interesting to understand the mechanism of this phenomenon, but this task was beyond the scope of the present study. Of note, TAM is a highly lipophilic small molecule, which is able to modulate structure and mechanical properties of the cell membrane.[62] One may speculate that TAM cytotoxicity in Jurkat cells is related to "off-target" mechanisms, including PKC inhibition or direct effects on mitochondria, as it was demonstrated for some types of cells.[18,19] Our present findings also pinpointed the mitochondria as an important TAM target (Section 3.4). A synergistic effect of G-36 may be related to its capacity to prevent autophagy, which will to be addressed in future studies.

3.8 | Gene expression profiling revealed up-regulation of autophagy- and apoptosis-related genes in Jurkat cells treated with TAM

Next, we were interested in knowing if TAM induces any change in gene expression, in particular in those genes related to cell survival, before the mechanism of cell death was triggered. First, RNA microarray analysis was performed using RNA isolated from Jurkat cells treated with 7.5 μM TAM during 24 h. Several genes of interest related to autophagy and apoptosis were selected based on microarray analysis results, and relative level of their expression was confirmed by RT-qPCR (Fig. 8).

It was revealed, that the autophagy-related *ATG5* gene which is an indispensable component involved in the control of autophagic vesicle

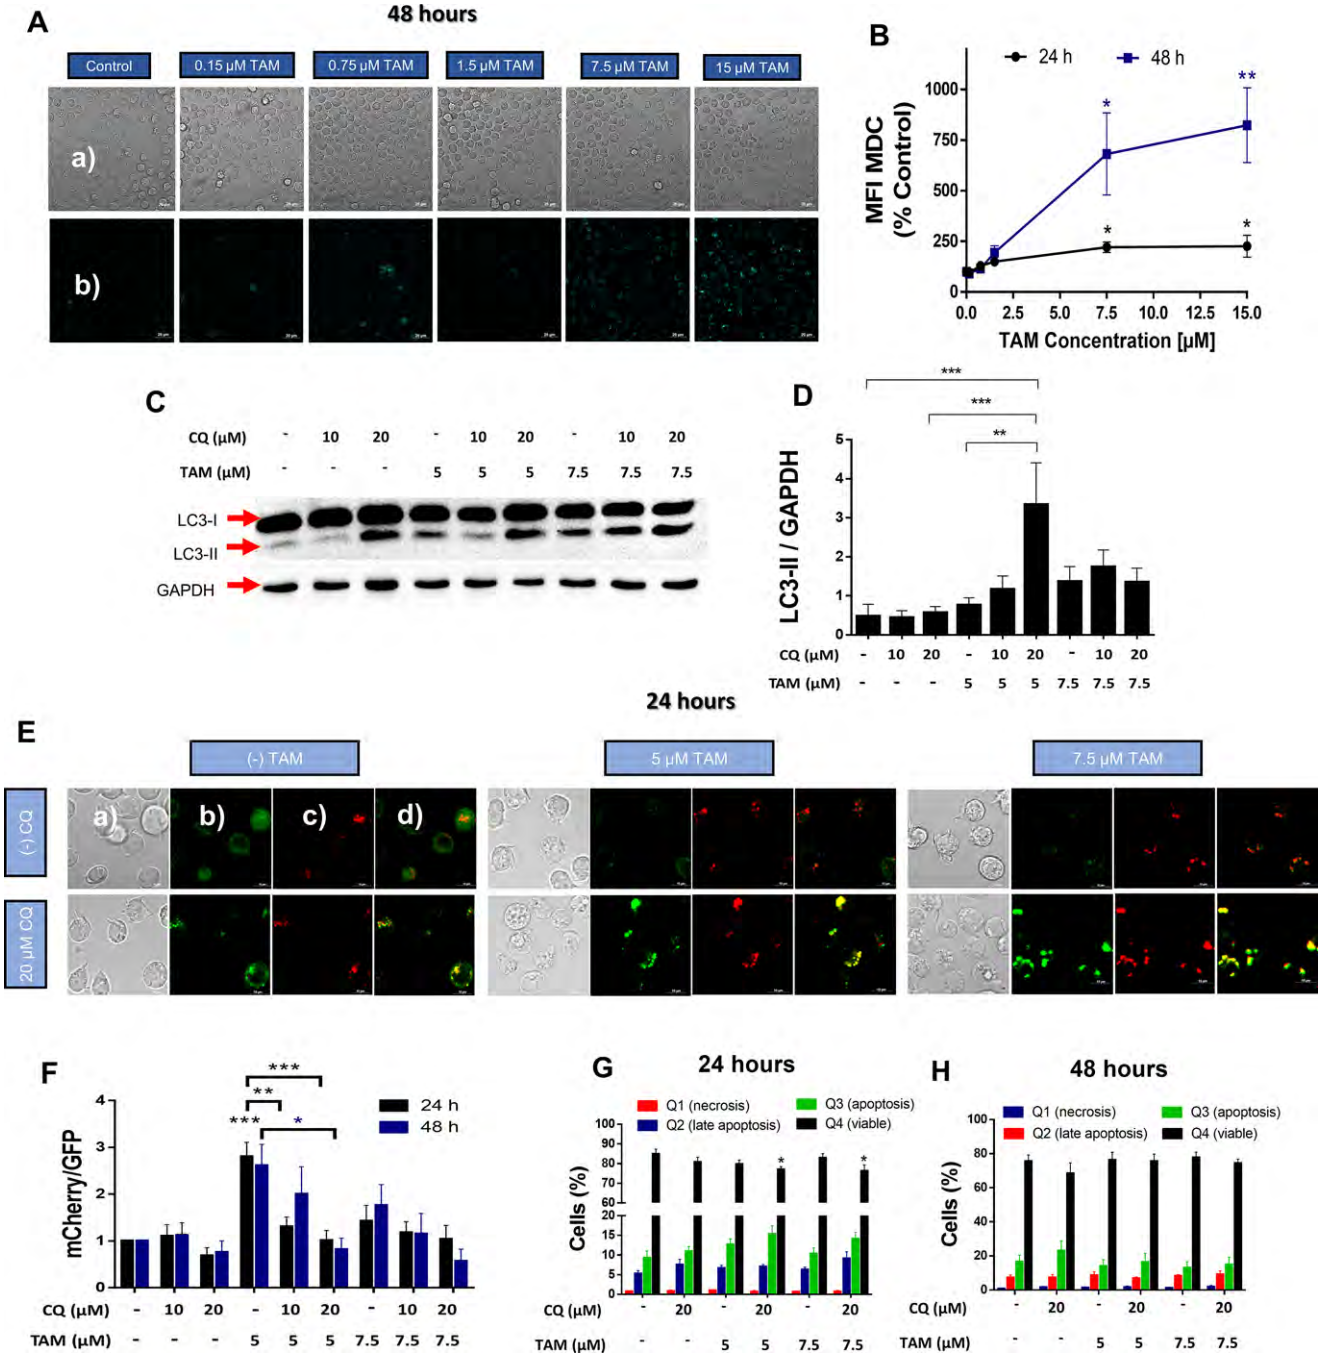

FIGURE 6 **Autophagy is induced by TAM in Jurkat cells.** (**A**) Autophagolysosomas accumulation caused by TAM, after 48 h of incubation revealed by MDC using confocal microscopy (×40). a) Bright field, b) MDC (autophagic lysosomes). formation and expansion in mammals is up-regulated. Remarkably, *Atg5* and LC3 conjugation are required for the canonical autophagy pathway.[63] Also, several apoptosis-related genes, involved in the extrinsic apoptotic pathway, including *CFLAR*, *CARD8*, and *TRADD* genes, were also overexpressed. Although the mechanisms linking autophagy and apoptosis are not fully defined yet, there are some evidences of their interactions. In particular, TAM in the range of 1–5 μM was demonstrated to stimulate Fas/CD95-dependent apoptosis in vitro in human cholangiocarcinoma cells,[64] and caspase-10 was shown to control autophagic cell death in multiple myeloma.[65]

Bcl-2 associated factor 1 (*BCLAF1*) was also up-regulated. *BCLAF1* has been shown to be related to thymocyte development and essential for T cell homeostasis. *BCLAF1* is able to interact with Bcl-2 family members. Although its overexpression was suggested to contribute to apoptosis, this hypothesis still remains a topic of debate.[66] On the other hand, *BCLAF1* has been associated with autophagic cell death in myeloma cells.[65] In addition, we observed a slight increase in *COX7AR*, a stress-inducible COX subunit.[67] On the other hand, we found down-regulation in *CYP1B1* gene, which is related to estrogenic metabolism.[68] Importantly, CYP1B1 protein is found to be overexpressed in various cancer tissues; it has been suggested as a tumor biomarker and a target for anticancer therapy.[68]

3.9 | TAM sensitized GC-resistant cells Jurkat to DEX treatment

GCs play central role in all protocols for ALL treatment representing the most effective agents.[69,70] These hormones are able to induce apoptosis in lymphoid cells acting through GC receptor (GR), a member

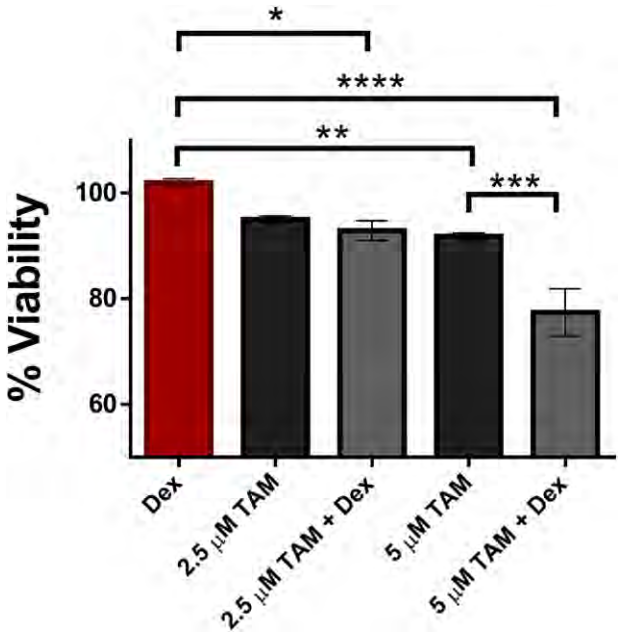

FIGURE 9 **TAM sensitized Jurkat cells to dexamethasone.** Evaluation was realized by resazurin-based metabolic assay. Data are mean ± SEM; $N \geq 3$; $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, $^{****}P < 0.0001$. Data were normalized to control (without treatment, considered as 100% viability). Comparison between DEX (0.021 μM) with other treatment combinations (TAM alone or TAM+DEX) was made by one-way ANOVA with Tukey post hoc testing

of the nuclear receptor family.[70] Although a significant number of LLA patients respond well to GC treatment during the initial phases, some patients show primary resistance; prolonged treatment sometimes leads to secondary resistance as well.[71] Generally, patient response to GC treatment has been proven to be a reliable prognostic indicator.[72] Although the underlying mechanism has not been completely understood yet, it was proposed that the resistance was due to alterations in GR expression. On the other hand, it was recently demonstrated, that in specimens derived directly from leukemia patients, GR alterations are rarely found.[73] Jurkat cell line used in the present study is GC-resistant, but expresses GR.[74] Taking into account the published data that GC-triggered cell death is related to autophagy process in early phases,[31] we decided to perform the experiments combining effective autophagy trigger TAM with GC DEX to treat GC-resistant Jurkat cell line. The results of these experiments are shown in the Fig. 9. Jurkat cells were exposed to a DEX concentration that corresponds to those reached in human plasma during chemotherapeutic treatment (0.021 μM). Since Jurkat is a GC-resistant cell line, no effect in cell viability was observed at this concentration. The viability of leukemic cells treated with DEX combined with 2.5 μM TAM, was slightly decreased. In contrast, when DEX was applied together with a TAM concentration effective in autophagy induction (5 μM), this combination caused a significant reduction of cellular vitality, when compared with DEX or TAM treatment alone ($P < 0.001$). Together with studies reported by Laane and collegues,[31] our data provide evidence about a possible relation between GC resistance and the autophagic pathway. We hope that our findings prompt further studies aimed at a better understanding of the mechanisms connecting autophagy and GC resistance of ALL.

4 | CONCLUDING REMARKS

Altogether, we have provided here the first evidence that: (1) lymphoblastic cell lines Jurkat, MOLT3, and CEM, derived from clinical T-ALL samples in relapse expressed high levels of GPER/GPR30 both at mRNA and protein level; (2) in contrast, studied cell lines derived from T-ALL samples did not express neither *ESR1* (ERα) nor *ESR2* (ERβ); (3) we were able to demonstrate dramatic differences in the expression pattern of ER and GPER between healthy activated T CD4^{+} cells and leukemic cells: activated T cells did express *ESR1* (ERα), *ESR2* (ERβ), and *GPER1*(GPER/GPR30); (4) TAM-reduced viability and proliferation of Jurkat cells in GPER-independent manner and induced cell cycle arrest in G1 phase; (5) TAM caused mitochondrial dysfunction in T-ALL Jurkat cell lines; (6) TAM treatment up-regulated autophagy-related gene *ATG5* and down-regulated cancer biomarker *CYP1B1* in Jurkat cells; (7) TAM treatment-induced autophagy in Jurkat cells in a GPER-dependent manner, which may partially sensitize these GC-resistant cells to DEX treatment.

Our findings are in agreement with recently published reports regarding antileukemic properties of TAM in myeloproliferative neoplasms, carried out using murine models.[75,76] Namely, it was shown that TAM, through apoptotic effects on malignant progenitors, inhibited the growth of JAK2^{V617F}-induced myeloproliferative neoplasms and sensitized MLL-AF9-induced myeloid leukemias to chemotherapy. Importantly, the effect of TAM in normal hematopoiesis was also studied. A potential effect of TAM on hematopoietic stem cells (HSC) and normal hematopoiesis is certainly an important issue, because a negative regulation of lymphopoiesis by estrogens is well known.[77] Numerous studies carried out on rodent and human models demonstrated that estrogen is involved in the regulation of proliferation and lineage commitment of pluripotent stem cells, and also in the modulation of the HSC niche in the bone marrow.[78] Adult bone marrow CD34^{+} cells were shown to express both ERα and ERβ,[79] though data regarding GPER expression is not available yet. As for specific TAM properties, it exerted antiestrogenic effects on breast cancer cells, but acted as an ERα agonist in the HSC. Remarkably, TAM treatment-induced contrasting effects in different types of HSC: it caused apoptosis in short-term HSC and multipotent progenitors, and simultaneously activated proliferation in quiescent long-term HSC.[75] As a result, although rapid reduction of bone marrow cellularity after TAM treatment was observed, long-term hematological parameters were almost unchanged, and TAM was considered to have a minor impact on a steady-state normal hematopoiesis.[75] Accordingly, antileukemic properties against myeloid leukemias[75] and T-ALL (this work), without negative effect on normal hematopoiesis,[75] and a long history of its clinical use, makes TAM a good candidate for future clinical trials with leukemic patients. Among the relevant issues for the immediate future research are: a) profiling of GPER expression and GPER-related effects in human HSC, hematopoietic precursors and mature leukocytes; and b) identification of the precise mechanisms of TAM-induced effects in leukemic cells, with a special focus on the link between autophagy and GC resistance in ALL.

We hope that further studies will reveal the underlying mechanisms of biologic effects of TAM in T-ALL, resulting in potential use of novel

TAM-based adjuvant therapy for this kind of disorders and representing a big challenge in patients' handling.

AUTHORSHIP

O.D. conceived and designed the study. L.T-L. conceived, designed, and performed most of experiments, analyzed the data, prepared the figures. P.M. conceived and designed autophagy experiments. A.L-R. contributed in primers' design and PCR data analysis. L.L-R. participated in acquisition and analysis of flow cytometry data. L.D-M. participated in experiments on mitochondria and cell proliferation analysis. C.M-R. performed the experiments on synergetic effect of DEX and TAM. I.D-E. contributed to the microarray and molecular biology data analysis, and designed the experiments on synergetic effect of DEX and TAM. O.D. and L.T-L. wrote the manuscript. O.D. and A.H-C. contributed to the experiments and received grants. L.T-L., P.M., A.L-R., L.L-R., L.D-M., I.D-I., C.M-R., C.V-J., A.H-C., and O.D. contributed to data analysis and result discussion, and reviewed the final draft of the manuscript.

ACKNOWLEDGMENTS

We thank Dr. Georgina Valencia-Cruz for expert technical assistance, MC Juan Salvador Valle-Reyes for purification and activation of $CD4^+$ lymphocytes, and for his contribution into statistical analysis, and Mr. Scott Hayes for his assistance in editing this manuscript. This study was funded by CONACyT: grant FC 2015-1/114 to OD, and Laboratorio Nacional de Canalopatías 279820 and (DGAPA-UNAM) PAPIIT-IN211616, IG200119 to AH-C. Doctoral fellowship and short academic stay fellowship to LTL.

DISCLOSURES

The authors declare no conflict of interest.

Quorum sensing (QS) is a communication mechanism between bacteria that allows specific processes to be controlled, such as biofilm formation, virulence factor expression, production of secondary metabolites and stress adaptation mechanisms such as bacterial competition systems including secretion systems (SS). These SS have an important role in bacterial communication. SS are ubiquitous; they are present in both Gram-negative and Gram-positive bacteria and in *Mycobacterium* sp. To date, 8 types of SS have been described (T1SS, T2SS, T3SS, T4SS, T5SS, T6SS, T7SS, and T9SS). They have global functions such as the transport of proteases, lipases, adhesins, heme-binding proteins, and amidases, and specific functions such as the synthesis of proteins in host cells, adaptation to the environment, the secretion of effectors to establish an infectious niche, transfer, absorption and release of DNA, translocation of effector proteins or DNA and autotransporter secretion. All of these functions can contribute to virulence and pathogenesis. In this review, we describe the known types of SS and discuss the ones that have been shown to be regulated by QS. Due to the large amount of information about this topic in some pathogens, we focus mainly on *Pseudomonas aeruginosa* and *Vibrio* spp.

Keywords: quorum, secretion, virulence, motility, competence

INTRODUCTION

Microorganisms coexist in competitive environments with other species, and they must develop different survival strategies to compete for space, nutrients and ecological niches. Bacteria have developed several molecular mechanisms that enable them to survive under stress conditions in different environments. The general stress response (RpoS) (Battesti et al., 2011), tolerance to reactive oxygen species (ROS) (Zhao and Drlica, 2014; Van den Bergh et al., 2017), energy metabolism (cytochrome *bd* complex) (Korshunov and Imlay, 2010) and Tau metabolism (Javaux et al., 2007), drug efflux pumps (Blanco et al., 2016), SOS response (Baharoglu and Mazel, 2014), (p)ppGpp signaling under starvation conditions (Hauryliuk et al., 2015), toxin-antitoxin (TA) systems (Wood et al., 2013) and quorum sensing (QS), which we will discuss in detail in this review, are the main molecular mechanisms of tolerance and bacterial persistence (Harms et al., 2016; Trastoy et al., 2018).

Quorum sensing acts by monitoring cell density through chemical signals that allow communication between bacteria in order to regulate the expression of genes involved in virulence, competition, pathogenicity and resistance (Nealson et al., 1970; Hawver et al., 2016; Paul et al., 2018). In general, QS systems are species-dependent and contribute to processes such as cell maintenance, biofilm formation and horizontal gene transfer. QS also plays a role in other events involving the synchronization of the whole population such as antibiotic production (Abisado et al., 2018), natural competence (Shanker and Federle, 2017), sporulation (Rai et al., 2015) and the expression of secretion systems (SS). In this review, we will focus on the relationship between QS networks and SS in two important bacterial pathogens *Pseudomonas aeruginosa* and *Vibrio* spp.

QS NETWORK

To explain the structure and functioning of the QS network, we will focus on Gram-negative bacteria, in which the signaling pathways are better described. In general terms, QS systems are composed of synthase proteins that produce QS signals, QS signals, and response regulators that bind QS signals and reprogram gene expression (Ng and Bassler, 2009). *N*-acyl homoserine lactones (AHLs) are the most common QS signals in Gram-negative bacteria (Geske et al., 2008). Other QS signals include autoinducer-2 (AI-2) in *Vibrio harveyi* (Surette et al., 1999), PQS (*Pseudomonas* quinolone signal) (Pesci et al., 1999), DSF (diffusible signaling factor) in *Xanthomonas campestris* (Barber et al., 1997), indole in *Escherichia coli* (Lee and Lee, 2010), and PAME (hydroxyl-palmitic acid methyl ester) in *Ralstonia solanacearum* (Flavier et al., 1997). The LuxI/LuxR QS system of *Vibrio fischeri* is the prototypical model system for Gram-negative bacteria (Engebrecht et al., 1983; Engebrecht and Silverman, 1984). Homologs of *luxI* (which encode synthase proteins) and *luxR* (which encode response regulators) are present in many bacteria (Case et al., 2008). AHL signals are produced inside the cell and most of them are transported freely to the local environment. When the concentration of AHL reaches a certain level outside of the cell, the molecule re-enters the cell (or binds surface receptors) and binds/activates the LuxR-type receptor to alter gene expression. AHL signals with small structural differences are involved in the process of gene regulation (Fuqua et al., 1994; Whiteley et al., 2017; Paul et al., 2018).

Pseudomonas aeruginosa possesses three well-known QS systems: LasI/LasR, RhlI/RhlR, and PQS (*Pseudomonas* quinolone signal)/PqsR (MvfR). The Las system consists of LasI, a synthase protein which produces the AHL *N*-(3-oxododecanoyl)-L-homoserine lactone (3O-C12-HSL), and LasR, the transcriptional regulator (Seed et al., 1995; Stintzi et al., 1998; Kariminik et al., 2017). Likewise, the RhlI/RhlR system produces the N-hexanoyl-L-homoserine lactone (C4-HSL) signal and the RhlR transcriptional regulator. Finally, the PQS system comprises 2-heptyl-3-hydroxy-4(1H)-quinolone (PQS signal) and the PqsR (MvfR) receptor (Xiao et al., 2006; Jimenez et al., 2012). In 2016, James and collaborators, analyzed the role of a new binding receptor for PQS signals, i.e., MexG, an inner membrane protein of the *mexGHI-opmD* operon and a component of a resistance-nodulation-cell division (RND) efflux pump (Hodgkinson et al., 2016).

Quorum quenching (QQ) enzymes have also been shown to be important in the functioning of QS systems (Zhang and Dong, 2004; Dong et al., 2007; Bzdrenga et al., 2017). Our research group has recently described a new QQ enzyme (AidA) which participates in the QS network in *Acinetobacter baumannii* clinical strains (Lopez et al., 2017b, 2018).

SECRETION SYSTEMS

Bacterial pathogens secrete proteins through their cell membranes in a fundamental process that enables them to attack other microorganisms, evade the host immune system, produce tissue damage and invade the host cells. Secreted proteins can act as virulence factors that generate toxic products to the host cells and may also facilitate adhesion to these cells. Translocation of proteins across the phospholipid membranes is carried out by several types of SS (Green and Mecsas, 2016). SS play a significant role in bacterial communication. To date, 8 types of SS (T1SS, T2SS, T3SS, T4SS, T5SS, T6SS, T7SS, and T9SS) have been made defined on their structure, composition and activity (**Figure 1**). These differences can be attributed to the differences between Gram-negative and Gram-positive bacteria (Desvaux et al., 2009; Sato et al., 2010; Costa et al., 2015). The characteristics of each type of SS are described in detail below.

T1SS

The type I secretion system is widely distributed in Gram-negative bacteria such as *P. aeruginosa*, *Salmonella enterica*, *Neisseria meningitidis,* and *E. coli* (Thomas et al., 2014).

The type I secretion system (T1SS), which has three structural elements (ABC transporter protein, a membrane fusion protein and an outer membrane factor), can transfer substrates across both bacterial membranes in Gram negative bacteria in a one-step process (Green and Mecsas, 2016). T1SS uses proteins as substrates, e.g., proteases and lipases of different sizes and with different functions; these proteins have a C-terminal uncleaved secretion signal which is recognized by the ABC transporter protein to form the translocation complex (Delepelaire, 2004; Kanonenberg et al., 2013).

There are two systems described so far that regulate the expression and secretion of substrates of T1SS, the Has system of *S. marcescens* and *P. aeruginosa,* and the hemolysins of *Vibrio cholerae*, *N. meningitidis* and in particular of uropathogenic *E. coli* (Thomas et al., 2014).

T2SS

The type II secretion system (T2SS), which is conserved in most Gram negative bacteria, is responsible for secreting folded proteins from the periplasm. These proteins are first transported through the IM by the general secretory (Sec) or twin-arginine translocation (Tat) pathways, and then secreted from the periplasm into the extracellular medium by the T2SS (Nivaskumar and Francetic, 2014; Green and Mecsas, 2016).

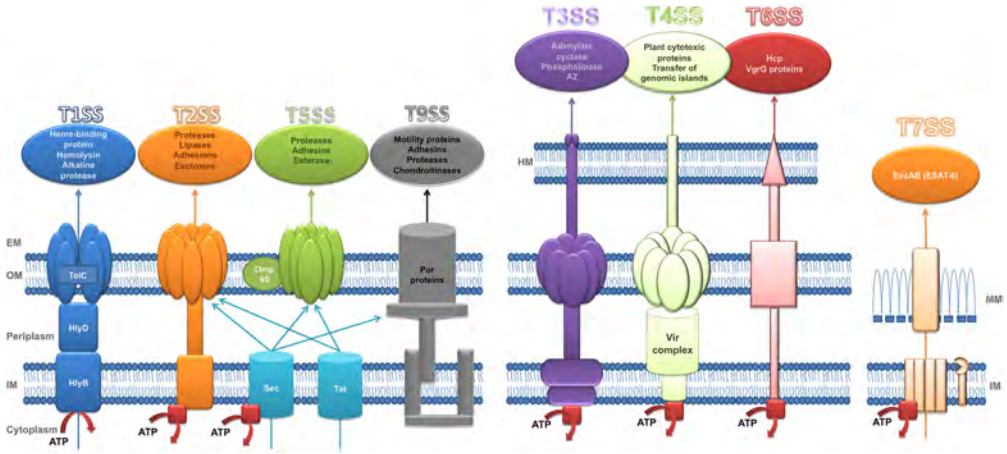

FIGURE 1 | Structure of secretion systems. Schematic representation of secretory systems: type I (T1SS), type II (T2SS), type V (T5SS), type IX (T9SS), type III (T3SS), type IV (T4SS), type VI (T6SS), and type VII (T7SS). The type I pathway is exemplified by hemolysin A (HlyA) secretion in *E. coli* where TolC, HlyD, and HlyB are the three components which constitute the channel to transport HlyA to extracellular space. Sec (general secretion route) and Tat (twin-arginine translocation pathway) transfer the substrates of T2SS and T5SS across the inner membrane. Sec also participates in the transport of T9SS substrates across de inner membrane. T9SS is also called Por Secretion System (PoSS). T4SS is represented by VirB/D system of *Agrobacterium tumefaciens*. The T7SS is based on a system in Mycobacteria. Red squares represent the ATPases. HM, host membrane; EM, extracellular medium; OM, outer membrane; IM, inner membrane; MM, mycomembrane. Substrates secreted by each secretory system are included in a circle in the top of the figure. Adapted from Tseng et al. (2009).

The Sec pathway consists of three structural parts: a protein targeting component, a motor protein and a membrane integrated conducting channel called SecYEG translocase. This mechanism transports unfolded proteins with a hydrophobic sequence at the N-terminus. Moreover, the secreted protein either remains in the periplasm or is transported to the extracellular space. The proteins may contain a SecB-specific signal sequence for transport to the periplasm or the extracellular milieu; however, if it has the signal recognition particle (SRP) signal it can follow the SRP pathway and remain in the inner membrane (Green and Mecsas, 2016; Tsirigotaki et al., 2017).

By contrast, the Tat secretion pathway consists of 2–3 subunits, TatA and TatB, which form a unique multifunctional protein in Gram-positive bacteria, and TatC. This mechanism translocates folded proteins with a twin-arginine motif. In Gram-positive bacteria, most proteins are transported out of the cell, while in Gram-negative bacteria the protein can remain in the periplasm or it can be translocated to the extracellular space by the T2SS (Patel et al., 2014; Green and Mecsas, 2016).

The T2SS, a complex structure composed of 15 proteins, named general secretion pathway proteins (Gsp) in *E. coli* (Korotkov et al., 2012), Eps in *V. cholera* (Abendroth et al., 2009; Sloup et al., 2017) and Xcp in *P. aeruginosa* (Filloux et al., 1998; Robert et al., 2005), has a wide range of substrates with diverse functions, although all share one feature, an N-terminal signal which enables them pass to the periplasm via the Sec or Tat secretion mechanisms (Nivaskumar and Francetic, 2014; Green and Mecsas, 2016).

The main function of the T2SS is to acquire nutrients (Nivaskumar and Francetic, 2014). It is responsible for secreting numerous exoproteins, most of which are hydrolytic enzymes and other proteins such as toxins, adhesins and cytochromes that have various roles in respiration, biofilm formation and motility (Nivaskumar and Francetic, 2014). The T2SS has been described in various environmental strains and also human pathogens such as *V. cholera* (Overbye et al., 1993), *P. aeruginosa, Aeromonas* sp. and enterotoxigenic *Escherichia coli* (ETEC) (Nivaskumar and Francetic, 2014).

T3SS

The type III secretion system (T3SS) or injectisome, is a double-membrane-embedded apparatus found in multiple pathogenic Gram-negative bacteria such as *Salmonella* spp., *Yersinia* spp., enteropathogenic and enterohemorrhagic *E. coli*, *Shigella* spp. and *Pseudomonas* spp. (Cornelis, 2006; Gaytan et al., 2016; Deng et al., 2017). This complex nanomachine promotes the transfer of virulence proteins called effectors from the bacterial cytoplasm into the eukaryotic cell in a single step (Galan and Waksman, 2018).

The T3SS is composed of approximately 25 proteins assembled in three main structures: the basal body, a set of rings spanning the two membranes of the bacterium; a hollow needle-shaped component through which the semi-unfolded effectors are transported (these first two structures are collectively called "needle complex"); and the translocon, made up of a hydrophilic protein that serves as a scaffold for forming a translocation pore, constituted by two hydrophobic proteins, which is inserted into the host cell membrane and through which effectors are directly translocated. A unique set of effectors is delivered by each pathogen, which subverts specific host-cell signaling pathways to allow bacterial colonization (Izore et al., 2011; Notti and Stebbins, 2016; Deng et al., 2017).

The export apparatus associated with the basal body is formed by five poly topic inner membrane proteins that are essential

for substrate secretion. This protein complex, together with a cytoplasmic sorting platform and the ATPase complex are responsible for substrate recruitment and classification, and for energizing the secretion process enabling chaperone-effector dissociation and protein unfolding for initial entry into the T3SS central channel that serves as the secretion pathway. These components are highly conserved between different T3SS systems and with the flagella, which is evolutionarily related to the injectisome (Abby and Rocha, 2012; Galan and Waksman, 2018; Lara-Tejero and Galan, 2019).

Several effectors of T3SS have been described such as ExoS, ExoT, ExoU, and ExoY in *P. aeruginosa*; Tir and EspE in *E. coli* and YopE, YopH, YopM, YopJ/P, YopO/YpkA, and YopT in *Yersinia* sp. (Cornelis and Van Gijsegem, 2000).

T4SS

The type IV secretion system family is found in Gram-negative and Gram-positive bacteria as well as in *Archaea*. T4SS is the most cosmopolitan secretion system and differs from other SS as it is able to transfer DNA in addition to proteins (Cascales and Christie, 2003). More specifically, T4SS is capable of performing contact-dependent secretion of effector molecules into eukaryotic cells, conjugative transfer of mobile DNA elements and also exchange of DNA without any contact with the outside of the cell (Green and Mecsas, 2016; Grohmann et al., 2018). T4SS can be divided on the basis of its functionality into two subfamilies: conjugation systems and effector translocators. Conjugation systems are responsible for the transfer of antibiotic resistance genes and virulence determinants among bacteria. The effector translocators introduce virulence factors into the host cell (Christie, 2016). However, in Gram-negative bacteria T4SS has been divided into two different subfamilies: IVA and IVB. The *E. coli* conjugation apparatuses and VirB/D system of *Agrobacterium tumefaciens* are the models used to study the structure of type IVA of T4SS (Grohmann et al., 2018). The VirB/D apparatus consists of 12 proteins which form a complex envelope-spanning structure that facilitate the translocation function. Two of these proteins, VirB2 and VirB5, make up the pilus, while another three proteins act as ATPases, and VirB1 is a lytic transglycosylase (Costa et al., 2015; Green and Mecsas, 2016). The *Legionella pneumophila* Dot/Icm (Defective for organelle trafficking/Intracellular multiplication) system is the model used to study the IVB subfamily of T4SS (Nagai and Kubori, 2011; Grohmann et al., 2018).

T5SS

The type V secretion system is unique because its substrates transport themselves across the outer membrane. The substrates use the Sec translocase to pass through the inner membrane to the periplasm space. Various different types of T5SS have been identified: autotransporters (T5aSS), two-partner passenger-translocators (T5bSS), trimeric autotransporters (T5cSS), hybrid autotransporters (T5dSS) and inverted autotransporters (T5eSS) (Henderson et al., 2004; Leo et al., 2012; Rojas-Lopez et al., 2017). In general, the T5SS transports proteins across the asymmetric outer membrane (OM) that contains lipopolysaccharides, through their own C-terminal translocation domain that inserts into the OM as a β-barrel to complete the secretion of the N-terminal passenger domain via the barrel pore. Several periplasmic chaperones also participate in transport through the OM, specifically the β-barrel assembly machinery (BAM complex) and the translocation and assembly module (TAM complex) facilitate protein secretion (Rojas-Lopez et al., 2017).

A T5SS has been described in human pathogens such as *Bordetella pertussis* and *Haemophilus influenzae*, which have two-partner SS and uropathogenic *E. coli*, which has chaperone-usher systems (Costa et al., 2015; Green and Mecsas, 2016).

YadA of *Yersinia enterocolitica* and SadA of *Salmonella* are T5SS type c (Leo et al., 2012). Intimin of *E. coli* and invasin of enteropathogenic *Yersinia* spp. are type Ve SS (Leo et al., 2012).

A self-transporter (T5aSS) (Wilhelm et al., 2007) and three T5bSS: LepA /LepB system (Kida et al., 2008), the CupB system (Ruer et al., 2008) and PdtA/PdtB system (Faure et al., 2014), have been reported in *P. aeruginosa*. In *B. cenocepacia,* four T5SS (Holden et al., 2009) have been found, two with pertactin domains and two with haemagglutinin autotransporters; this last type is also present in *S. maltophilia* (Ryan et al., 2009).

T6SS

The type VI secretion system is widely represented in Gram-negative bacteria (Coulthurst, 2013; Gallique et al., 2017b). T6SS is an integrated secretion device within the membrane and it transfers substrates, which are toxic effectors to eukaryotic (Pukatzki et al., 2007) and prokaryotic cells (Russell et al., 2014). It plays a crucial role in the pathogenesis and competition among bacteria (Ho et al., 2014; Zoued et al., 2014; Costa et al., 2015; Gallique et al., 2017a). The origin of T6SS is related to bacteriophages (Leiman et al., 2009). T6SS is a huge apparatus and consists of 13 core components organized into a *trans*-membrane complex, a baseplate-like structure at the cytoplasmic face of the inner membrane, and a sheathed inner tube, which is the effector delivery module that is ejected to the target cell. The tube-sheath complex is assembled from the baseplate in the cytoplasm and the hollow tube is built from hexamers of the hemolysin co-regulated protein (Hcp). The sheath contracts and pushes the tube with the associated effectors into targeted cells, using a puncturing mechanism similar to the one used by the contractile tails of phages (Russell et al., 2011, 2014; Cianfanelli et al., 2016; Green and Mecsas, 2016; Galan and Waksman, 2018).

T7SS

Type VII secretory system has been described in some Gram-positive bacteria such as *Staphylococcus aureus* and in species of *Mycobacterium* and *Corynebacterium*. This SS was reported for the first time in 2003 in *Mycobacterium tuberculosis* and it was called ESX-1 (Stanley et al., 2003), which is an important virulence factor in *M. tuberculosis*. To date, five T7SS have been identified in *Mycobacterium* sp. but the transport mechanisms across the mycobacterial membrane are almost unknown (Costa et al., 2015; Ates et al., 2016; Green and Mecsas, 2016).

Most of the substrates of T7SS belong to EscAB clan which includes six protein families: Esx, PE, PPE, LXG, DUF2563,

and DUF2580. ESAT-6 is a *M. tuberculosis* protein which belongs to Esx family and which is secreted with EsxB (CFP-10) (Ates et al., 2016).

T9SS

The type IX secretion system (T9SS) or Por secretion system (PorSS) is the most recently discovered system (Lasica et al., 2017). Its function is to transport molecules across the outer membrane. Its substrates must include a Sec signal, which allows transfer of proteins through the inner membrane with the aid of the Sec system. The T9SS system has been described in almost all members of the phylum *Bacteroidetes,* but it has mainly been studied in oral pathogens such as *Porphyromonas gingivalis* and *Tannerella forsythia.* In *P. gigivalis*, the T9SS system consists of 16 proteins with structural and functional activity, and another two proteins involved in the regulation of the transport process (Sato et al., 2010; Lasica et al., 2017).

REGULATION OF SECRETION SYSTEMS BY QUORUM SENSING NETWORKS (TABLE 1)

Pseudomonas aeruginosa

T1SS

Transcriptional studies in *P. aeruginosa* suggest that in this bacterium T1SS is positively regulated by QS, since the expression of its effector, the alkaline protease AprA, depends on QS. In addition, the genes of the AprA inhibitor *aprI* and the structural genes *aprDEF* also appear to be positively regulated by QS (Hentzer et al., 2003; Schuster et al., 2003; Wagner et al., 2003).

T2SS

Three T2SS systems, the Xcp, Hxc and Txc systems, have been described in *P. aeruginosa*. The first of these, Xcp, secretes the QS regulated virulence factors elastase A and B (LasA and LasB) as well as the exotoxin A (ExoA) and it is itself positively regulated by QS (**Figure 2**). Accordingly, recently it was demonstrated by ChIPseq analysis that MvfR (the receptor of the PQS autoinducer) is able to directly bind *xcpQ-xcpP-xcpR* regions and this is related to their induction in the presence of MvfR (Maura et al., 2016).

The second T2SS, Hxc, is regulated by the availability of phosphate and secretes LapA a low-molecular weight alkaline phosphatase (Wagner et al., 2003; Michel et al., 2007). Two genes, *xphA* and *xqhA*, which encode the PaQa subunit of the Xcp functional hybrid system, have been described. These genes, which are located outside the *xcp* locus, are regulated by environmental conditions but not by QS, in contrast to what occurs with the rest of the Xcp system (Michel et al., 2007, 2011). In contrast to the first two systems, the third system Txc has just recently been described and so far only identified in a region of genome plasticity of the strain PA7; it is regulated by a two component system (TtsSR) and secretes the chitin binding protein CpbE (Cadoret et al., 2014).

T3SS

Current evidence suggest that as in *Vibrio* spp., QS in *P. aeruginosa* negatively regulates the expression of T3SS, specifically the RhlI/RhlR system, as transcription of the T3SS genes and secretion of ExoS increase significantly in a *rhlI* mutant and return to basal levels on the addition of exogenous C4-HSL (Bleves et al., 2005; Kong et al., 2009; **Figure 2**). In agreement, the expression of *exoS* is also negatively regulated by QS, specifically by the RhlI/RhlR system, as well as by the stationary phase sigma factor RpoS (Hogardt et al., 2004).

The fact that the T3SS genes do not appear to be repressed by QS in some global transcriptomic studies with mutants may be explained by the presence of high calcium concentrations in the media, or by the lack of resolution of DNA microarrays (Hentzer et al., 2003; Schuster et al., 2003). More striking is the fact that some QS inhibitors like 6-gingerol and coumarin inhibit rather than increase the expression of T3SS (Zhang et al., 2018). Nevertheless, these studies were done in the presence of high calcium, and QS-independent inhibition of T3SS has not been ruled out. Moreover, a recent study in the PA01 strain, using a *lasR rhlR* double mutant, demonstrated that it remains virulent in a murine abscess model, despite that it does not produce QS-dependent virulence factors and that the secretion of ExoT and ExoS is fully functional in this mutant. Hence the authors hypothesized that T3SS is the cause of the remaining virulence (Soto-Aceves et al., 2019).

The *P. aeruginosa* QS network and its T3SS are also related by the fact that VqsM, an AraC-family transcription factor, binds to both the promoter region of *lasI* and the promoter of *exsA*, which encodes a master regulator of the T3SS, regulating both mechanisms (Liang et al., 2014; **Figure 2**).

T6SS

The T6SS is involved in iron transport, and a connection has been observed between T6SS and QS through the TseF protein, which is a substrate of T6SS and interacts with PQS (Lin et al., 2017; **Figure 2**).

In *P. aeruginosa,* three loci which encode T6SS have been found to be regulated by QS proteins (LasR and MvfR) (Lesic et al., 2009). Expression of the second loci, H2-T6SS, is regulated by the Las and Rhl QS systems in PAO1 strains (Sana et al., 2012; **Figure 2**) and by the direct binding of MvfR in PA14 (Maura et al., 2016).

Vibrio sp.

T2SS

The formation of biofilms has multifactorial regulation in *V. cholerae* as in other pathogens. The QS network controls directly biofilm production which is related to type II secretion system in *V. cholerae* (Teschler et al., 2015). Several proteins such as RbmA, RbmC and Bap1, which are involved in the formation of biofilms, are transported by T2SS. In addition, mutant strains with inactivated T2SS have reduced biofilm formation (Johnson et al., 2014; Teschler et al., 2015).

TABLE 1 | Pathogens and QS elements related to secretion systems.

Type secretion system	SS element	QS regulation	QS element	Microorganisms	References

T3SS

In *V. parahaemolyticus* and *V. harveyi* (unlike in *E. coli*), both the HAI-1 and AI-2 QS systems inhibit the expression of T3SS genes (Henke and Bassler, 2004). QS also represses T3SS during *V. harveyi* infections of gnotobiotic brine shrimp (Ruwandeepika et al., 2015). Waters et al. (2010) have described the regulatory pathway by which QS controls T3SS. At low cell density when LuxR is repressed, which entails the derepression of two promoters of the *exsBA* operon and the *exsA* operon, ExsA activates the expression of genes that encode the structural proteins of the type III secretion system. However, when the cell density is high, LuxR directly represses transcription of the PB promoter, preventing the production of ExsA and consequently decreasing the expression of structural genes of T3SS (Waters et al., 2010; Ball et al., 2017). OpaR inhibits the T3SS1 in *V. parahaemolyticus* which is the most important factor in its cytotoxicity (Gode-Potratz and McCarter, 2011).

T6SS

Several researchers have demonstrated the regulation of T6SS by QS networks in *Vibrio* spp. We present the main findings in this field here. In *V. alginolyticus*, activation of T6SS and the QS network has been found to be coordinated by the serine/threonine kinase PpkA cascade (Yang et al., 2018). PpkA2 is autophosphorylation and it transfers the phosphate group to VstR. Phosphorylated VstR promotes the expression of both of the T6SS in *V. alginolyticus* through the inhibition of LuxO activity, which acts to impede the expression of LuxR, a promoter of the T6SS. LuxR inhibits the expression of the first T6SS (T6SS1) or promotes the expression of the second T6SS (T6SS2) (Yang et al., 2018).

At low cell population density, LuxO is phosphorylated, which activates the expression of specific small regulatory RNAs (sRNAs) in conjunction with alternative sigma factor σ^{54} (Sheng et al., 2012). sRNAs inhibit the expression of LuxR with the help of RNA chaperone Hfq (Liu et al., 2011). However, at high cell population density, LuxO is dephosphorylated turning off the transcription of the sRNAs and allowing the translation of LuxR (Waters and Bassler, 2005; Milton, 2006). Sheng et al. (2012) also demonstrated that the expression of the *hcp* T6SS gene is growth phase-dependent and the QS regulators controls the haemolysin co-regulated protein, which is one of the main proteins of the T6SS functioning as an effector of the system and/or an effector binding protein (**Figure 2**). The phosphatase PppA also acts on the QS (modulating the transcription of LuxR) and the expression and secretion of *hcp1* and *hcp2* (Sheng et al., 2013). It is important to highlight that PppA permits the cross-talk between the two T6SS in *V. alginolyticus* (Sheng et al., 2013).

Rpo N (σ^{54}) collaborates with QS in the regulation of T6SS genes. It is involved in the regulation of the expression of *hcp* and *vgrG3* operons that encode T6SS secreted molecules, but does not control the genes that encode the structural and sheath components of T6SS (Ishikawa et al., 2009; Dong and Mekalanos, 2012).

There are a few more studies in *V. cholerae* related to this topic than other species. Two QS autoinducers, CAI-I (cholerae autoinducer) and AI-2 (autoinducer-2), co-operate to control the gene expression depending on the cell density

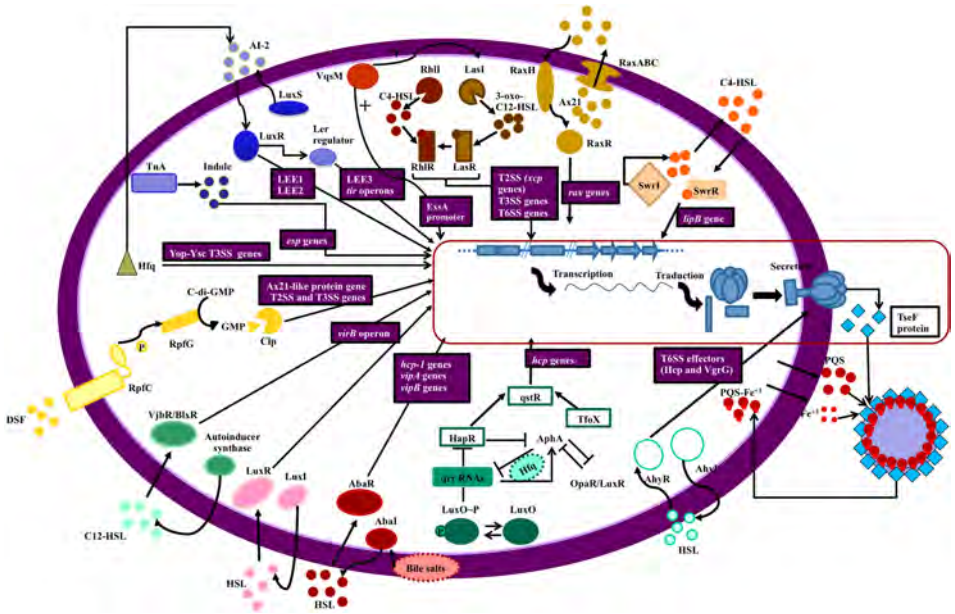

FIGURE 2 | Secretion systems and QS network elements. The figure shows the relationship between QS networks and expression of secretion systems (blue squares). The genes regulated by QS are in purple boxes. Each QS network is represented by a different color. Starting at the top right of the figure: The swr QS system of *S. liquefaciens* controls the *lipB* genes of the T1SS (orange); Ax21 (QS effector) and QS system Rax regulate RaxABC TOSS (T1SS) in gram negative bacteria (ochre); QS (RhlIR and LasIR) regulates expression of T2SS, T3SS, and T6SS in *P. aeruginosa* (brown); VqsM (an AraC family transcription factor) interacts with the LasIR and ExsA promoters (a master regulator of T3SS) in *P. aeruginosa* (dark orange); T2SS is regulated by LuxS/LuxI/AI-2 QS in *E. coli* and indole production by TnA (tryptophanase) regulates *esp* genes expression (T2SS) in this bacterium (blue); in *Yersinia* sp. the Hfq chaperone is connected with QS (AI-2) and regulates the Yop-Ysc type III secretion system (T3SS) (green); in *Xanthomonas* sp. T2SS and T3SS are regulated by DSF (diffusible signal factor) which is a quorum sensing signal (yellow); T4SS (*virB* operon) is regulated by VjbR (LuxR like protein) and LuxI in *Brucella* (turquoise) and *Roseobacter* (pink), respectively; a connection between *Acinetobacter baumanii* QS (AbaI/AbaR, controlled by bile salts) and T6SS has been established (maroon); in *Vibrio* sp. there is a complex network which relates QS (LuxO/HapR/TfoX) with T6SS (aquamarine); AhyRI (a QS network) in *Aeromonas* sp. and *P. atrosepticum* is involved in Hcp and VgrG secretion (sky blue) and finally, iron is transported across the cell membrane accompanied by PQS, a quorum sensing signal in *P. aeruginosa*, and this process depend on Tse a substrate of T6SS, which binds to OMVs (outer membrane vesicles) containing PQS- Fe^{3+}.

(Ng and Bassler, 2009). Two enzymes are necessary for the biosynthesis of these autoinducers: CqsA and LuxS, respectively (Schauder et al., 2001; Miller et al., 2002; Chen et al., 2002; Higgins et al., 2007). These signal molecules are detected by two sensor kinases, LuxQ (sensor of CAI-I) and CqsS (sensor of AI-2). Both pathways merge on LuxU, a phosphotranfer protein. At low cell density (LCD), the two sensor kinases phosphorylate LuxU due to the absence of their respective autoinducers. There are two histidine kinases which also contribute to the phosphorylation of LuxU: VpsS and CqsR (Jung et al., 2015). Then, LuxU transfers the phosphorylate group to a DNA-binding response regulator protein called LuxO. Phosphorylated LuxO activates the expression of sRNA molecules (known as qrr1-4) when the cell density is low thanks to the interaction with the alternative sigma factor σ^{54} (Freeman et al., 2000; Lenz et al., 2004). In conjunction with the RNA-binding protein Hfq, LuxO represses the expression of HapR (Lenz et al., 2004), a TetR-family global transcriptional regulator which acts on QstR (Tsou et al., 2009; Shao and Bassler, 2014; Watve et al., 2015; **Figure 2**). HapR is accumulated when the cell density is high (Lenz et al., 2004) because LuxO is not phosphorylated and transcription of the sRNAs is blocked. QstR is a master regulator of the T6SS belonging to the LuxR-type family of regulators (Jaskólska et al., 2018). QstR binds to the promoter region of the T6SS cluster inducing the expression of the genes. The regulation of the T6SS by cAMP-CRP pathway is not clear, but it is possible that it influences T6SS genes through regulation of QS and chitin-induced competency (Liang et al., 2007; Blokesch, 2012). It is known that CRP positively regulates T6SS (Ishikawa et al., 2009). Apart from the activation of QstR via QS, it is also regulated by chitin and arabinose (Lo Scrudato and Blokesch, 2012, 2013).

The expression of the three T6SS gene clusters in *V. cholerae* requires TfoX, CytR, HapR, and QstR for the highest level of expression (Watve et al., 2015). CytR and TfoX are required for the expression of the T6SS genes but their regulatory effects are only mediated by QstR (**Figure 2**).

Other Pathogens

T1SS

The *swr* QS system, which controls swarming motility, regulates the Lip secretion system, a T1SS responsible for the secretion of lipases, metalloproteases and S-layer proteins in *Serratia liquefaciens* MG1 (Riedel et al., 2001). The *swr* QS system consists of SwrI, which synthesizes C4-HSL, and SwrR, which regulates gene transcription after binding the diffusible signal C4-HSL.

QS-mediated regulation of *lipB*, which encodes the LipB exporter, was demonstrated in *swrI* mutants with *luxAB* insertions, in which the level of secreted proteins was lower (Riedel et al., 2001; **Figure 2**). Other relationships between T1SS and QS have also been observed. The rice pathogen recognition XA21 receptor recognizes a sulphated peptide (axY^S22) derived from the Ax21 protein (activator of XA21-mediated immunity) and confers resistance to *Xanthomonas oryzae* strains. Ax21 may have a key biological role because it is conserved in *Xanthomonas* spp., *Xylella fastidiosa,* and *Stenotrophomonas maltophilia*. Ax21 requires RaxABC TOSS (type I secretion system) for secretion and activity. The expression of *rax* genes which encode T1SS has been demonstrated to be QS-dependent due to the cell-density dependency (Han et al., 2011). These data indicate that Ax21 could have a role as a signaling molecule and a direct relationship between the QS network and T1SS is established (**Figure 2**; Lee et al., 2006).

T2SS

In *Xanthomonas* species, QS is mediated by the diffusible signal factor (DSF). A proteomic analysis conducted in 2013 revealed 33 proteins that are controlled by DSF. Their putative functions are associated with QS and include cellular processes, intermediary metabolism, oxidative adaption, macromolecule metabolism, cell-structure, protein catabolism, and hypothetical functions (Qian et al., 2013). In this study, it was observed that three genes encoding T2SS-dependent proteins and one gene which encodes Ax21 (activator of XA21-mediated immunity)-like protein are regulated by QS and are essential for virulence-associated functions, including extracellular protease, cell motility, antioxidative ability, extracellular polysaccharide biosynthesis (EPS), colonization, and biofilm (Qian et al., 2013; **Figure 2**).

T3SS

The relationship between QS and T3SS in *E. coli* was first demonstrated by Sperandio et al. (1999), who showed that expression of the locus of enterocyte effacement (LEE) operons that encode the T3SS is activated by QS in both enterohemorrhagic (EHEC) and enteropathogenic (EPEC) *E. coli* due to transcriptional control of the LEE operons by LuxS, which directly activates the LEE1 and LEE2 operons and indirectly activates (via the Ler regulator) the LEE3 and *tir* operons (**Figure 2**). These researchers proposed that activation of the T3SS by the AI-2 autoinducer synthesized by commensal *E. coli* resident in the large intestine could explain the high infectivity of *E. coli* O157: H7, which has an infectious dose of about 50 bacterial cells (Sperandio et al., 1999).

The major virulence factors of EHEC and EPEC are intimin (T5eSS), Tir (the receptor for intimin) and the three secreted proteins EspA, EspB and EspD. T3SS functions in the secretion of the Tir and Esp proteins. The LuxR-type response regulator SdiA negatively regulates the expression of EspD and intimin in the same bacterium, indicating multifactorial regulation of the T3SS by bacterial QS signals (Kanamaru et al., 2000).

Indole, which is produced by tryptophanase (TnA) in enteric bacteria and reaches high concentrations in the gut, is another signaling molecule that influences expression of T3SS in *E. coli* (Lee et al., 2007, 2008). Indole increases the production and secretion of the translocators EspA and EspB in EHEC O157:H7 (Hirakawa et al., 2009; **Figure 2**); hence, indole promotes the development of attaching and effacing (A/E) lesions in HeLa cells.

The involvement of the RNA chaperone protein Hfq, which also participates in QS, in T3SS expression was demonstrated in *Yersinia pseudotuberculosis* and *Yersinia pestis* (Schiano et al., 2014; **Figure 2**). Moreover, Schiano et al., 2014 have demonstrated the regulation of T3SS by QS through virulence regulators LcrF and YmoA in *Y. pseudotuberculosis* (Amy, 2018).

In *Aeromonas hydrophila*, an unique QS system, encoded in *ahyR/ahyI* loci, has been described (Vilches et al., 2009; Garde et al., 2010). Vilches et al. (2009) have used the *A. hydrophila* AH-3 strain to study the T3SS regulation. AH-3: ahyI and AH-3: ahyR mutants have reduced activity of the *aopN-aopB* promoter (promoter of T3SS components) compared to the wild-type strain (**Figure 2**). So they concluded that QS could be involved in the positive regulation of the production of the T3SS component in the AH-3 strain (Vilches et al., 2009).

T4SS

In *Brucella abortus,* there is a clear relationship between the QS network and T4SS. For the *virB* operon, which encodes the T4SS regulated by VjbR, a LuxR-type QS is responsible for the virulence characteristics of *B. abortus* (Li et al., 2017). The *virB* operon is responsible for establishing the replicative niche of the bacterium once it enters the host cell. The T4SS in *B. abortus,* as in other bacteria, translocates effector proteins into the host cell to avoid the immune defense mechanisms, making it one of the two main virulence factors for *Brucella.* Arocena et al. (2010) described the binding site of VjbR to the *virB* operon (Li et al., 2017). Otherwise, the conjugation process between two members of the *Roseobacter* group mediated by T4SS, encoded in RepABC-type plasmids, is controlled by the QS network. This was demonstrated by construction of *luxI* mutant and the addition of external long chain AHLs, which restored the phenotype (Patzelt et al., 2013, 2016; **Figure 2**).

T6SS

Quorum sensing has been reported to control expression of T6SS toxin-immunity systems in *Burkholderia thailandensis*. Moreover, a new role for T6SS in constraining the proliferation of QS mutants has been described in *B. thailandensis* (Majerczyk et al., 2016). Interestingly, it has been observed that T6SS effectors function as cell-to-cell signals in a *Pseudomonas fluorescens* MFE01 strain lacking the AHL QS pathway (Gallique et al., 2017b).

In *A. hydrophila*, Hcp and VgrG- two of the "core" proteins and also effectors of the T6SS- secretion have been suggested to be regulated by the AhyRI QS regulon (Khajanchi et al., 2009; **Figure 2**). Finally, our research group has described the association between T6SS machinery and the activation of the QS system by bile salts in *A. baumannii* clinical strains (Lopez et al., 2017a; **Figure 2**).

T7SS

As with other bacteria, *Mycobacterium* spp regulate biofilm formation by QS (Virmani et al., 2018). The second messenger c-di-cGMP, an intracellular signaling molecule, coordinates

biofilm production and QS signaling (Sharma et al., 2014). Both *M. tuberculosis* (Kulka et al., 2012) and diverse species of non-tuberculous mycobacteria (*M. smegmatis, M. marinum, M. fortuitum, M. chelonae, M. ulcerans, M. abscessus, M. avium,* and *M. bovis*) produce biofilm depending on certain environmental conditions such as the availability of nutrients or the pH of the medium (Hall-Stoodley et al., 1998; Bardouniotis et al., 2003; Ojha et al., 2005; Marsollier et al., 2007; Johansen et al., 2009; Rhoades et al., 2009).

In the recent work of Lai et al. (2018) it was demonstrated that *the espE, espF, espG,* and *espH* genes, located in the T7SS ESX-1 operon, are crucial for sliding motility and biofilm formation in *M. marinum*. Esp proteins, which regulate substrate transport, are involved also in virulence. This paper clearly demonstrates the role of *M. marinum* T7SS in the production of biofilm which, as already mentioned, is related to QS (Lai et al., 2018).

The T7SS of *S. aureus*, a virulence factors export machinery, plays a key role in the promotion of bacterial survival and long-term persistence of subpopulations of staphylococci. The expression of T7SS is regulated by the bacterial interaction with host tissues (Lopez et al., 2017c) mediated by the secondary sigma factor (σB) (Schulthess et al., 2012). Schulthess et al. (2012) reported that the repression of *esxA* by σB is due to the transcription of *sarA* induced by σB, which leads to a strong repression of *esxA*. The activation of the *esxA* transcript, on the other hand, is stimulated by *arlR*, the response regulator of the ArlRS two-component system, SpoVG, a σ-dependent element, and the Agr quorum detection system (Schulthess et al., 2012). Agr QS system is composed by AIP (self-activating peptide), the inducer ligand of AgrC which is the receptor of the agr signal. In the case of the QS Agr system, the effector of global gene regulation is an important regulatory RNA, RNAIII (Novick and Geisinger, 2008).

T9SS

Moreover, an important relationship between T9SS and biofilm formation has been observed in periodontopathogenic pathogens such as *Capnocytophaga ochracea*, *Porphyromonas* spp., *Fusobacterium* spp. and *Prevotella* spp. (Kita et al., 2016). In the study by Kita et al. (2016), the participation of T9SS in the formation of biofilm of *C. ochracea* is demonstrated. The formation of biofilm of *C. ochracea* is crucial for the development of dental plaque and the same happens with other periodontal pathogens, in which it has also been seen that genes related to T9SS are present. Therefore, the components of the T9SS could be potential targets to inhibit the formation of biofilm and thus avoid the formation of dental plaque (McBride and Zhu, 2013; Kita et al., 2016). However, in depth analysis of the relationship between T9SS and QS network in different pathogens is required.

DISCUSSION

To date, the T1SS, T2SS, T3SS, T4SS, T6SS, T7SS, and T9SS SS have been found to have important relationships with QS networks. The involvement of the T1SS system (Lip B which is part of the Lip exporter) in the QS network (*swr* quorum system) of *S. liquefaciens* MG1 has been investigated (Riedel et al., 2001). In *P. aeruginosa,* two QS systems (*lasR/lasI* and *rhLR/rhlI*) are linked to T2SS system by microarrays and proteomic studies (Chapon-Herve et al., 1997; Wagner et al., 2003; Michel et al., 2007), and DSF-type systems are also linked to T2SS in *Xanthomonas* species through proteome analysis (Qian et al., 2013). The QS signal AI-2 has been associated with a T3SS system in *E. coli* (Sperandio et al., 1999) and *Vibrio* spp. (Henke and Bassler, 2004). Moreover, this T3SS system has been related to QS proteins in another two pathogens, *P. aeruginosa* and *Yersinia* spp. (Liang et al., 2014; Schiano et al., 2014).

Several T4SS (*virB* operon) are controlled by VjbR protein which is a LuxR-type quorum-sensing regulator in *B. abortus* (Arocena et al., 2010; Li et al., 2017). Moreover, in the *Roseobacter* group, the conjugation of plasmids, which encode T4SS, is QS-controlled and the QS system may detect a broad range of long-chain AHLs at the cell surface (Patzelt et al., 2013, 2016).

There is a wealth of information relating the T6SS to QS in pathogens such as *Vibrio* spp. For example, Hcp and VasH from the T6SS system in *V. cholerae* are involved in QS (Ishikawa et al., 2009; Zheng et al., 2010; Kitaoka et al., 2011; Leung et al., 2011; Yang et al., 2018). For *Pseudomonas* spp,. there are numerous works where the different T6SS are regulated by QS networks (Lesic et al., 2009; Gallique et al., 2017b; Lin et al., 2017). In other pathogens as *Burkholderia thailandensis* (Majerczyk et al., 2016), and in *A. baumannii,* the relationship between QS and SS has begun to be studied (Lopez et al., 2017a).

In *M. marinum,* the relationship between biofilm formation, which is tightly connected with QS, and T7SS, has been demonstrated (Lai et al., 2018). Also in *S. aureus,* the Agr QS network has been related to T7SS (Schulthess et al., 2012). An important relationship between T9SS and biofilm formation has been observed in periodontopathogenic pathogens (Kita et al., 2016). Finally, although the involvement of T5SS secretion system in virulence, motility and competence is well-known, these systems and their association with QS must be studied in greater depth in order to clarify their roles.

Taking *P. aeruginosa* as a reference point, the positive effect of QS in the expression of T1SS and T2SS could be related to the fact that this organism secretes exoproducts that are public goods (proteases and lipases); hence, it is better to produce and secrete these compounds when a high cell density is reached, since these products are costly and the benefits associated to their production are higher at high cell densities. Similarly, the T6SS, which is involved in killing competitors by contact, will be more efficient at high cell densities since the probability of finding target bacteria is higher. In contrast, the T3SS appears to be negatively regulated by QS, and this may be related to its role in an acute infection and its "inhibition by QS" may be a way to facilitate the transition to a chronic infection state. In addition to its well established role in infections, T3SS has a broader ecological role suggested by its role in killing biofilm associated *Acanthamoeba castellanii* amoeba (Matz et al., 2008). Furthermore, it was recently demonstrated that T3SS is susceptible of cheating by mutants that do not produce it, allowing their establishment in infections (Czechowska et al., 2014); hence, the selective forces that act over T3SS are complex.

Therefore, research into the relationship between QS and SS must be further developed in order to better understand human infections.

AUTHOR CONTRIBUTIONS

RTP, LB, AA, BG-P, LF-G, ML, IB, and GB developed the redaction of the manuscript, figures and table. RG-C, TW, and MT designed the review, assigned writing tasks to co-authors, contributed to writing and proofread the final version.

FUNDING

This study was funded by grant PI16/01163 awarded to MT within the State Plan for R+D+I 2013–2016 (National Plan for Scientific Research, Technological Development and Innovation 2008–2011) and co-financed by the ISCIII-Deputy General Directorate for Evaluation and Promotion of Research – European Regional Development Fund "A way of making Europe" and Instituto de Salud Carlos III FEDER, Spanish Network for the Research in Infectious Diseases (REIPI, RD16/0016/0001 and RD16/0016/0006) and by the Study Group on Mechanisms of Action and Resistance to Antimicrobials, GEMARA (SEIMC, http://www.seimc.org/). MT was financially supported by the Miguel Servet Research Programme (SERGAS and ISCIII). RTP and LF-G were financially supported by, respectively, a post-speciality grant awarded by the Fundación Novoa Santos (CHUAC-SERGAS, Galicia) and predoctoral fellowship from the Xunta de Galicia (GAIN, Axencia de Innovación). RG-C research is supported by the grant PAPIIT-UNAM number IN214218. BG-P was supported by grants PAPIIT-UNAM IN209617 and CONACYT 284081.

Abstract

Wolbachia sp. has colonized over 70% of insect species, successfully manipulating host fertility, protein expression, lifespan, and metabolism. Understanding and engineering the biochemistry and physiology of *Wolbachia* holds great promise for insect vector-borne disease eradication. *Wolbachia* is cultured in cell lines, which have long duplication times and are difficult to manipulate and study. The yeast strain *Saccharomyces cerevisiae* W303 was used successfully as an artificial host for *Wolbachia w*AlbB. As compared to controls, infected yeast lost viability early, probably as a result of an abnormally high mitochondrial oxidative phosphorylation activity observed at late stages of growth. No respiratory chain proteins from *Wolbachia* were detected, while several *Wolbachia* F_1F_0-ATPase subunits were revealed. After 5 days outside the cell, *Wolbachia* remained fully infective against insect cells.

bioenergetics, endosymbiosis, oxidative phosphorylation, *Saccharomyces cerevisiae*, *Wolbachia pipientis*

1 | INTRODUCTION

Construction of artificial ecosystems mimicking symbiotic relationships have been proposed to study ecology and evolution of symbioses (Hosoda et al., 2011; Momeni, Chen, Hillesland, Waite, & Shou, 2011), to engineer microbial consortia (Brenner, You, & Arnold, 2008; French, 2017; Frey-Klett et al., 2011; Mee & Wang, 2012), and to host uncultivable bacteria (Stewart, 2012). Synthetic mutualism of species that do not interact naturally has been established in co-culture between bacteria, yeast, amoeba, alga, cell lines, and tissues (Buchsbaum & Buchsbaum, 1934; Hosoda & Yomo, 2011; Hosoda et al., 2011; Kubo et al., 2013; Lőrincz et al., 2010; Shou, Ram, & Vilar, 2007). Several bacterial endosymbionts have been found in yeast (Kang, Jeon, Hwang, & Park, 2009; Saniee & Siavoshi, 2015) as

INFORME DE LABORES 2019

well as in fungal hyphae and spores (Bertaux et al., 2003; Bianciotto et al., 2004; de Boer et al., 2004; Hoffman & Arnold, 2010; Lumini, Ghignone, Bianciotto, & Bonfante, 2006; Partida-Martinez & Hertweck, 2005; Sato et al., 2010). In this work, we cultured the obligate endosymbiont bacterium *Wolbachia* in an artificial host: the nonpathogenic yeast *Saccharomyces cerevisiae*.

Wolbachia pipientis is an exceedingly successful obligate endoparasite/endosymbiont in nematodes and arthropods (Taylor & Hoerauf, 1999; Werren, 1997; Werren, Baldo, & Clark, 2008). The size of the *Wolbachia* genome varies widely depending on the strain. Arthropod endoparasites have much larger genomes than nematode endosymbionts (Bandi, Slatko, & O'Neill, 1999; Darby et al., 2012; Foster et al., 2005; Klasson et al., 2008; Salzberg, Puiu, Sommer, Nene, & Lee, 2009; Wu et al., 2004). In regard to a possible aerobic metabolism, the *Wolbachia* from the plant hopper *Leodelphax stratellus* (*wStr*) is ten times more sensitive to paraquat than the insect host cell, suggesting that *wStr* does not possess the enzymes needed for reactive oxygen species (ROS) detoxification and thus it may be anaerobic or microaerophilic (Fallon, Kurtz, & Carroll, 2013). In contrast, eliminating *Wolbachia* with tetracycline in filaria, increases respiratory-chain gene expression in the host and causes an early death. This result, lead to the hypothesis that at least in filariae *Wolbachia* contributes as an energy generator for the host (Strübing, Lucius, Hoerauf, & Pfarr, 2010; Darby et al., 2012, 2014).

Culturing obligate intracellular bacteria is a challenge. Insect cells support *Wolbachia* growth, but culture times are long and cells are difficult to manipulate. Alternative systems such as mammalian blood have proven helpful to grow intracellular organisms such as *Sodalis* (Dale & Maudlin, 1999). However, *Wolbachia* did not seem to grow in blood and this was not pursued further (Result not-shown; see Methods). In contrast, *Saccharomyces cerevisiae* did support the growth of *Wolbachia* strain *w*AlbB.

As it can be extensively manipulated, *S. cerevisiae* is widely used as a model organism in biochemistry and molecular biology. In *S. cerevisiae*, it is possible to study processes such as the Crabtree effect observed in tumor cells (Diaz-Ruiz, Rigoulet, & Devin, 2011) and to model cell death in response to anoxia or ischemia/reperfusion (Stella, Burgos, Chapela, & Gamondi, 2011). In addition, it is used as a host to study DNA and RNA viral replication (Alves-Rodrigues, Galão, Meyerhans, & Díez, 2006), to identify and characterize bacterial effectors and toxins (Siggers & Lesser, 2008) and to analyze the function of heterologously expressed proteins such as the *Yarrowia lipolytica* and the mammalian brown-fat mitochondrial uncoupling proteins (UCPs) (Guerrero-Castillo et al., 2011). Thus, when it was observed that *Wolbachia* grew in *S. cerevisiae*, the system was characterized and the effects of *Wolbachia* infection on its host were analyzed.

Growing *Wolbachia* in insect cell cultures or in live hosts presents difficulties that have precluded detailed biochemistry and physiology studies (Baldridge et al., 2014; Khoo, Venard, Fu, Mercer, & Dobson, 2013). Here, we used the *S. cerevisiae* strain W303 as an alternative host for *Wolbachia* *w*AlbB and analyzed the host/endosymbiont system. Infected yeasts died earlier than controls. This probably resulted from an abnormally high mitochondrial oxidative phosphorylation activity observed at late stages of growth. Understanding *Wolbachia* and host-*Wolbachia* interactions holds great promise for medical, parasitological, and biotechnological applications.

2 | EXPERIMENTAL PROCEDURES

2.1 | Aa23 cell line maintenance

Aa23 cell line (*Aedes albopictus* infected with *w*AlbB) (O'Neill et al., 1997) was kindly donated by Professor Anne Fallon (U. Minnesota) and maintained in Eagle's minimal essential medium (MEM, Sigma Chemical Co. M0643). MEM was supplemented as indicated elsewhere (Shih, Gerenday, & Fallon, 1998). The medium was filter-sterilized (Millipore, 0.22 μm) and stored in 200 ml aliquots at 4°C. Prior to use, heat-inactivated fetal bovine serum (FBS; 30 min at 56°C) was added to a final concentration of 10% (Shih et al., 1998). The insect cell line was grown on True Line TR 4003 140 mm sterile petri dishes at 27°C in a 5% CO_2 atmosphere (ESCO CelCulture CO_2 incubator or in Corning culture flasks, Shanghai, China). Subcultures were performed in a 1:10 split at 90% confluence. A sample from this cell line was treated with tetracycline to eliminate *Wolbachia* infection (Aa23Tet) (Dobson, Marsland, Veneti, Bourtzis, & O'Neill, 2002).

2.2 | Cell viability assays

Viability of Aa23 cell line, *Wolbachia* or yeast was assessed using the BacLight live-dead staining kit (Molecular Probes, Carlsbad, CA). Ten microliters of cell suspension were stained according to the manufacturer suggested protocol and viewed in an epifluorescence NIKON microscope.

2.3 | Failed attempts to grow *Wolbachia* ex-vivo and a serendipitous finding

The original idea was to find a system where *Wolbachia* would grow ex-vivo. To do this, diverse protocols used for other endosymbionts such as *Sodalis* and *Coxiella* were followed (Dale & Maudlin, 1999; Omsland et al., 2009, 2013). It was found that some components did improve survival in isolated *Wolbachia*, even if we never observed substantial growth. Some of these agents were: (1) Trehalose and other compatible solutes such as mannitol, glycerol and sucrose, known to stabilize pollen (Crowe, Reid, & Crowe, 1996; Leslie, Israeli, Lighthart, Crowe, & Crowe, 1995) and isolated proteins (Sampedro & Uribe, 2004) (2) Actin, which supports binding and movements of some endosymbionts in vivo. (3) Catalase which deactivates hydrogen peroxide (Dale & Maudlin, 1999) and (4) Blood from large mammals, which has been used to grow *Sodalis* (Dale & Maudlin, 1999) and increases *Wolbachia* titers (Amuzu, Simmons, & McGraw, 2015; McMeniman, Hughes, & O'Neill, 2011). Human blood was also effective.

First, we tried growing *Wolbachia* using sheep blood. However, it was easily contaminated at the sites of extraction, so cultures

INFORME DE LABORES 2019

had to be discarded often. On one occasion we obtained positive *wsp* gene amplification from a yeast colony grown in one of the agar plates. Out of curiosity, we studied the host, which turned out to be *S. cerevisiae*. From this accidental finding we decided to test a known strain of *S. cerevisiae* as an alternative host. We learned that, in order to support growth of *Wolbachia*, yeast culture media needed to be supplemented with blood, which eventually was substituted with ammonium ferric citrate with excellent results and none of the contamination problems. Neither compatible solutes, nor catalase nor actin enhanced growth. The second addition needed was bovine fetal serum, which was present in all original growth media but not in yeast culture media. FBS was titrated and we ended up using 1%.

Among laboratory strains, infection was successful in W303 and NB40, while infection % in BY was milder (Figure 1). The *S. cerevisiae* strain W303-1A (MATα; ura3-1; trp1Δ 2; leu2-3,112; his3-11,15; ade2-1; can1-100) (Gutierrez-Aguilar et al., 2014), where *Wolbachia* was abundant at 10 days of infection was chosen for further experiments (See Results).

2.4 | *Wolbachia* wAlbB infection of the *Saccharomyces cerevisiae* W303 yeast strain (*wScW303*)

A first yeast infection was performed following a modified cell line infection protocol (Dobson et al., 2002). All procedures were performed under sterile conditions. The Aa23 cell line (containing *Wolbachia*) was grown in Corning cell culture flasks (225 cm^2) as described in (Shih et al., 1998). After 20 days of culture, cells were scrapped and concentrated by centrifugation at 3,000*g* for 5 min. For homogenization, ~$1*10^7$ cells were resuspended in 10 ml Eagles medium and vortexed for 10 min with (50% v/v) 3 mm sterile borosilicate glass beads (Rasgon, Gamston, & Ren, 2006). The homogenate was centrifuged at 3,000*g* for 10 min to remove unbroken cells. The supernatant was passed through a 2.7 μm syringe filter and the filtrate containing bacteria was centrifuged at 16,500*g* for 10 min. The pellet was resuspended in 2 ml of Mitsuhashi-Maramorosch medium (MM) supplemented with 1 mmol L^{-1} ammonium ferric citrate and 20% fetal bovine serum (FBS) (MM Fe FBS). In parallel, yeasts were

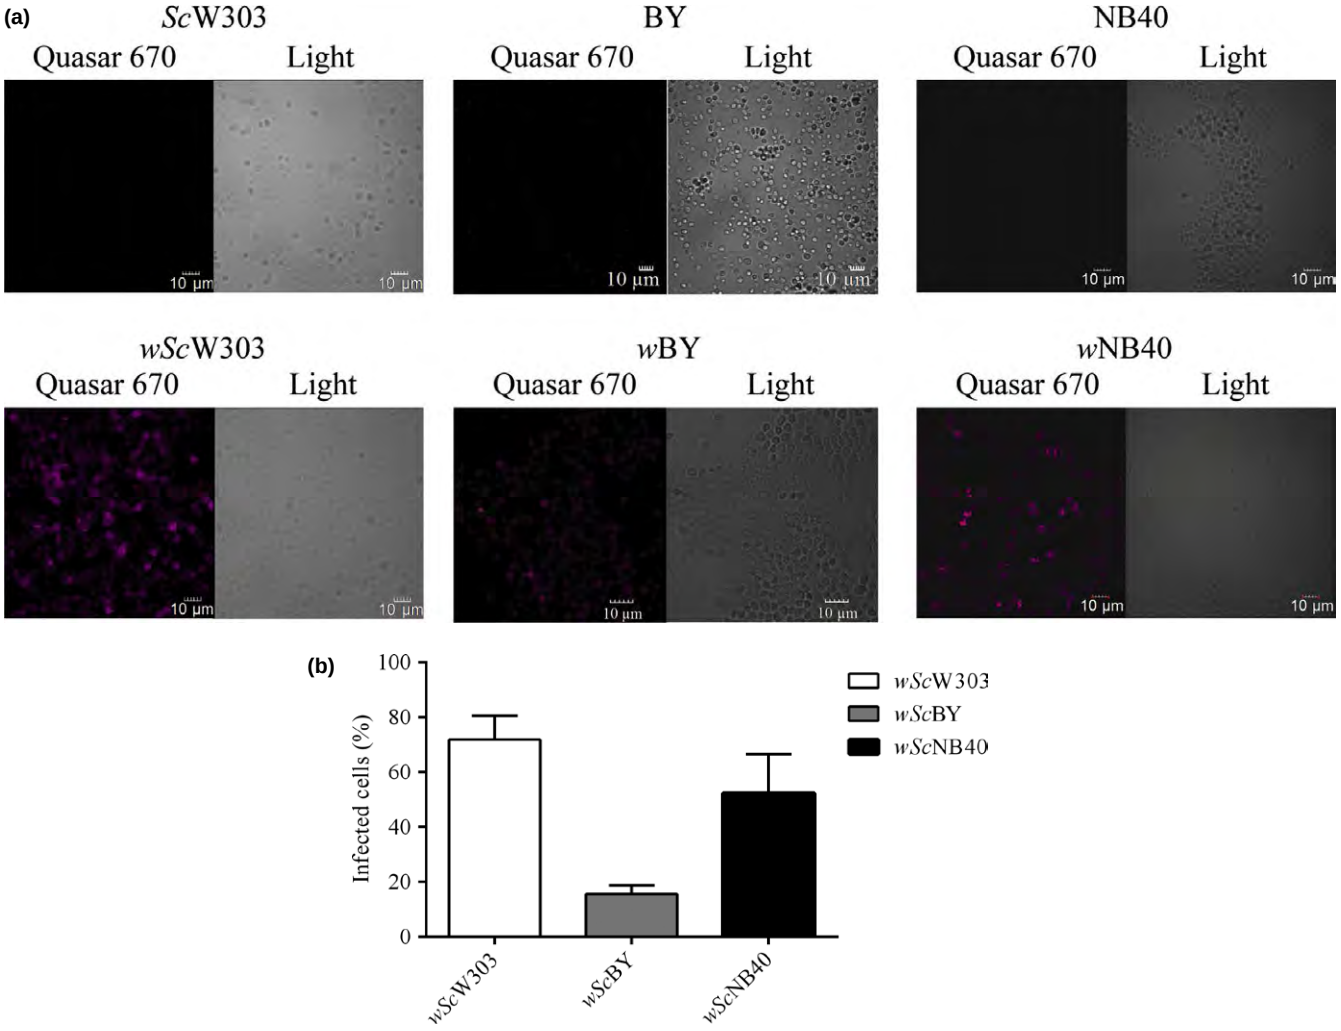

FIGURE 1 Infection of *Saccharomyces cerevisiae* with *Wolbachia*. (a) FISH using a *Wolbachia* 16S rDNA specific probe labeled with Quasar 670 (pink) was performed on 14 day old cultures of infected and control *S. cerevisiae strains* W303 (*Sc*W303), BY (*Sc*BY), and NB40 (*Sc*NB40) (b) After 14 days postinfection, the percentage of infected cells were counted as those with positive hybridization.

INFORME DE LABORES 2019

grown in a liquid YPD culture for 3 hr, harvested and centrifuged at 3,000*g* for 3 min. Culturing yeast in low oxygen environments prevents thickening of the cell wall (Aguilar-Uscanga & Francois, 2003; Smith et al., 2000; Avrahami-Moyal, Braun, & Engelberg, 2012). To induce contact between bacteria and yeast both bacteria (the whole 2 ml sample) and yeast (60 mg ww) were mixed and centrifuged at 2,500*g* for 1 hr at 20°C (Dobson et al., 2002). Bacteria-infected yeast were plated (all 2 ml) on a Petri dish containing MM supplemented with 1 mmol L^{-1} ammonium ferric citrate plus 25% v/v outdated human packaged erythrocytes and 2% agar (MM Fe-blood) and incubated at 27°C in a 5% CO_2 chamber (ESCO, Cell Culture CO_2 incubator, Singapore) for 14 days (Dale & Maudlin, 1999). Infection was confirmed by FISH and PCR. Infected yeast was transferred to a fresh agar plate every month for up to 6 months, then yeast was discarded and a new sample was used. Some aliquots were added with 40% glycerol, frozen and stored at −80°C, these samples have remained infective for nearly 10 months.

To transfer *Wolbachia* from yeast to yeast, slight modifications to the protocol were made: An aliquot of 100 µl of yeast taken from a glycerol-frozen sample or a loophole of infected yeast cells was diluted in 2 ml YPD Fe 20% FBS and plated in YPD Fe-blood agar plates, which were grown in 5% CO_2. After 14 days, all cells grown in a Petri dish were collected and washed by centrifugation at 3,000*g* for 3 min at 20°C with sterile water and the pellet was suspended in 10 ml MM. The suspension was vortexed for 10 min in the presence of 0.425–0.600 mm sterile borosilicate glass beads (60% v/v) to disrupt yeast cells (note that beads were smaller than those used for insect cell lines). Disrupted yeasts were centrifuged at 3,000*g* for 10 min and the supernatant was centrifuged again 3,000*g* for 10 min. The washed supernatant was filtered through different 0.8–0.65–0.45 µm syringe filters. Again, we used filters with smaller pores than those used for cell lines due to the small size of yeast cells. The last filtrate was centrifuged at 16,500*g* for 10 min. The pellet (~60 mg ww) was suspended in 2 ml MM Fe FBS and used to infect yeast from 3-h cultures as described above. The yeast–bacterium mixture was plated in a YPD Fe agar plate and incubated at 27°C with 5% CO_2 for at least 7 days. Infection was evaluated using FISH and PCR.

2.5 | Culture and maintenance of *w*AlbB-infected *Saccharomyces cerevisiae* W303

Infected *S. cerevisiae* strains were kept in YPD plus 1 mmol L^{-1} ammonium ferric citrate agar plates. When transferring to liquid medium, a loophole from the desired strain was suspended in 100 ml of sterile YPDS and incubated at 28°C, 130 rpm for 48 hr. Precultures were decanted in one liter YPDS and incubated at the same conditions for up to 14 days. When transferring from solid to solid media, a loophole of yeast was suspended in 1 ml YPD supplemented with 1 mmol L^{-1} ammonium ferric citrate plus 20% FBS and plated on YPD agar. A cell passage every 2–3 weeks was performed in order to maintain the infection. When it was desired to eliminate *Wolbachia* from yeast, tetracycline 30 µg/ml was added five consecutive times to the medium as passages were performed (Dobson et al., 2002).

2.6 | *Wolbachia* wAlbB infection of the C6C36 *Aedes albopictus* cell line

To determine whether *Wolbachia* cells retained its infective ability after all treatments, *Wolbachia* were isolated from *S. cerevisiae* grown in liquid YPD Fe 1% FBS and they were tested for infection against a C6C36 insect cell line.

2.7 | *Wolbachia* surface protein (*wsp*) gene PCR identification

The *Wolbachia wsp* gene was amplified using the following primers: *wsp* 81F (5′ TGGTCCAATAAGTGATGAAGAAAC 3′) and *wsp* 691R (5′ AAAAATTAAACGCTACTCCA 3′) (Braig, Zhou, Dobson, & O'Neill, 1998) in a 25 µl reaction volume using recombinant Taq DNA polymerase (Thermo Fisher Scientific). PCR amplification was performed as reported elsewhere (Braig et al., 1998; Xi, Khoo, & Dobson, 2006). The PCR product was electrophoresed on a 1% agarose gel and stained with ethidium bromide. PCR product was purified using a GeneJET PCR purification Kit (Thermo Fisher Scientific) and sequenced in the Molecular Biology Unit at the Institute of Cellular Physiology, UNAM.

2.8 | Fluorescence in-situ hybridization (FISH)

Wolbachia 16S rDNA oligonucleotide probe labeled with Quasar 670 dye (λ_{em}647, λ_{ex}670) W1, 5′-AATCCGGCCGARCCGACCC-3′ was used for FISH assays (Heddi, Grenier, Khatchadourian, Charles, & Nardon, 1999). One milliliter of the desired culture was centrifuged at 3,000*g* for Aa23, C6C36 and yeast, and 18,500*g* for purified *Wolbachia* for 5 min. Protocol was followed as reported elsewhere (Genty, Bouchon, Raimond, & Bertaux, 2014). Samples were viewed in a FluoView FV-1,000 Olympus confocal microscope, NA 1.4 with a 100X objective. Images were analyzed with the FV-Viewer Olympus software.

2.9 | Z-cut images for cell reconstruction

Fourteen day old infected and noninfected yeast samples were visualized with a Olympus-FV1000 or FV-3000 microscopes. Z-cut images were reconstructed using Imaris 7.2.1 and Image J software. Calcofluor-white (0.05 mmol L^{-1} in 20% DMSO-20 mmol L^{-1} Bicine Buffer) was used to stain fungus cell wall.

2.10 | Antibodies

Primary antibodies: Mouse monoclonal Anti-*Wolbachia* Surface Protein NR-31029 was from BEI Resources, NIAID, NIH. Mouse monoclonal Anti-VDAC was from Abcam. Secondary antibody: HRP

INFORME DE LABORES 2019

coupled Anti-mouse antibody from Jackson ImmunoResearch (West Grove, PA).

2.11 | Western blot

A loophole from yeast grown in solid media was suspended in 200 µl of water; otherwise, 200 µl from liquid culture samples were centrifuged at 3,000*g* for 5 min and washed twice in water. The pellet was solubilized in 200 µl RIPA buffer (25 mmol L^{-1} Tris•HCl pH 7.6, 150 mmol L^{-1} NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS) supplemented with protease inhibitors 1 mmol L^{-1} PMSF (Sigma-Aldrich) and Complete protease inhibitor cocktail (Roche-CO-RO) as recommended by the abcam protocol. Samples were lysed in a Sonics VibraCell sonicator (Sonics & materials, Inc., Newtown, CT) at 80% amplitude for 10 s and left under agitation in a Multi-Vortex V-32 (Biosan, Riga, Latvia) for 30 min at 4°C. Samples were centrifuged at 15,160*g* for 5 min. The supernatant was recovered and protein concentration was measured by Bradford in a PolarStar Omega (BMG labtech, Ortenberg, Germany) [(Bradford, 1976) #64]. Samples were diluted in a 4X buffer (500 mmol L^{-1} Tris, pH 6.8, 10% glycerol, 10% SDS, 0.05% beta-mercapto-ethanol, and 0.01% bromophenol blue) and boiled for 5 min. SDS/PAGE was performed in 10% polyacrylamide gels and electrotransferred to poly(vinylidenedifluoride) membranes as reported elsewhere (Chiquete-Felix et al., 2009). Membranes were blocked with 5% Blotto nonfat dry milk in TBS-T (50 mmol L^{-1} Tris, 104 mmol L^{-1} NaCl, pH 7.6, 0.1% Tween 20) for 1 hr, and incubated overnight at 4°C with the primary antibody. Membranes were washed with TBS-T and incubated at 37°C for 1 hr with secondary antibody. Membranes were washed again and the bands were developed by chemiluminescence using an ECL kit (Amersham Biosciences, GE, Healthcare) (Chiquete-Felix et al., 2009). PVDF membranes were stripped as indicated by abcam protocol using a mild-stripping buffer, blocked with 5% Blotto nonfat dry milk in TBS-T and reprobed with a different antibody as indicated.

2.12 | Transmission electron microscopy of *wSc*W303

Infection was assessed by transmission electron microscopy (TEM) following a protocol from (Sun et al., 2015). Briefly, 500 µl of cells were harvested from 100 ml cultures of infected and uninfected *Saccharomyces cerevisiae* cultures form the first unintentional infection (*wSc*) at 10 days and *wSc*W303 of fourteen days. Yeast and *Wolbachia* samples were washed twice in distilled water at 740 g for 5 min for yeast and 23400 g for 10 min for bacteria in an Eppendorff Centrifuge 5415C. Samples were fixed in 2% $KMnO_4$ at 4°C overnight. Next day, samples were washed for 15 min with deionized water six times and dehydrated with sequential 10-minute washes with 50%, 70%, 80%, 90% ethanol and three washes with 100% ethanol. Samples were washed with ethanol-propanone (1: 1) for 8 min, then with anhydrous propanone for 5 min, then with propanone-EPON 821 (3: 1) for 1 hr and left in propanone-EPON 821 (1 : 3) overnight. Next day, samples were concentrated and resuspended in propanone-EPON 821 (1: 1) for 1 hr. Then, samples were concentrated again and left in resin for 24 hr. Then they were incubated for 12 hr at 37°C and then further incubated for 36 hr at 60°C. Resins were cut into 70 nm slices on an ultra-microtome (Ultracut Reicheit-jung) and observed in a JEOL JEM-1200 EXII electron microscope. Data were processed using Gatan Digital Micrograph Software.

2.13 | Mitochondrial (or Mitochondria/*Wolbachia* mixture) isolation

Yeast were centrifuged at 3,000*g* for 5 min, washed twice in water and resuspended in MES-mannitol buffer (5 mmol L^{-1} MES, 0.6 mol L^{-1} mannitol, 0.1% BSA pH 6.8 adjusted with triethanolamine). Yeast were disrupted using a Bead Beater cell homogenizer (Biospec Products, OK, USA, final volume 50 ml) with 0.425–0.6 mm glass beads during three 20 s pulses separated by 40 s resting periods in ice (Uribe, Rangel, Espínola, & Aguirre, 1990). The homogenate was differentially centrifuged to isolate mitochondria similar to described in (Peña, Piña, Escamilla, & Piña, 1977). Briefly, cells were centrifuged at 1,100*g* for 5 min. The supernatant was centrifuged at 9,798*g* for 10 min and the pellet was resuspended in MES-mannitol buffer and centrifuged at 3,000*g* for 5 min. Finally, the supernatant was centrifuged at 17,500*g* for 10 min. The resulting pellet was resuspended in minimal volume and protein concentration was measured by Biuret (Gornal, 1957) using a Beckman Coulter spectrophotometer at 540 nm.

2.14 | Oxymetry

Mitochondrial high resolution respirometry was assessed in an Oroboros oxygraph (Oroboros Intrs Corp, Innsbruck, Austria) using 5 mmol L^{-1} MES, 0.6 mol L^{-1} mannitol pH 6.8, 10 mmol L^{-1} KCl and 4 mmol L^{-1} Pi at 30°C. Final volume in the closed chamber was 1.5 ml with a protein concentration of 0.5 mg prot/ml. Bacterial protein concentration of 0.5 mg prot/ml was used. The trace was started by the addition of 5 mmol L^{-1} of the indicated substrate: glycerol-3-phosphate, ethanol, NADH, pyruvate-malate, succinate, glutamine or glutamate. For Complex IV evaluation, 5 mmol L^{-1} ascorbate (pH 7.6)- 0.05 mmol L^{-1} TMPD was used (Uribe, Ramirez, & Peña, 1985). Respiratory control was measured using 0.5 µl/ml ethanol to induce state II respiration and 1 mmol L^{-1} ADP to induce the phosphorylated state (Uribe et al., 1985). Respiratory chain inhibitors were used in the following concentrations: 0.1 µmol L^{-1} rotenone, 0.15 mmol L^{-1} flavone, 0.1 µmol L^{-1} antimycin A, and 2 mmol L^{-1} cyanide (Uribe et al., 1985).0.5 µmol L^{-1} CCCP was added as an uncoupler. Data were analyzed using the Oroboros Lab software.

2.15 | Electrophoretic techniques and in-gel activities

Blue native gel electrophoresis (BN-PAGE) and high-resolution clear native electrophoresis (hrCN-PAGE) were performed as in (Wittig,

INFORME DE LABORES 2019

Braun, & Schägger,2006; Wittig, Karas, & Schägger, 2007). Whole cells were solubilized with 2 mg dodecylmaltoside/mg protein plus 1 mmol L^{-1} PMSF and Complete protease inhibitor cocktail (Roche-CO-RO) and shaken for 30 min at 4°C. Membranes were centrifuged at 23,680*g* at 4°C for 1 hr. Protein concentration in the supernatants was determined by Bradford (1976). Between 0.1 and 0.15 mg of protein were loaded in 5%–15% polyacrylamide gradient gels. When hr-CN PAGE electrophoresis was performed 0.01% Lauryl maltoside and 0.05% sodium deoxycholate were added to the cathode buffer [(Wittig et al., 2007) #69]. Gels were run for about an hour at 15 mA/gel in a Bio-rad electrophoresis chamber. In-gel NADH-NBT oxido-reductase (100 μg protein), succinate-NBT oxido-reductase (150 μg protein), cytochrome *c* oxidase (100 μg protein), and in-gel ATPase (100 μg protein) activities were done as reported previously (Uribe-Alvarez et al., 2016). 20 μg protein of solubilized Bovine Heart Mitochondria (BHM) were loaded in each gel as controls.

2.16 | LC-MALDI-MS/MS

Indicated bands from hr-CN PAGE or BN-PAGE were enzymatically digested, separated on a HPLC EkspertnanoLC 425 (Eksigent, Redwood City CA) and analyzed in a MALDI-TOF/TOF 4800 Plus mass spectrometer (ABSciex, Framingham MA) (Shevchenko, Tomas, Havli, Olsen, & Mann, 2006) in the Unidad de Genómica, Proteómica y Metabolómica, CINVESTAV-IPN. Generated MS/MS spectra were compared using Protein Pilot software v. 4.0 (ABSciex, Framingham MA) against the *Saccharomyces cerevisiae* ATCC 204508 database (downloaded of Uniprot, 6721 protein sequences) and *Wolbachia* genus database (downloaded of Uniprot, 47781 protein sequences) using Paragon algorithm.

3 | RESULTS

3.1 | At the expense of its own viability, the artificial host *Saccharomyces cerevisiae* W303 supports growth of *Wolbachia* wAlbB

To study *Wolbachia* (wAlbB) large biomass yields plus a host that is easy to manipulate are needed. After testing different alternatives (see Methods), it was discovered that different *S. cerevisiae* strains were susceptible to infection and supported active *Wolbachia* proliferation. At 14 days of infection, *Wolbachia* grew efficiently in *S. cerevisiae* strains W303 (*Sc*W303) and NB40 (*Sc*NB40), while strain BY (*Sc*BY) supported only a weak infection (Figure 1a). After 14 days the percentage of infected cells counted by FISH using probes against the *Wolbachia* 16S rDNA was 71.8% ± 8.7% for *Sc*W303 and 52.3% ± 14.3% for *Sc*NB40, while in *Sc*BY less than 20% cells were positive for FISH (Figure 1b). Strain *Sc*W303 was chosen for further studies. *Sc*W303 maintains high rate of oxidative phosphorylation regardless of the carbon source, it is highly resistant to oxidative stress (Ocampo, Liu, Schroeder, Shadel, & Barrientos, 2012) and it has a weak cell wall (Avrahami-Moyal et al., 2012). Strains used in this study are detailed in Table S1.

3.2 | Proliferation of *Wolbachia* in *Sc*W303 was further confirmed using different independent methods as follows (Figure 2)

3.2.1 | PCR of the *Wolbachia* outer surface protein gene (*wsp*)

Both the Aa23 cell line (Figure 2a) and infected *S. cerevisiae* (*wSc*W303) (Figure 2b) amplified 650 bp fragments exhibiting sequences 100% identical to the surface protein of the *Wolbachia* endosymbiont of *Aedes albopictus* (NCBI database: KC242223.1) (Table S2). PCR amplification bands were not observed in the tetracycline-treated Aa23 cell line (Figure 2a, Aa23 Tet) and in the noninfected yeast (Figure 2b, *Sc*W303). Tetracycline used continuously in cell cultures is reported to kill *Wolbachia* (Dobson et al., 2002).

3.2.2 | Western Blot analysis detected *Wolbachia* wsp in *S. cerevisiae*

In the Aa23 cell line, a ~37 kDa protein corresponding to the *Wolbachia* Surface protein (wsp) was revealed with anti wsp antibodies (Bei resources, NIH, MD) (Figure 2c, Aa23). This band disappeared after growth in the presence of tetracycline (Aa23 Tet). VDAC (Voltage dependent anionic channel) protein was used as a loading control. In non–infected yeast wsp was not detected, (Figure 2c, *Sc*W303), while in infected yeast the wsp western blot signal was first detected at day 3 and increased gradually up to day 10, remaining stable until day 14 (Figure 2c, *wSc*W303). (For images of original Western Blots, see Figure S1a). When tetracycline was added to the medium, the wsp signal decreased, disappearing by day 10 (Figure S1b, *wSc*W303Tet).

3.2.3 | Normal growth and early death were observed in infected *S. cerevisiae*

During the first 12 days of culture, growth curves of infected *wSc*W303 were similar to the controls (Figure 3a). Then, beginning at day 14, *wSc*W303 absorbance decreased. Cell wall degradation (Figure S2) and viability staining (Figure 3b) confirmed that *wSc*W303 viability was rapidly lost during the late stages of the stationary phase, from 14 to 18 days of culture.

In addition, during growth the transcriptional activity of both *S. cerevisiae* 18S rRNA and the *Wolbachia wsp* were tested. Transcription was high in *S. cerevisiae* from the first day, decreased at day fourteen and became negligible at days 16 and 18 (Figure 3c). In contrast, transcription of the *wsp* from *Wolbachia* became detectable only after 3 days, increased exponentially until day 10 and remained constant until day 14. Then, at days 16 and 18, transcription decreased abruptly (Figure 3c). Transcription data in the *Wolbachia/S. cerevisiae* system indicated that *Wolbachia* activity grew later than *S. cerevisiae*, reaching a maximum at 10 days. Later, beginning at 14 days both transcription activities decreased abruptly in parallel with the death of the host.

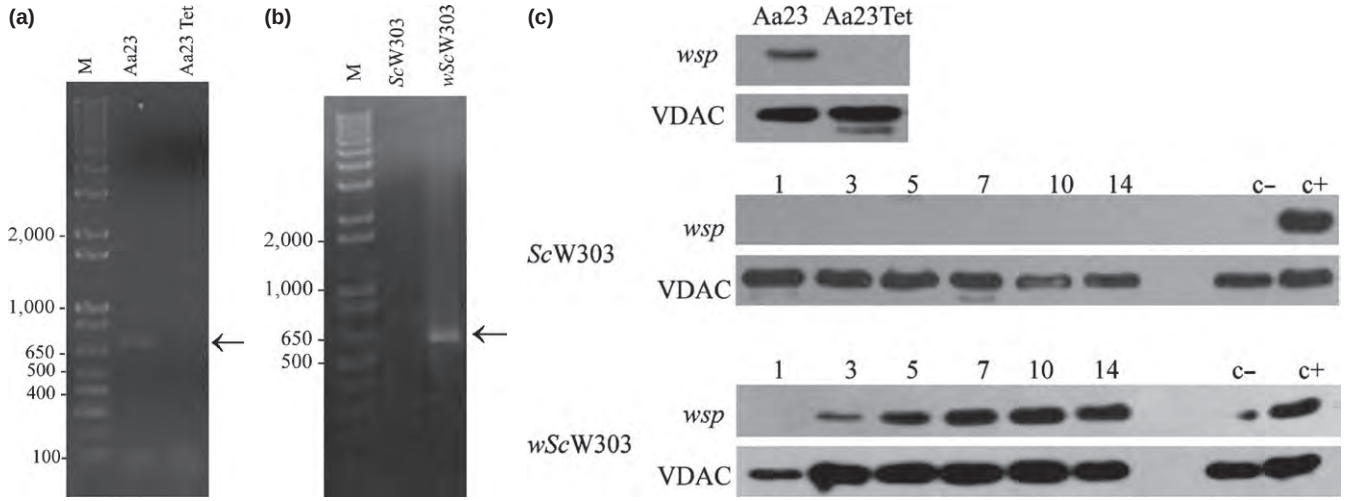

FIGURE 2 Detection of *Wolbachia* in *Saccharomyces cerevisiae* W303. (a) Agarose gel electrophoresis of the *wsp* PCR products predicted as a ~600 bp band in the Aa23 cell line. Lanes: M, Invitrogen 1 kb plus DNA ladder; Aa23, infected cell line; Aa23 Tet, noninfected cell line. (b) Agarose gel electrophoresis of the *wsp* PCR products for *S. cerevisiae*. Lanes: M, Invitrogen 1 kb plus DNA ladder; *Sc*W303, uninfected original yeast; *wSc*W303, infected yeast. (c) Western blot against the wsp and VDAC proteins. First row, first lane Aa23 infected cell line and second lane Aa23Δw tetracycline-cured cell line. Yeast samples were taken at 1, 3, 5, 7, 10, and 14 days postinfection. A positive control was taken from a 20 day YPD-2% agar culture infected-*wSc*W303. Negative control was a noninfected sample *Sc*W303

3.2.4 | Yeast cell/endosymbiont images were observed by staining *S. cerevisiae* with Calcofluor white and *w*AlbB with Quasar 670

Both the western blot and the RT-PCR experiments suggested that *Wolbachia* grew in the presence of *S. cerevisiae* becoming abundant at days 10–14. In order to determine whether *Wolbachia* was inside yeast, samples from infected and noninfected yeast cells from 14-day old cultures were hybridized using a *Wolbachia* specific 16S rDNA probe labeled with Quasar-670 (FISH). Then, the yeast cell wall was stained with Calcofluor white (Figure 4, Movie S1, Movie S2), Staining of the *S. cerevisiae* cell wall allowed observation of labeled bacteria inside yeast. Figure 4 shows that the Quasar-670 label was detectable only in *wSc*W303 and not in *Sc*W303. Merge of the Calcofluor, Quasar-670 and Clear field (Light) images show bacteria are inside the cell (Figure 4). Tridimensional reconstructions of z-cuts performed in a *wSc*W303 sample show the intracellular location of different bacteria (movies S1 and S2). In the periphery of movies S1 and S2, few independent bacterial labels were detected, which we speculate, may come from bacteria inside heavily deteriorated host cells whose cell wall was not stained by Calcofluor (movies S1 and S2).

3.2.5 | TEM images detected *Wolbachia* inside *S. cerevisiae*

Transmission electron microscopy images further suggested the intracellular location of *Wolbachia*. Cultures of 10 and 14 days of control and infected *S. cerevisiae* were analyzed. In infected yeast cells (Figure 5b–f, g), bacteria-like bodies (Figure 5, labeled *) that are not present in the uninfected yeast (Figure 5a and d) can be observed. At 10 days both infected and noninfected yeast present mitochondria, which can be identified by the presence of inner membrane cristae (Figure 5, labeled m). In contrast 14 day-old cultures of *Sc*W303 lost most mitochondrial structures, which suggest that these organelles are dysfunctional probably because cells are in late stationary phase. In contrast, 14 days-old infected *wSc*W303 show *Wolbachia* plus mitochondria where the typical cristae pattern may be observed, suggesting abnormal preservation of mitochondria in infected yeast (Figure 5e–g). In *wSc*W303 cultures, we can observe different cell images: most cells had an intact plasma membrane and contained mitochondria and bacteria-like bodies inside (Figure 5e). Other cells exhibited damaged membranes but the bacteria like structures were still present (Figure 5f). Among the whole population, we found some budding yeast, where bacteria-like bodies can be seem concentrated in the bud (Figure 5g). None of the latter populations was found in control *Sc*W303 cultures.

3.2.6 | *Wolbachia*-infected yeast retained high mitochondrial oxidative phosphorylation activity for abnormally long periods

A possible mechanism for the early death of infected yeast was explored in our infected *Sc*W303/*w*AlbB system. This system exhibited an abnormal preservation of mitochondria (Figure 5), so it was logical to explore aerobic metabolic activity. The relationship between *Wolbachia* and aerobic metabolism in the host is a matter of controversy. Some authors have proposed that these endo-cellular organisms possess an aerobic metabolism that contributes to overall activity (Strübing et al., 2010) while others suggest that *Wolbachia* optimizes aerobic metabolism by supplying heme groups for respiratory complexes (Darby et al., 2012; Fallon, Baldridge, Carroll, &

INFORME DE LABORES 2019

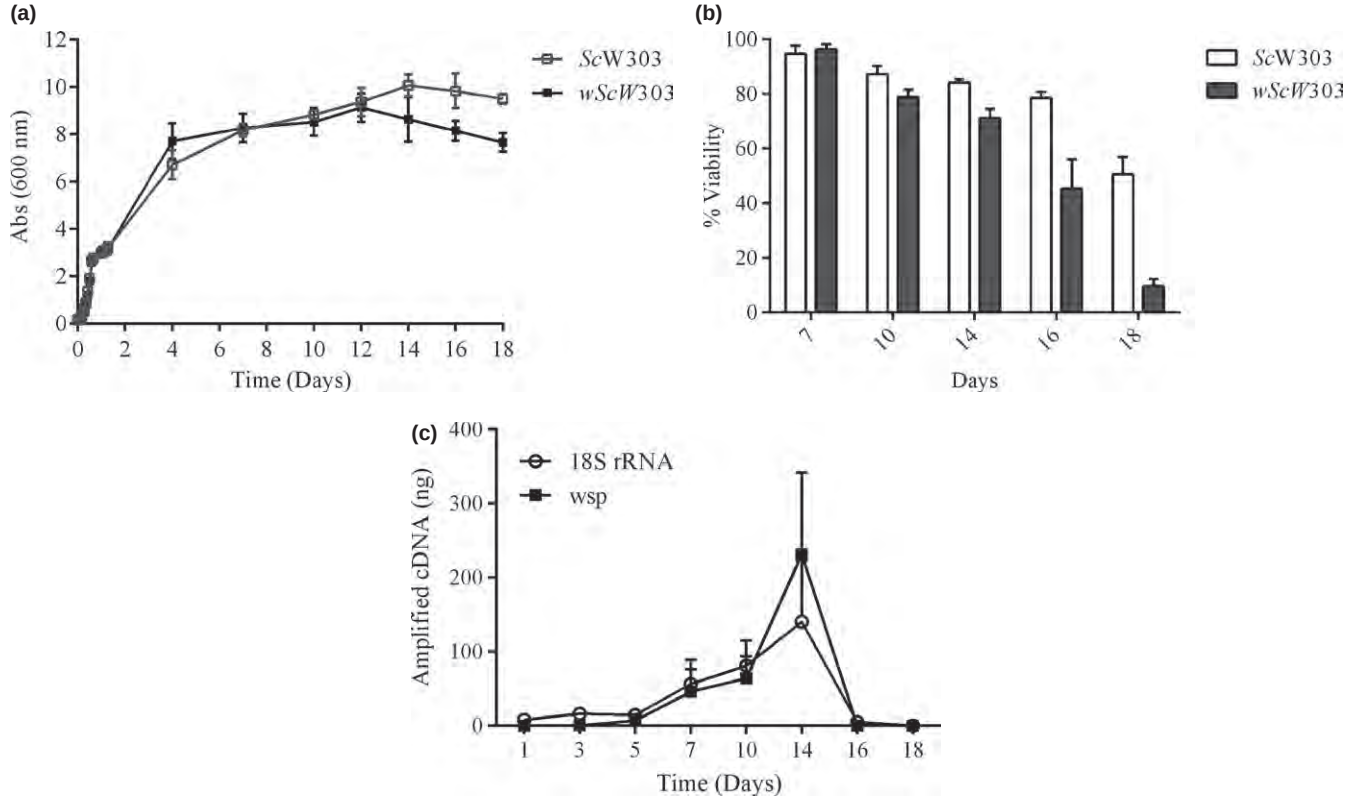

FIGURE 3 *S. cerevisiae* growth, viability, and transcriptional activity in the absence and presence of *Wolbachia*. (a) Growth curves of *Sc*W303 and *wSc*W303 grown in YPDS at 30°C, 130 rpm for 18 days. (b) Yeast cell viability in different days of culture quantified by microscopy with the BacLight viability kit. (c) Amplification of the *wsp* gene of *Wolbachia* and the 18S rRNA gene of *S. cerevisiae* of samples taken at different days of culture

Kurtz, 2014; Foster et al., 2005; Heddi et al., 1999; Strübing et al., 2010). Thus, we decided to evaluate oxidative phosphorylation activities in our system, which preserved mitochondrial structure beyond the stationary phase (Figure 5).

When isolation of *Wolbachia* was attempted, it was found that the bacterium and mitochondria migrated together (Baldridge et al., 2014; Uribe et al., 1985). Thus, it was decided to characterize oxidative phosphorylation activity in the mitochondria/*Wolbachia* mixture and then determine the contribution of each entity using different bioenergetics techniques. The rate of oxygen consumption was measured using ethanol as a substrate (Table 1). We isolated the mitochondria/*Wolbachia* fraction from either one-day cultures

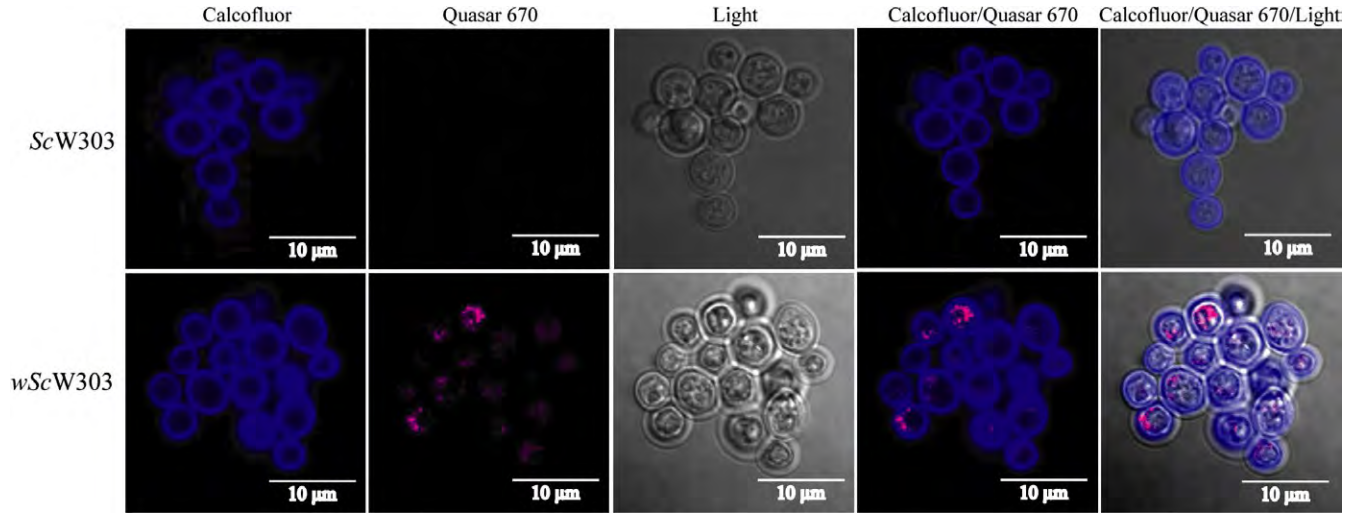

FIGURE 4 *Wolbachia* in calcofluor-labeled *S. cerevisiae*. Infected (*wSc*W303) and noninfected (*Sc*W303) *S. cerevisiae* cells were hybridized with the 16S rDNA *Wolbachia* probe (Quasar 670, pink). Then, the yeast cell wall was stained with calcofluor-white (Calcofluor, blue) to confirm the endosymbiosis. Merge images are shown to evaluate the presence of *Wolbachia* inside yeast

INFORME DE LABORES 2019

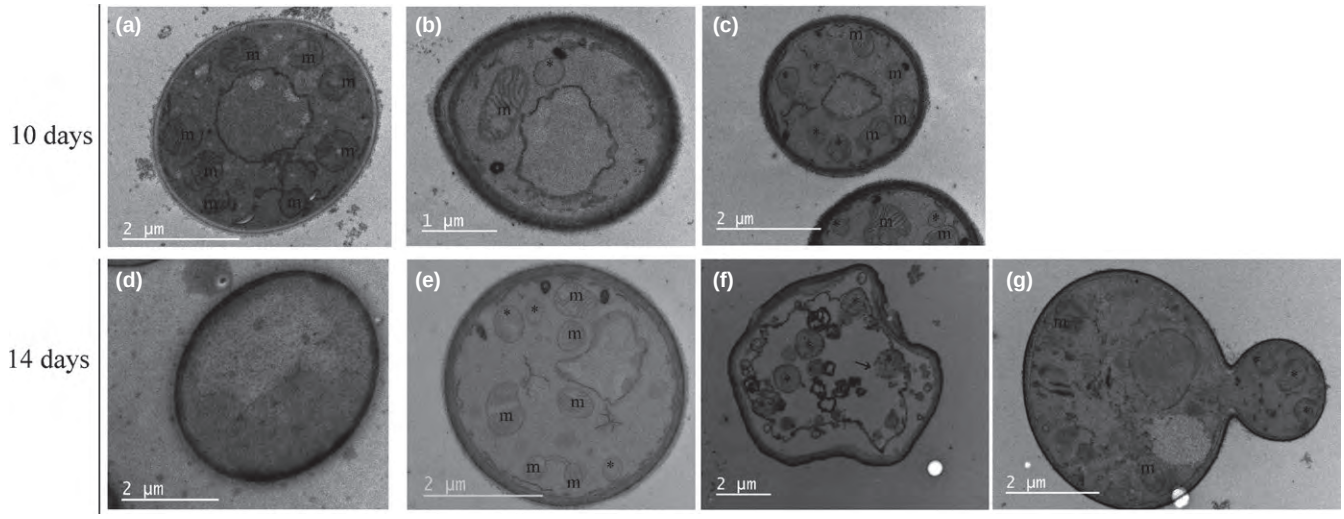

FIGURE 5 Electron microscopy images of infected and noninfected *Saccharomyces cerevisiae* at different times of incubation. Transmission electron microscopy images confirm the intracellular location of *Wolbachia*. 10-day images were taken with uninfected (a) *Sc* and infected (b–c) *wSc*; 14 day-old images were taken with (d) *Sc*W303 and (e–g) *wSc*W303. Images show the presence of bacteria-like bodies (*) that are not present in uninfected yeast and mitochondria (m) whose cristae can be easily identified

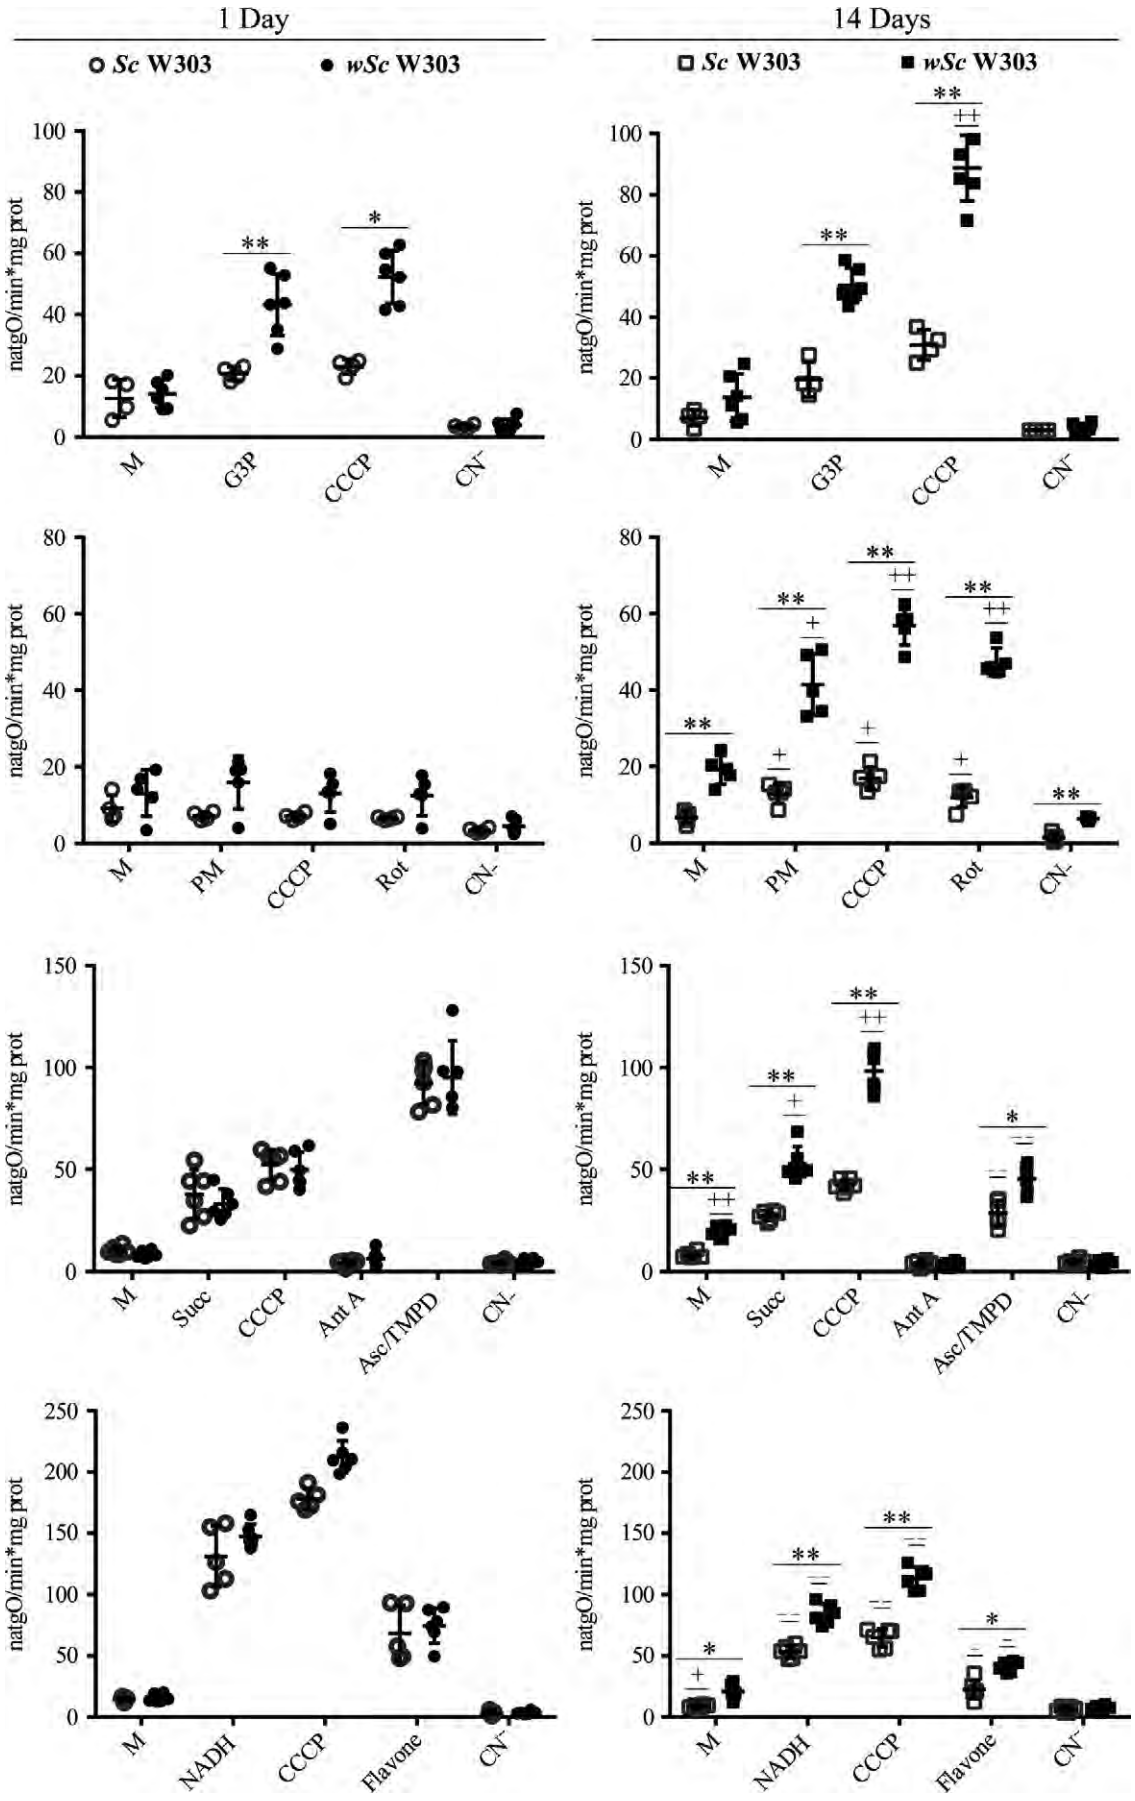
TABLE 1 Oxygen consumption rates of mitochondrial fractions from 1 and 14 day-old cultures of *Wolbachia*-infected (*wSc*W303) and noninfected (*Sc*W303) *Saccharomyces cerevisiae* cells

	State IV (natgO/min*mg prot)	State III (natgO/min*mg prot)	RCIII/IV
1 Day *Sc*W303	25.2 ± 3.1	52.5 ± 6.8	2.1 ± 0.15
1 Day *wSc*W303	27.4 ± 4.6	65.4 ± 9.0	2.4 ± 0.2
14 Days *Sc*W303	22.6 ± 5.1	29.0 ± 6.3	1.3 ± 0.2
14 Days *wSc*W303	34.2 ± 5.1	73.3 ± 11.1	2.1 ± 0.1



Reaction mixture: 0.6 mol L^{-1} mannitol, 5 mmol L^{-1} MES, pH 6.8, 4 mmol L^{-1} Pi, 10 mmol L^{-1} KCl. As substrate, 5 mmol L^{-1} ethanol. For state III, 1 mmol L^{-1} ADP.

where there are very few *Wolbachia* cells or from 14-day cultures, where *Wolbachia* numbers were high (Table 1). In one-day cultures from *Sc*W303 and *wSc*W303 respiratory activities were very similar. However, at 14 days the rates of oxygen consumption and respiratory controls (RC) were widely different as follows: In noninfected yeast, both the rate of oxygen consumption and respiratory control decreased at the expense of state 3 inhibition, while in contrast, *wSc*W303 retained high rates of oxygen consumption plus high respiratory controls, i.e. in 14-day old *Wolbachia*-infected yeast exhibited high oxidative phosphorylation activity, consistent with the presence of mitochondria observed by TEM in the infected cells (Table 1).

3.2.7 | In the presence of *Wolbachia* the activity of different mitochondrial respiratory complexes was preserved

In the isolated mitochondria/*Wolbachia* mixture, we tested specific substrates for each respiratory chain complex/enzyme (Table S3). In one-day cultures the rates of oxygen consumption were similar in infected and noninfected *S. cerevisiae* (Figure 6). In aged mitochondria from noninfected yeast, external NADH dehydrogenase (NDH2e, Pyruvate-Malate), succinate dehydrogenase (Succinate) and Complex IV (Ascorbate-TMPD) activities were strongly diminished. In contrast, in the 14 day-old mitochondrial fractions from *Wolbachia*-infected cells, respiratory activities in the presence of glycerol-3-phosphate, pyruvate-malate, and succinate were increased in comparison to 1-day cultures. Since *S. cerevisiae* does not have complex I and pyruvate-malate dependent respiration was insensitive to rotenone, redox activity was most likely from the mitochondrial NDH2 and not a bacterial complex I. Succinate oxidation was completely inhibited by antimycin A, indicating the absence of an alternative oxidase. Complex IV and NADH-dependent oxygen consumption rates were still decreased as compared to mitochondria from one-day cultures (Figure 6). Other respiratory substrates, namely glutamate and glutamine, which are used by Rickettsia (Winkler & Turco, 1988) where assayed and they did not support oxygen consumption. The respiratory activities measured indicate that the mitochondria/*Wolbachia* fractions from the infected and noninfected yeast consume the same substrates and are inhibited by the same respiratory chain inhibitors.

INFORME DE LABORES 2019

INFORME DE LABORES 2019

FIGURE 6 *Wolbachia*–mediated effects on the oxygen consumption activity of isolated yeast mitochondria. High-resolution respirometry. 1 day-old cultures of noninfected (1 Day *Sc*W303) and infected (1 Day *wSc*W303) yeast and 14 day-old cultures of noninfected (14 Days *Sc*W303) and infected (14 Days *wSc*W303) yeast. 5 mmol L^{-1} from each substrate was added as indicated: glycerol-3-phosphate (G3P), NADH, pyruvate-malate (Pyr-Mal), succinate (Succ), and ascorbate-TMPD (Asc/TMPD). Where indicated, 0.5 µmol L^{-1} CCCP, 0.1 µmol L^{-1} rotenone (Rot), 0.1 µmol L^{-1} antimycin A (Ant A), 1 mmol L^{-1} cyanide (CN-), and 0.15 mmol L^{-1} flavone. 0.5 mg prot/ml of mitochondria (M) were added. Data represent mean ± SEM. T test $^{*}p < .005$, $^{**}p < .001$ for *Sc*W303 versus *wSc*W303 yeast on the same day. *T* test $^{-/+}p < .05$ $^{--/++}p < .001$ ($^{-}$, decrease; $^{+}$, increase) for *Sc*W303 in day one versus day 14 cultures or *wSc*W303 in day one versus day 14 cultures

3.2.8 | Under the experimental conditions tested, infected *wSc*W303 oxygen consumption activity was mitochondrial

The experiments above suggested that either *Wolbachia* has the exact same electron transport chain as mitochondria or *Wolbachia* respiratory proteins may be damaged when the mitochondria/*Wolbachia* fraction is isolated and exposed to oxygen.

To explore this possibility further, we measured in-gel activities in the mitochondria/bacterium fraction. As eukaryote and prokaryote respiratory complexes I, II, III, and IV have different molecular masses the contribution from each organism to a given activity would be easily detected by native gel electrophoresis. The in-gel activities for each complex from infected and noninfected yeast from 1 and 14 day-old cultures were analyzed and, in all cases, activities were detected only at MWs corresponding to the mitochondrial enzymes (Table S3, Figure 7) suggesting that in the artificial *Sc*W303/*w*AlbB system and under the specific conditions of growth reported here, *Wolbachia* did not express any functional respiratory chain proteins. The above results suggest that mitochondria were responsible for all the observed oxygen consumption activity. Still, one NADH dehydrogenase (Table S4) was weakly expressed making it impossible to conclude on whether different *Wolbachia* strains may be aerobic or not.

3.2.9 | F_1F_0-ATPase subunits from *Wolbachia* were detected in *wSc*W303

In the in gel ATPase activity from the mitochondria/*Wolbachia* isolate no differential bands were observed. This was expected as the proposed MWs are similar for of both ATPases: 543 kDa for the eukaryote *S. cerevisiae* and 530 kDa for prokaryotes *Escherichia coli* and *Paracoccus denitrificans* (Bakhtiari, Lai-Zhang, Yao, & Mueller, 1999; Jonckheere, Smeitink, & Rodenburg, 2012; Morales-Rios, Montgomery, Leslie, & Walker, 2015; Robinson et al., 2013; Schagger, 2002). However, the ATPase activity band (Figure 7A1, Table S4) sequence exhibited a mixture of yeast and *Wolbachia* ATPase proteins. BN and hrCN-PAGE results indicate that if *Wolbachia* expresses any electron transport chain proteins (still a possibility), under our experimental conditions their concentration was negligible when compared to the mitochondrial proteins and to its own F_1F_0-ATPase.

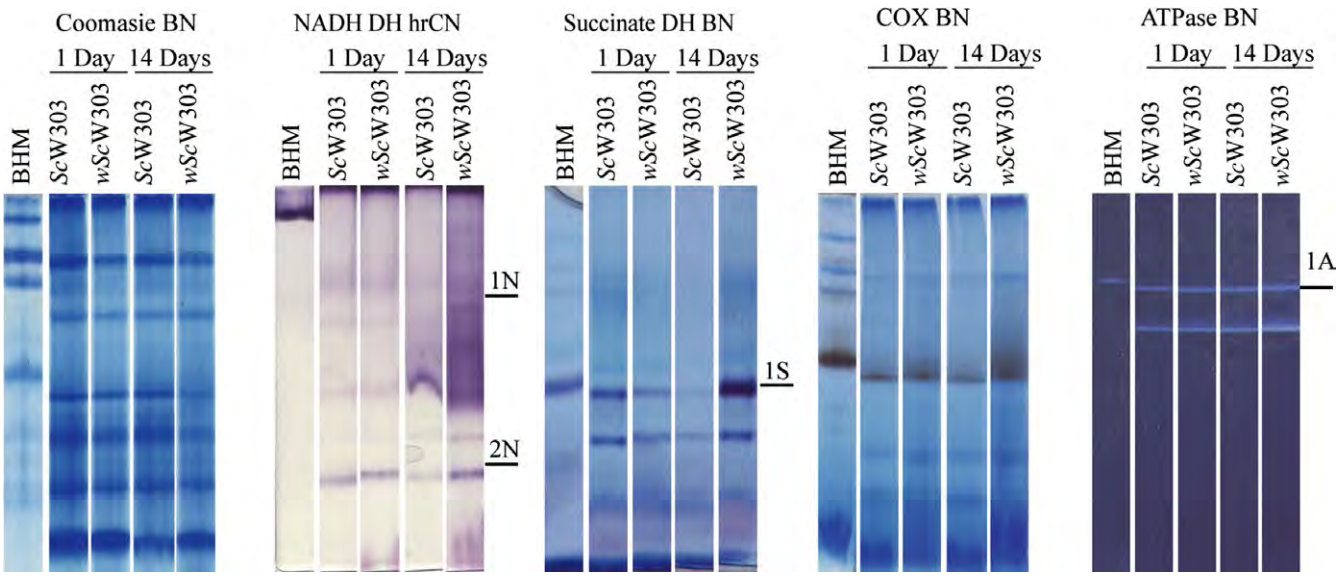


FIGURE 7 *Wolbachia*–mediated effects on the activity of each mitochondrial respiratory complex. BN-PAGE Coomassie-stained gel of *Sc*W303 and *wSc*W303 cells harvested at one and 14 days. In gel NADH-NBT oxido-reductase, succinate dehydrogenase, cytochrome *c* oxidase and ATPase enzyme activities in hrCN-PAGE or BN-PAGE, from 14 day old culture of *wSc*W303. Bands 1N, 2N, 1S, and 1A were sequenced (Table S4). Bovine heart mitochondria (BHM) were used as a control

INFORME DE LABORES 2019

3.2.10 | *Wolbachia* remains infective against insect cell lines

After being cultured in a yeast cell, the question arose on whether *Wolbachia* remained viable and infective when isolated. To test this, we extracted *Wolbachia* from *wSc*W303, incubated it in isolation for 5 days and then infected a C6C36 insect cell line which was previously reported to support bacterial infection (Baldridge et al., 2014). Aged *Wolbachia* infection was successful as assessed by specific staining using FISH (Figure 8 Movie S3).

4 | DISCUSSION

Growing obligate endosymbionts in cell lines yields low biomass at high costs (Baldridge et al., 2014; Khoo et al., 2013). To circumvent this problem, we built a synthetic host–endosymbiont system by artificially infecting the commonly used yeast *Saccharomyces cerevisiae* strain W303 with *Wolbachia* wAlbB from *A. albopictus* (Figures 1–5, Movies S1–S2). Culturing *Wolbachia* in yeast allowed us to study the complex relationship between the host and the bacterium. Using *S. cerevisiae* as an artificial host confers benefits such as a high resistance to changing environments (Gasch, 2002; Gasch & Werner-Washburne, 2002), use of inexpensive liquid cultures and most importantly, the ease of manipulating and genetically engineering the host cell. Following our approach, it may be possible to construct other synthetic parasite-mutualistic systems for obligate endosymbionts. Our system requirements for a successful infection were: supplementing YPD with iron and bovine fetal serum, plus low speed agitation of the nonbaffled Erlenmeyer flask and keeping the temperature between 28 and 30°C. These adjustments resulted in successful yeast infection and considerable *Wolbachia* yields in 14 days as compared with available methods that need up to 100 days. Even if the *Saccharomyces*/*Wolbachia* system is only a model of the interactions that occur in a naturally infected eukaryote cell, its manageability is outstanding and it may yield results that are not possible in cell lines.

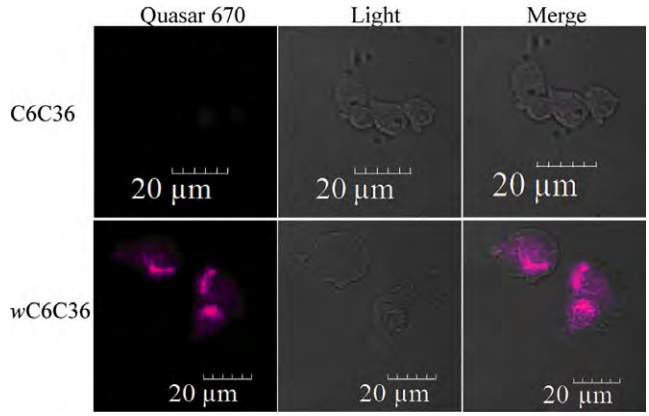

FIGURE 8 *Wolbachia* remains infective after being cultured in *S. cerevisiae*. FISH (Quasar 670-pink) of the *w*C6C36 cell line. Light/Quasar images show hybridization only inside the infected cell line. The noninfected cell line C6C36 does not have any of the pink hybridization mark identified as *Wolbachia*

Since *Wolbachia* is an alpha-proteobacterium closely related to mitochondria, it seemed likely that the aerobic metabolic machinery of *Wolbachia* might mimic, enhance, or supplement the respiratory activity from the host. (Strübing et al., 2010). However, under our conditions, *Wolbachia* respiratory chain proteins were not detectable, instead, we found an increase in host mitochondrial activity. Another obligate endosymbiont, the *Sytophilus oryzae* Principal Endosymbiont (SOPE), has also been reported to increase the mitochondrial activity in the host, probably by providing nutrients such as riboflavin (Heddi, Lefebvre, & Nardon, 1993; Heddi et al., 1999). Several authors suggest that *Wolbachia* provides riboflavin or heme groups to their arthropod and nematode hosts (Brownlie et al., 2009; Darby et al., 2012; Foster et al., 2005; Wu et al., 2009). This may vary with strains as *Wolbachia* from *Brugia malayi* (*wBm)* contains complete sets of riboflavin, heme and nucleotide biosynthesis genes the filarial host lacks (Darby et al., 2012; Foster et al., 2005; Klasson et al., 2008; Wu et al., 2004). In return, the host provides amino acid, proteins and a safe, stable environment (Brownlie et al., 2009; Darby et al., 2012; Foster et al., 2005; Wu et al., 2009). The possibility that *Wolbachia*, behaves as SOPE, donating riboflavin or heme groups to the host may be explored in auxotrophic yeast mutants. *S. cerevisiae* libraries have a mutant for almost every enzyme on the riboflavin and heme synthesis pathways e.g. *S. cerevisiae* genome database (https://www.yeastgenome.org/).

Under the conditions tested here, expression of *Wolbachia* electron transport proteins was not detected. The reported *Wolbachia pipientis* wAlbB genome (Mavingui et al., 2012) shows that some respiratory complex subunits are missing, e.g. *nuo*C and *nuo*D for a functional complex I (Sazanov, 2015); yet other *Wolbachia* sequenced genomes contain all the genes necessary for a functional electron transport chain (Klasson et al., 2008), so maybe under different growth conditions, hosts and *Wolbachia* strains, bacterial respiratory proteins may be detected. It is suggested that other *Wolbachia* strains should be tested in order to determine whether some consume oxygen.

In our hands, *Wolbachia* infection resulted in activation of mitochondria beyond the stationary growth phase. It may be speculated that such activation constitutes an advantage for *Wolbachia* either due to quenching of oxygen in the cytoplasm (Rosas-Lemus et al., 2016) or because *Wolbachia* needs high ATP that an active mitochondria provides (Potter, Badder, Hoade, Johnston, & Morten, 2016). It has already been suggested by experiments using paraquat that *Wolbachia* sensitivity to free radicals is higher than that of the host (Fallon et al., 2013) and it cannot survive outside a host cell unless it is kept in a 5% CO_2 atmosphere (Rasgon et al., 2006). Also, high agitation speeds, which would increase oxygen concentrations, lead to loss of the *Wolbachia* infection (Result not shown). Thus, it is possible that *Wolbachia* enters the cytoplasm to hide from high atmospheric oxygen and then it optimizes cell metabolism to both, use host metabolites and find low cytoplasmic oxygen concentrations.

INFORME DE LABORES 2019

Avoidance, i.e. hiding from oxygen, is a common behavior in oxyconformers (Rosas-Lemus et al., 2016). In air, oxygen saturation concentration is ~21% (200 μmol L^{-1}) while intracellular oxygen concentration ranges between 13.2% and 14% (126–133 μmol L^{-1}) for rhabdomyosarcoma (RD) cells (Potter et al., 2016) or HEK293T cells (Abcam, 2016). When cells are exposed to lower ambient oxygen, intracellular oxygen concentration is also decreased: HEK293T cells exposed to 6% oxygen (50 μmol L^{-1}) have an intracellular oxygen concentration below 2% (19 μmol L^{-1}) (Abcam, 2016); RD cells exposed to 10% or 5% ambient oxygen reduce their intracellular oxygen concentration to 5.4% and 2.1% respectively (Potter et al., 2016). In addition, there is an intracellular oxygen gradient in the area surrounding the mitochondria in rat heart and hepatocytes, where oxygen concentration ranges between 3 (Gnaiger, 2003) and 6 μmol L^{-1} (Jones & Kennedy, 1982; Tamura, Oshino, Chance, & Silver, 1978). Thus, a mitochondrion-containing host such as cell lines and yeast would probably provide the endosymbiont with a microaerobic environment. The mechanism for the increase in host mitochondrial activity needs to be defined.

In conclusion, we describe the infection of *S. cerevisiae* strain W303 by *Wolbachia w*AlbB. Infection led to premature death of the host and to an abnormal pattern of oxygen consumption. Further experiments using other yeast and other *Wolbachia* strains are needed to further explore oxidative phosphorylation patterns in the host/endosymbiont relationship. This system holds a large potential for different evaluations of biochemical and genetical processes in *Wolbachia*. Large biofermentors may be used to yield large amounts of biomass as required for different genomics and proteomics studies.

ACKNOWLEDGMENTS

Aa23 cell line was kindly donated by Dr. Ann Fallon from the University of Minnesota. The wsp antibody was a kind gift from Bei resources. CUA is a CONACYT PhD fellow enrolled in the Biochemistry PhD Program at UNAM. LMG is a CONACYT PhD fellow enrolled in the Biomedical Sciences PhD Program at UNAM. We received technical help from the Molecular Biology, the Microscopy and the Computation Units at IFC, UNAM. MALDI-TOF sequencing was performed by E. Abstract

The impact of performing exercise on the immune system presents contrasting effects on health when performed at different intensities. In addition, the consequences of performing chronic exercise have not been sufficiently studied in contrast to the effects of acute bouts of exercise. The porpoise of this work was to determine the effect that a popular exercise regimen (chronic/moderate/aerobic exercise) has on the proportion of different immune cell subsets, their function and if it affects the cannabinoid system with potentially functional implications on the immune system. A marked increase in several immune cell subsets and their expression of cannabinoid receptors was expected, as well as an enhanced proliferative and cytotoxic activity by total splenocytes in exercised animals. For this study male Wistar rats performed treadmill running 5 times a week for a period of 10 weeks, at moderate intensity. Our results showed a significant decrease in lymphocyte subpopulations (CD4+, Tγδ, and CD45 RA+ cells) and an increase in the cannabinoid receptors expression in those same cell. Although functional assays did not reveal any variation in total immunoglobulin production or NK cells cytotoxic activity, proliferative capability of total splenocytes increased in trained rats. Our results further support the notion that exercise affects the immunological system and extends the description of underlying mechanisms mediating such effects. Altogether, our results contribute to the understanding of the benefits of exercise on the practitioner´s general health.

Introduction

The beneficial impact of exercise on the practitioner's general health is a well-known fact [1–3]. Studies suggesting a connection between physical activity and the improvement of health have generated information that ranges from describing adipose tissue loss to changes in genetic expression [4,5]. It is well known that the proper composition of the immune system (IS) and its correct function will allow it to actively overcome challenges that otherwise would compromise the organism's health, such as infections, autoimmune diseases, cancer, etc. It is worth mentioning that the acknowledgment of those benefits conferred by the regular practice of exercise has led to its implementation as an alternative/complementary therapy against metabolic diseases [6,7], and in recent works even for the treatment of cancer [8].

Nonetheless, data regarding the changes induced by exercise in cell subpopulations of the IS and their function seems to be controversial [9–11]. This may be partly explained by the use of different exercise paradigms. Along with this, a classic idea has been established about such changes promoted by exercise, being those models of moderate/chronic exercise the promoters of an enhanced IS, while acute/high intensity models the responsible of hindering it. Finally, evidence suggesting a beneficial effect of the performance of exercise, on modalities previously described as detrimental, has been gathered and old data reinterpreted as in Campbell and Turner's review [12], so nowadays evidence debunking the previous conception of high intensity/long duration or chronic exercise evoked immune suppression increases, at least for several aspects of the immune function. On the same line, many studies document the immediate changes on the IS induced by a single bout of exercise, as opposed to the effects of its chronic performance, which suggest different outcomes and in some cases opposite effects over the IS [11,13,14]. Less attention has been paid to such studies and to the long-term alterations that it may produce on the IS. For instance, macrophages extracted from mice trained for 12 weeks exhibited increased phagocytic activity, superoxide anion production and glucose consumption when compared to macrophages obtained from sedentary mice [11]. Consistently other studies have shown that chronic exercise alters the function of T cells, affecting their production of pro- and anti-inflammatory cytokines, including the up-regulation of IL-2, an important cytokine related to proliferation and activation [14]. Likewise, trained rats presented increased glucose consumption, IL-2 production and IL-2R expression by their lymphocytic subpopulations. Furthermore, those changes obtained in trained animals seem to last days after the last exercise bout [14].

Many molecular pathways that are affected by exercise possess an immunoregulatory potential, ranging from variations in the energy substrates [15,16] to the activation of signaling pathways with direct immune-regulatory relevance, such as: the release of IL 6 by skeletal muscle [4,13], release of stress hormones, catecholamines [4,17] and neurotransmitters by the sympathetic and para-sympathetic system, among others. Hence, in order to contribute to the further understanding of these effects we decided to evaluate the cannabinergic system (CBS). Regarding this system, some studies have reported a subtle increase of anandamide, a widely studied molecule that acts as a CB1 and CB2 receptor agonist, after short bouts of aerobic exercise. Such increase was sustained up to several minutes after the conclusion of the physical activity [18–20]. Furthermore, both receptors are widely distributed in the immune cells and IS structures [21–23] and when activated, together or independently, produce changes in the function of several immune cells, suggesting that their activation is able to modulate the IS function. These modulatory actions have been explored *in vitro* [24,25] and *in vivo* [23]. Likewise, the expression of cannabinergic receptors (CBR) on the surface of immune cells, varies according to their activation and inflammatory status. Given that new data suggests its relevance as an immune-modulatory system, the expression of these receptors provides us with interesting and relevant information about the IS status.

INFORME DE LABORES 2019

Altogether, the objective of our study is to explore the long-term changes that chronic exercise (CE) produces in the proportion of splenocytes from the adaptive and innate immunity, and to assess the effects that it has on their function (by performing proliferation tests and cytotoxicity test with total splenocytes *in vitro*), and finally to determine if the expression of CBR in these cells is affected by this model of exercise. Furthermore, coherently with previous works on this topic, we expect that the changes evoked by CE will alter the composition of several of the immune cell subsets studied, mainly those from lymphoid origin. CE will also boost their cytotoxic activity and proliferative capacity. In terms of the cannabinoid receptor expression, we anticipate that CE will increase their expression in the entire cell subsets studied.

Finally, this study provide relevant information about those changes elicited on the IS by a way of exercising chosen by a big proportion of the society nowadays. Besides, our results further support the notion that exercise affects the IS and extends the description of underlying mechanisms mediating such effects.

Materials and methods

Ethic statement

Animal care and experimental practices were conducted at the Animal Facilities of the Instituto de Fisiología Celular (IFC), Universidad Nacional Autónoma de México (UNAM). All procedures in the experimental animals were approved by the Institutional Care and Animal Use Committee (CICUAL), adhering to Mexican regulation (NOM-062-ZOO-1999), in accordance with the recommendations from the National Institute of Health (NIH) of the United States of America (Guide for the Care and Use of Laboratory Animals). Euthanasia of experimental animals was performed in a humanitarian way.

Animals

For this study, male Wistar rats ranging between 250 to 300 g were used, proceeding from our own breeding at the animal facilities of IFC, UNAM. The animals were housed at IFC with controlled temperature (22˚C) and 12h light-dark cycles, with water and Purina LabDiet 5015 chow *ad libitum* (Purina, St. Louis MO). Sacrifice of those animals used exclusively for flow cytometry or samples extraction for cellular culture, was carried out by cervical dislocation after pentobarbital sodium (Pisabental®, México) anaesthesia. Animals that also were used for the extraction of the brain were sacrificed by an overdose of pentobarbital sodium (Purina, St. Louis MO). All procedures were carried out in a humanitarian way ensuring the maximisation of efforts in order to alleviate suffering.

Exercise protocol

Animals were set in one of three experimental groups: Exercised (EXE), Treadmill control (TC) and sedentary group (SED). Animals in the exercised group performed treadmill running 5 times a week for a period of 10 weeks, for which a previous habituation of one week was completed. During the habituation week, animals were placed inside the treadmill and then it was turned on at minimum capacity (4m/min) for 5 minutes per day. Once the habituation period was completed, animals started training. On the first day of training, rats ran at 7.5 m/min for 10 minutes, then speed and duration of exercise was escalated gradually each consecutive day, in order to achieve a daily exercise bout of 40 minutes at 15 m/min by the third week. Remaining weeks of training were kept constant in speed and duration until the sacrifice of the animals. It is noteworthy, that this training protocol equals to moderate chronic exercise, as it has been demonstrated in the works by Pilis and Carvalho [26,27] through the calculation

INFORME DE LABORES 2019

of the velocity at the lactate threshold. No electrical stimulus was used to incentive animals to run inside the treadmill.

Animals sited in the TC group were placed inside the treadmill at minimum capacity (4m/min) for 10 minutes, 5 times per week, for the same period of time than the exercised group (10 weeks). While being inside the treadmill, animals from TC group were exposed to the same context than animals from the EXE group without being exercised, reflecting any effect in the results prompted by sources other than exercise itself. Animals conforming the SED group were kept alive in standard conditions for the same amount of time than the other two groups.

At the end of the training period animals from every group were allowed to rest for one day in order to eliminate any possible effect of acute exercising. Afterwards, animals were sacrificed either by an overdose of pentobarbital sodium or by anesthesia with the same product followed by cervical dislocation (Pisabental®, México), afterwards the samples were taken.

Flow cytometry

Spleens were manually disaggregated using a 50μm nylon mesh, and cells resuspended in PBS. Erythrocytes in the solution were lysed using ACK buffer (150 mM NH_4Cl, 10mM $KHCO_3$, 0.1mM Na_2EDTA, pH 7.3) for 10 minutes and washed three times with PBS, then cells were resuspended in FACS buffer (PBS, FBS, 0.02% NaN_3).

Approximately $1x10^6$ cells were incubated with the following antibodies in order to characterize spleen immune subpopulations: Alexa Fluor® 488-conjugated- anti rat CD3 (IF4, Biolegend), PE Cy5-conjugated- anti rat CD4 (biolegend), PE-conjugated anti rat CD8a (Biolegend), PE-conjugated -anti rat CD45RA (Biolegend), Alexa Fluor® 647-conjugated-anti rat CD161 (biolegend), biotin-conjugated- anti rat CD11b (OX-42, Bioloegend), PE-conjugated anti rat TCR (V65, Biolengend). For the determination of macrophages, additionally to the use of anti CD11b antibody, a different gating was used, corresponding to bigger and more complex cells, in order to exclude other cells from the myeloid linage. Staining of the cell subpopulations was made by duplicate in order to additionally mark on each set one of the cannabinoid receptors.

For the staining of cannabinoid receptors, the polyclonal primary antibodies used were: rabbit anti Cannabinoid receptor I (abcam®) and rabbit anti Cannabinoid receptor II (abcam®), followed by the Secondary antibodies: AlexaFluor® 488- conjugated goat anti rabbit IgG (ThermoFisher Scientific) and DyLight® 649- conjugated- anti rabbit IgG (Vector laboratories).

In order to assess proliferation, a Cell Trace™ CFSE cell proliferation kit was used (Invitrogen™). Propidium iodide was used to determine viability of cells during cytotoxic assays. Attune Cytometer (life technologies) was used to obtain data which was further analyzed with FlowJo software (Treestar Inc.).

Proliferation assays

Total splenocytes were obtained as previously described and quantified on a Neubauer chamber. Subsequently, splenocytes were marked with CFSE cell tracer, which was used according to the manufacturer's protocol. Finally, cells were resuspended in RPMI-1640 medium (ATCC® 30 2001™). Splenocytes were cultivated in RPMI-1640 medium plus Ionomicyn (SIGMA-ALDRICH® 10634™) and PMA (SIGMA-ALDRICH® P8139-1MG™) at concentrations100 nm and and 25ng/ml for 72 hours. Proliferation was assessed using an Attune cytometer (Life Technologies) with blue and red lasers, obtained data was further analyzed with FlowJo software (Treestar Inc.).

INFORME DE LABORES 2019

Cell culture

Yac 1 cell line (ATCC® - TIB 160™) was cultivated in RPMI 1640 medium (ATCC® 30–2001™) supplemented with 10% Fetal bovine serum (FBS, ATCC® 30–2020™) and kept with air, 95%; carbon dioxide (CO^2), 5% at 37°C. Yac 1 cells were expanded for a week then counted on a Neubauer chamber and finally stained with CFSE kit for further use in cytotoxic assays.

In vitro cytotoxic assay

Yac 1 cells were stained with cell trace™ CFSE kit according to the manufacturer's protocol and used as target cells for the assay. A single cell splenocyte suspension was obtained from rats in the different experimental conditions as previously described, they were counted and used as the effector cells in the assay. Finally both, effector and target cells were co-cultivated in RPMI medium supplemented with 10% FBS for 4 hours, into 96 round well plates. Thereafter co-cultures were removed from the incubator and stained with Propidium Iodide and washed with Facs buffer. Acquisition was performed in an Attune Cytometer (life technologies) and data further analyzed with FlowJo software (Treestar Inc.).

Corticosterone and IgG levels assesssment

Animals were anesthetized and sacrificed one day after concluding their experimental condition, at the same time that they had been set for exercising (14:00–16:00 hr.). Cardiac puncture was performed in order to extract blood, which was immediately centrifuged at 4000rpm to collect the blood serum. Subsequently, blood serum was divided into two aliquots and stored at -70°C for later use. Corticosterone levels were assessed with a Corticosterone ELISA kit (Abcam® ab-108821) and procedures underwent according to manufacturer's protocol. Assessment of the levels of IgG in serum were carried out on a 96 flat bottom well plate. The plate was previously sensitized with a dilution of blood serum (1:1000), washed and blocked with a 1% albumin solution. Subsequently, the plate was incubated for 2 hours antibodies α IgG rat HRP were incubated, and once incubation finished, several washes were performed, chromogen was added to the wells, the reaction was stopped and the reading of the plate was carried out on a Stat Fax 4200 microplate reader (Awarness Technology).

Statistical analysis

For data regarding the changes of every cell subpopulation, a one-way ANOVA ($\alpha = 0.05$) was performed followed by a Tukey post-hoc test. Differences were considered significant when $p < 0.05$, with the actual p value and n being stated in each figure legend. Before the selection of the ANOVA test the normal distribution of the data was assessed via Shapiro-Wilk test. A similar process was carried out for the statistical analysis of the data regarding the proliferation and cytotoxicity tests, as well as for the data concerning the levels of corticosterone and IgG in serum. For the assessment of the expression of CBR, a two-way ANOVA ($\alpha = 0.05$) was performed, because of the consideration of two independent variables (group and CBR), followed by a Bonferroni post-hoc test with the same significant difference criterion. Data from all the experiments were charted as mean ± standard error, and analysed with Prism 5 software for Mac (GraphPad Software Inc.)

Results

Chronic-moderate exercise affects body composition parameters but not total ingestion of food or water

After ten weeks of rats being exposed to each experimental condition, animals were weighted, and results showed a significant gain of weight on those animals corresponding to both control

INFORME DE LABORES 2019

groups (SED, 490.8g; TC, 495.8g) against those from the EXE group (452g). ANOVA, $p = 0.0007$, $n = 6$, $P<0.05$. Accordingly, when samples were extracted, an observable difference in fat accumulation was perceived among the experimental groups, being those animals that performed the physical activity the ones with the lower amount of visceral fat. Interestingly water and food ingestion per week did not change among animals from the different experimental groups ($p = 0.3309$, $n = 6$, $P<0.05$, and $p = 0.3312$, $n = 6$, $P<0.05$ respectively).

Chronic-moderate exercise alters the composition of splenocyte subpopulations

Distribution of immune cells is a parameter that provides information about deficiencies or alterations from the IS, therefore we decided to evaluate several cell subpopulations from the innate and adaptive immune system in the spleen of rats that underwent different experimental conditions (S1 Fig). The immune cell subpopulations from the innate immune response that were analyzed corresponded to: NK cells (CD161+) and macrophages (CD11b+) for which flow cytometry analysis did not reflect a significant difference among groups (Fig 1). Analyzed cells from the adaptive immune response were: total T lymphocytes (CD3+), T helper lymphocytes (CD4+), cytotoxic T lymphocytes, Tγδ lymphocytes (Tγδ+) and B lymphocytes (CD45 RA+). For those cells studied, flow cytometry analysis reflected a decrease in the proportion of T helper lymphocytes (Fig 2) and in B lymphocytes (Fig 3) from the EXE group when compared to both control groups, SED and TC (Fig 2 and Fig 3), therefore considering such changes an effect of CE. On the other hand Tγδ lymphocytes showed an increase in the EXE group when compared to SED and TC groups (Fig 2), once more reflecting a change attributable to training. On the other hand, T cytotoxic cells decreased in TC and EXE groups in contrast to SED control group, reflecting an effect non attributable to exercise, but to the exposure to the treadmill (Fig 2). Total T lymphocytes (CD3+), did not show changes among the experimental groups (Fig 2).

Modulation of CBR Expression in splenocytes after chronic exercise

CBR are widely distributed among immune cell subpopulations and structures from the IS. The expression of CBR on immune cells has been demonstrated to vary depending on activation or inflammatory profile, among other parameters. Thus, we decided to evaluate if CE would promote changes in the expression of CBR on splenocytes.

From the innate immune system, NK cells (CD161+) and macrophages were analyzed. NK cells from EXE and TC groups showed a decrease in CB2 expression, compared to SED, while no change was observed in CB1 expression. Macrophages (CD11b+) did not present changes in the expression of any CBR among groups (Fig 4). From the adaptive immune response, T helper lymphocytes (CD4+ cells) presented an increase in the expression of CB1 in animals from EXE group when compared to both control groups SED and TC, while no statistically

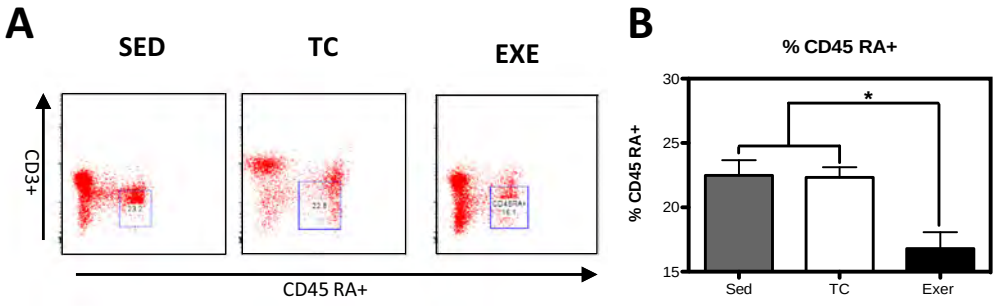

Fig 3. Changes in the composition of B-lymphocytes from spleen. (A) Representative dot plot of the cytometric analysis of the subpopulation percentages. (B) Determination of B-lymphocytes of spleen of rats in the different groups: SED, TC and EXE; data from 4 independent experiments are expressed as mean ± SE. B lymphocytes showed a statistically significant change (ANOVA, p = 0.3601, n = 10). * Means statistically different from the two other groups, P<0.05.

https://doi.org/10.1371/journal.pone.0220542.g003

significant difference was observed regarding CB2 expression. A similar phenomenon was observed in Tγδ subpopulation from EXE animals, which showed a higher expression of CB1 when compared to SED and TC groups (Fig 5), with no change in the expression of CB2. The expression of CBR did not vary in the subpopulations of T lymphocytes (CD3+) and cytotoxic T lymphocytes when experimental groups were compared (Fig 5).

On the other hand, B lymphocytes from the spleen of EXE animals showed a significant increase in CB2 expression, compared to those from SED and TC groups, whilst no change was reflected between groups in the expression of CB1 (Fig 6).

Immunoglobulin G levels are not altered by chronic exercising

Immunoglobulin G (IgG) is the most abundant type of immunoglobulins and a reliable parameter to assess the function of plasmatic cells. A change in the amount of IgG could represent an ongoing infectious process or an alteration on the normal function of plasmatic cells when observed in intact animals. We decided to assess if the total production of IgG would vary among our experimental groups. To do so, we performed a direct semi-quantitative ELISA. When data was analyzed statistically (ANOVA, n = 6, p = 0.0676) results did not show

any significant difference among the experimental groups: SED (optic density 2.731),TC and EXE (OD 2.973 and 2.871 respectively, S2 Fig).

Chronic exercise enhances proliferative capacity but not cytotoxic activity of total splenocytes

Proliferative capacity and cytotoxic activity have been tested before in order to assess the degree of competence of a subject's immune system. In order to observe if chronic exercise has any effect on both features we performed *in vitro* tests. For the proliferation assay we obtained total splenocytes and cultivated them on complete RPMI medium plus PMA and ionomycin for 72 hours. Data analyzed reflected no difference among groups in their proliferation index (Fig 7B). Nevertheless, total splenocytes from EXE group showed a higher proportion of dividing cells when compared to SED and TC groups (Fig 7C). Furthermore, we decided to test the proliferative capacity of the immune cell subpopulations and we found that B lymphocytes and NK cells from the EXE group exhibited a higher proportion of dividing cells than both SED and TC groups (Fig 7D).

INFORME DE LABORES 2019

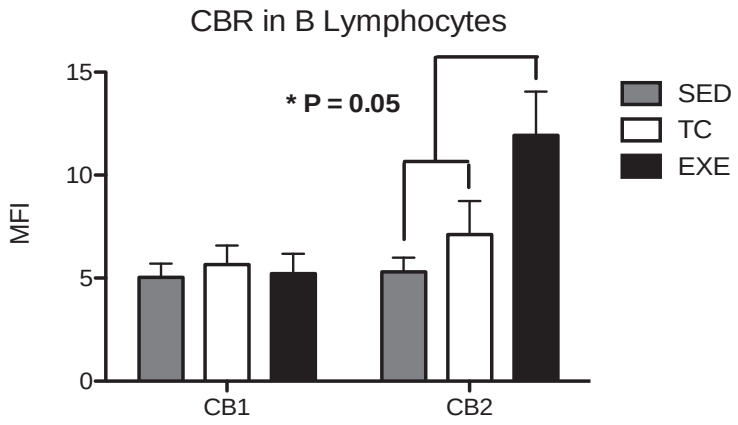

Fig 6. Expression of CBR in B lymphocytes from spleen. Lines connecting bars represent comparison among groups, * $p<0.05$. Two way ANOVA and Bonferroni post-test, n = 10.

https://doi.org/10.1371/journal.pone.0220542.g006

In order to measure the cytotoxic capacity of splenocytes from the different groups, we performed a cytotoxicity test utilizing Yac1 cells as target cells and cultivating them with total splenocytes from animals of the different groups. Yac1 cells were previously marked with CFSE, and at the end of the test dead cells were dyed with propidium iodide, so double positive cells represented the target cells killed. The assay was carried out at three different effector/target ratios: 10:1, 50:1 and 100:1 and none showed any significant difference among treatments after the statistical analysis (Fig 8).

Corticosterone level is not altered by chronic exercise

Corticosterone level is considered a reliable stress marker in animals. In order to further comprehend the data obtained, we decided to analyze if corticosterone levels of blood serum differ among groups, reflecting a possible long-term effect of stress in exercised animals. When data was statistically analyzed (ANOVA, n = 6, p = 0.0473, Tukey's) results show a significant difference among the experimental groups. Nonetheless, The post hoc analysis did not show any significant interaction among the experimental groups. Means of the groups: TC and EXE (102.6 and 96.5 ng/ml respectively) were notoriously higher than that of the SED group (46.8 ng/ml, S3 Fig).

Discussion

Although widely studied, the consequences of physical activity over the IS remain as a promising field not only to expand our comprehension on basic physiology, but also on physiopathology and the different processes that take part on the orchestration of the immune response. At first instance, our investigation tries to emulate in rats a popular paradigm of exercising in modern times across the global population, which involves the chronic performance of medium intensity aerobic exercise. Such particularities in our model have led us to asses its raw impact over the IS composition and its function. Notwithstanding, the vast majority of studies have focused in the effects of short bouts of exercise over the immediate changes in composition and function of the IS [1,11,28,29], and neglecting those focused on the effect of CE and its long lasting effects over the IS [13,30]. In this study we observed that components

INFORME DE LABORES 2019

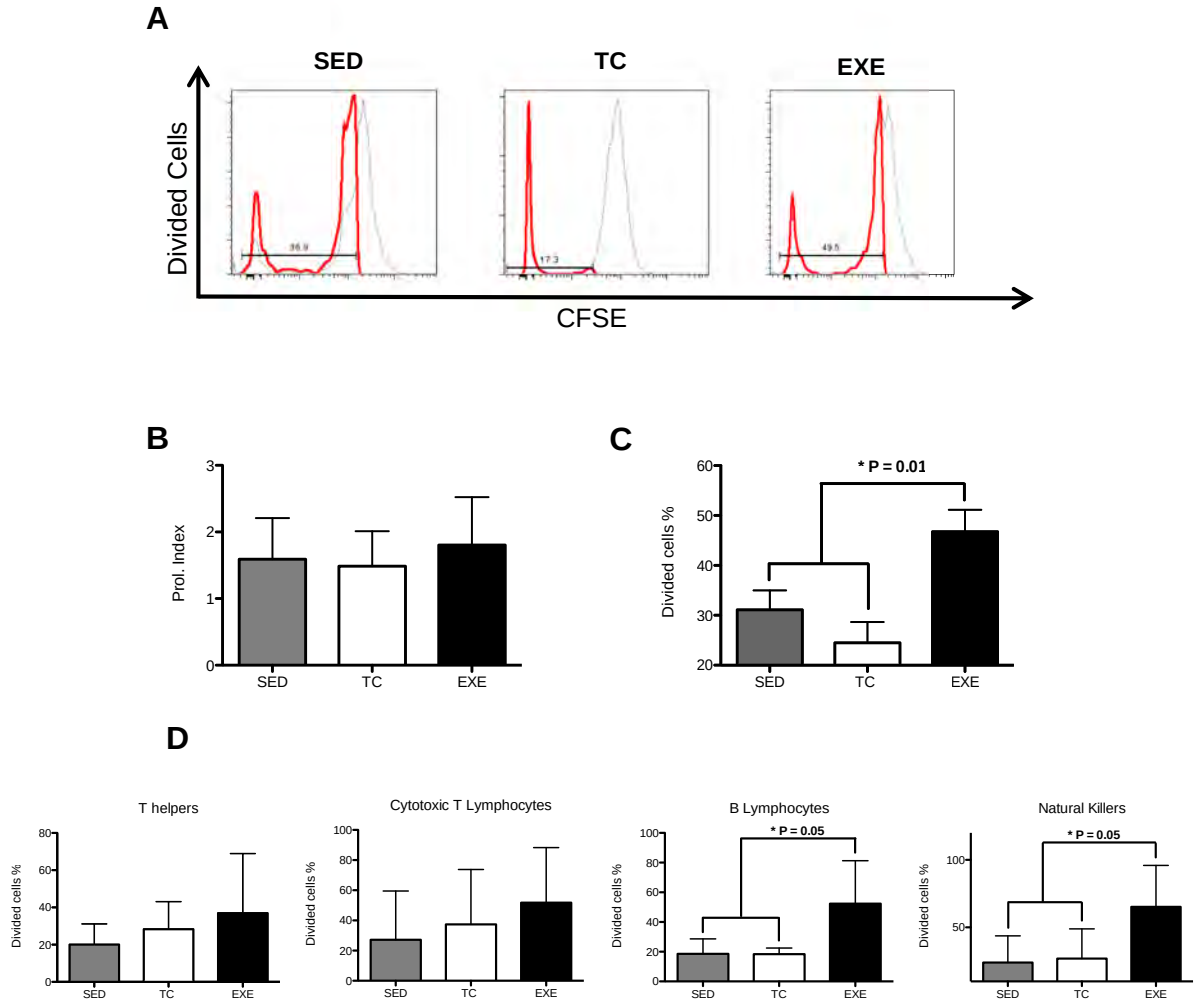

Fig 7. Effect of chronic exercise on splenocyte proliferation. (A) Representative histograms of cytometric analysis of dividing cells. Two parameters were considered to assess the proliferative capacity of splenocytes: (B) the proliferation index, which did not change due to chronic exercise and (C) the proportion of dividing cells, where we observed an increase in the exercised group when compared to both control groups (ANOVA, $p = 0.0092$, $n = 5$). (D) Analysis of proliferative capacity of specific splenocyte subpopulations: T helper lymphocytes (ANOVA, $p = 0.4543$, $n = 5$) and cytotoxic T lymphocytes (ANOVA, $p = 0.5248$, $n = 6$) did not show any change between groups; B lymphocytes (ANOVA, $p = 0.0006$, $n = 6$) and Natural killers (ANOVA, $p = 0.0191$, $n = 6$) from EXE did show an in increase in the proportion of dividing cells when compared to both control groups. In graphic bars SED is represented by shaded bar, TC by white bar and EXE by the solid bar.

https://doi.org/10.1371/journal.pone.0220542.g007

from the innate immune response were not affected by chronic-moderate exercise, while elements from the adaptive immune response did change in those animals that underwent physical training. T helper lymphocytes and B lymphocytes were decreased in trained animals, contrary to what would be expected according to the popular statement of moderate exercise enhancing a pro-inflammatory state [31,32]. On the other hand, Tγδ lymphocytes increased in animals from the EXE group, increase that could reflect an intensification in surveillance and protection of the upper respiratory tracts (URT) and mucosa tissue, idea that would be in accordance with the strengthened resistance against URT infections due to moderate exercising and opposite to the supposed effect of higher susceptibility to these infections in high performance athletes [29,33–37]. Nonetheless, the reduction of T helper and B lymphocyte populations was unexpected, since these cells play a major role at recognizing antigens and

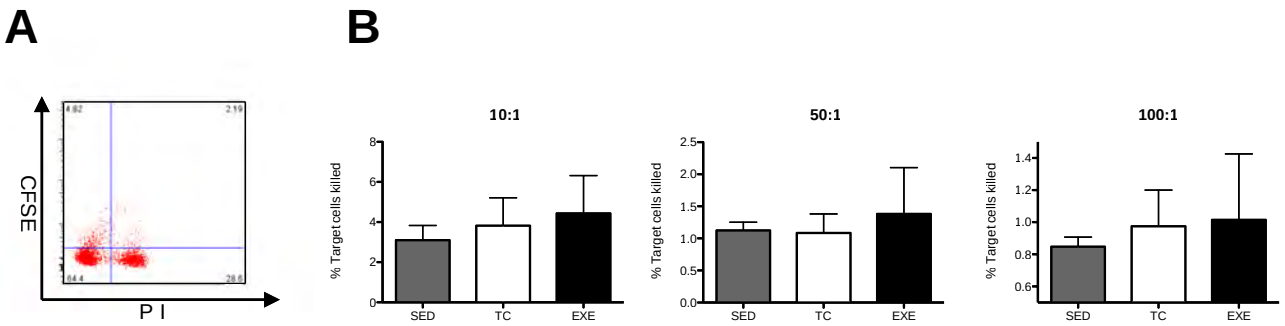

Fig 8. Cytotoxic activity of total splenocytes in vitro. (A) Representative dot plot of cytometric analysis of killed target cells percentage. (B) Cytotoxic activity of total splenocytes was assessed in vitro at three different ratios (effector cells: target cells, 10:1, 50:1 and 100:1); data from 2 independent experiments are expressed as mean ± SE, with an n = 6 for each condition. No differences were found among the groups at any of the different ratios. In bar graphics SED is represented by the shaded bar, TC by the white bar and EXE by the solid bar.

https://doi.org/10.1371/journal.pone.0220542.g008

therefore at orchestrating immune responses against new and already known threats and once activated they can polarize towards a pro-inflammatory or anti inflammatory state which modulates the activity of several other components from the innate and adaptive immune response. Consequently, the decrease of T helper lymphocytes as well as that of B lymphocytes made us wonder if it could be translated into a deficient immune response of animals of the EXE group.

Once we determined that our exercising paradigm did affect the composition of immune cells subpopulations, our next goal became to assess if those changes would be translated into functional alterations. To accomplish our purpose, we determined total IgG in serum among experimental groups and we also performed proliferation and cytotoxicity test *in vitro*. On the proliferation test, two parameters were evaluated: the proliferation index and the percentage of dividing cells. The first represents the mean of divisions that dividing cells underwent during the assay, which showed no difference among groups. In turn, the percentage of dividing cells among groups during the experiment showed statistical differences, being higher in splenocytes from the EXE group. Altogether, this data suggests that cells from EXE group are not more efficient at dividing once they have been activated but that more cells in proportion from EXE group are prone to proliferate once they have been exposed to PMA and ionomycine. These results made us wonder if this trend would be persistent in basal conditions, so we compared the percentage of proliferation in splenocytes among the experimental groups without activation by PMA and ionomycine and the statistical analysis showed no difference among them, reflecting a response produced by activation and not an anomaly that could reflect an inflammatory state that in turn could favor an autoimmune response. Thereafter, we evaluated the percentage of dividing cells from specific subpopulations, T helper cells, cytotoxic T cells, B lymphocytes and NK cells, showing an increase in the percentage of dividing cells in the last two subpopulations by effect of exercise. On the other hand, statistical analysis from the cytotoxicity test did not show variation among the experimental groups in any of the target/effector cell ratios tested, so data provided from this experiment does not suggest a higher cytotoxic activity from NK cells as a consequence from exercise. Nonetheless, exercise enhances the amount of NK cells that proliferate, which may indicate a higher immune-surveillance against transformed and virally infected cells in chronically exercised subjects.

Even though we found a decrease in major lymphocyte subpopulations (CD4+ and CD45 RA+ cells), which has been reported before for other immune cells in long term exercised individuals [32,38–40], we also determined that a bigger proportion of splenocytes is prone to

INFORME DE LABORES 2019

activate when stimulated, plus other functions of splenocytes from the EXE animals were not impaired. Given the fact that long-term exercised subjects do not report any kind of immune suppression, we have come to hypothesize that the decrease in the composition of some cell subpopulations may represent a more efficient IS, which requires less elements but presents a stronger reaction when needed. This idea is also supported by the results shown by the ELISA test, which showed that levels of IgG did not change among the groups, even though the subpopulation of B lymphocytes is decreased in EXE animals.

Finally, recent works have denominated the endocannabinoid system (ECS) as an immunomodulatory system; inhibiting the function of highly reactive and pro-inflammatory cells [25,41,42]. The ECS exerts its functions through the activation of its receptors, which expression vary greatly depending on cell subpopulation, activation or inflammatory status [24,41,43,44], being increased in the surface of more reactive cells. In this work we demonstrated that CE promotes changes in the expression of both CBR's in splenocytes, through the staining of each receptor on different cell suspension aliquots and due to the shared epitope for the secondary antibody. Our findings concur with previous works showing that during moderate exercise bouts there is an increase of circulating ECS agonists [18,19]. We must emphasize that changes in CBR's expression remained after one skipped day of training, which suggests that subjects exercising on a daily basis or in intervals of every two days might be maintaining this alterations. Our methodology allowed us to determine differences in the expression of CBR among cell subpopulations even between control groups. These differences might be explained by the intrinsic variability among cell subpopulations [21,45]. We also assessed an increased expression of CB1 receptor in the subpopulations of T helper and Tγδ lymphocytes and an increase in the expression of CB2 receptor in B lymphocytes of exercised animals. Therefore enhanced expression of CB1 in T helper, Tγδ, and CB2 in B lymphocytes could represent a mechanism to down regulate the activity of these probable high metabolic cells from EXE animals, as reflected by the proliferation tests. Some of these data differ from anterior reports concerning expression of CBR, nonetheless most of those reports used different techniques and did not measure the protein conforming CBR's but mostly mRNA [21,46,47], which highlights the novelty of the data presented in this work, by showing a direct measure of the expressed protein in question under this particularly conditions of exercise. On the same line, the increased expression of CBR in splenocytes, particularly in lymphocytes from the EXE group, concurs with previous data reporting changes in the expression of the protein through the assessment by different techniques, like western blot and immunofluorescense [21,48,49], adding validity to our results.

We would like to address those changes presented on this work that can not be attributable to CE, like the composition of cytotoxic T cells for which TC and EXE groups differ when compared against SED group, reflecting an effect relying probably on the stress produced by the placement of the animals inside the treadmill, being that, the one thing that those groups had in common. The same explanation seems plausible for the expression of CBR in NK and cytotoxic T cells. Nevertheless analysis of corticosterone did not showed significant difference among the experimental groups, different sensitivity to several molecules has been reported for the wide variety of cells from the IS, leaving the possibility of other molecular interactions that escaped our control and awareness.

Supporting information

S1 Fig. Gating strategy for the flow cytometric analysis of rat spleen subpopulations and their expression of CB1 and CB2 receptors. Single cell suspension was prepared and stained with fluorochrome-conjugated antibodies to separate splenocyte subpopulations and to mark

cannabinoid receptors (CB1 and CB2). Data was analyzed with FlowJo software 8.7 for Mac. Lymphocytes were identified by their scatter properties (FSC-A x SSC-A plot). Splenocyte subpopulations were characterized by surface staining and gated for their quantity assessment. Subsequently each cellular subpopulation was analyzed for their expression of both cannabinoid receptors in their surface.
(TIFF)

S2 Fig. Levels of IgG are not affected by chronic exercise. The analysis of total IgG was assessed for every experimental group with the use of a direct semi-quantitative ELISA. Statistical analysis did not show any significant difference among the experimental groups: SED (shaded bar), TC (white bar) and EXE (Solid bar). $P>0.05$. ANOVA, $p = 0.0676$, $n = 6$.
(TIF)

S3 Fig. Serum corticosterone concentration one day after the last exercising bout. Data is shown as mean (ng/ml) +- SE for each group. There was no significant difference among group values in concentration of serum corticosterone. Groups analyzed: SED (shaded bar), TC (white bar) and EXE (Solid bar). When data was statistically analyzed (ANOVA, $n = 6$, $p = 0.0473$, Tukey's) results show a significant difference among the experimental groups. Nonetheless, The post hoc analysis did not show any significant interaction among the experimental groups. Means of the groups: TC and EXE (102.6 and 96.5 ng/ml respectively) were notoriously higher than that of the SED group (46.8 ng/ml).

Front. Cell. Neurosci. 13:215. doi: 10.3389/fncel.2019.00215

During midbrain development, dopamine neuron differentiation occurs before birth. Epigenetic processes such as DNA methylation and demethylation as well as post-translational modification of histones occur during neurogenesis. Here, we administered histamine (HA) into the brain of E12 embryos *in vivo* and observed significant lower immunoreactivity of Lmx1a+ and Tyrosine Hydroxylase (TH)+ cells, with parallel decreases in the expression of early (*Lmx1a*, *Msx1)* and late (*Th*) midbrain dopaminergic (mDA) genes. With MeDIP assays we found that HA decreases the percentage of 5-methylcytosine of *Pitx3* and *Th*, without changes in 5-hydroxymethylcytosine. Additionally, HA treatment caused a significant increase in the repressive epigenetic modifications H3K9me3 in *Pitx3* and *Th*, and also more H3K27me3 marks in *Th*. Furthermore, HA has a long-term effect on the formation of the nigrostriatal and mesolimbic/mesocortical pathways, since it causes a significant decrease in midbrain TH immunoreactivity, as well as alterations in dopaminergic neuronal fibers, and significant lower TH-positive area in the forebrain in whole-mount stainings. These findings suggest that HA diminishes dopaminergic gene transcription by altering several epigenetic components related to DNA and histone modifications, which affects mDA neuron progression during development.

Keywords: midbrain development, dopamine neuron differentiation, epigenetic modifications, neuroepigenetics, ultrasound-guided injection in utero

INTRODUCTION

Midbrain dopaminergic (mDA) neurons are essential for motor function control as well as for the regulation of reward and emotions (van Heesbeen et al., 2013). Development of mDA neurons can be divided into three stages: neural plate regionalization, midbrain cell fate determination and terminal differentiation to mDA neurons (Gale and Li, 2008). Each step presents activation of

different cascades of transcriptional factors triggered by extrinsic signals (Ang, 2006; Abeliovich and Hammond, 2007; Huang et al., 2015). During the specification stage, dopaminergic neural progenitors express specific genes such as *Lmx1a/b*, *Foxa2*, *Msx1/2*, and *Ngn2* (Ang, 2006; Gale and Li, 2008; Nakatani et al., 2010; Yan et al., 2011). At this stage neural progenitors acquire mDA neuronal fate and start the last stage to become post-mitotic neurons (Yi et al., 2014). The activation of *Nurr1* and *Pitx3* allows the expression of late-differentiation genes associated to the dopaminergic neuron phenotype, as they regulate the expression of enzymes such as Tyrosine Hydroxylase (TH), the rate limiting enzyme in the production of dopamine (Gale and Li, 2008; Jacobs et al., 2009; Kadkhodaei et al., 2009). Terminally differentiated mDA neurons extend their axons to reach the *striatum* (ST) and release dopamine to regulate motor function in the basal ganglia (Hegarty et al., 2013).

Histamine (HA) is a neurotransmitter/neuromodulator that participates in the sleep/awake cycle, motor activity, cognition, feeding and energy balance in the adult brain (Panula and Nuutinen, 2013). During rat embryonic development, the cerebral concentration of HA reaches higher levels than those observed in the adult; its highest concentration is found at embryonic days (E) 14–16 (Vanhala et al., 1994; Nissinen and Panula, 1995; Molina-Hernández et al., 2012). This amine has a cell proliferation and neuronal differentiation effect on cortical neural stem/progenitor cell (NSPC) cultures, through multiple effects, including: elevation of intracellular Ca^{2+}, up-regulation of FGF receptors and increased expression of proneural genes (Molina-Hernández and Velasco, 2008; Rodríguez-Martínez et al., 2012; Molina-Hernández et al., 2013). Similar effects of HA, have been observed on adult NSPC at the subventricular zone (Bernardino et al., 2012). In addition, the *in vivo* effects of HA injected at E12 include a decrease in NSPC proliferation in the ventricular zone and also a decrease in TH staining in the midbrain, without affecting serotoninergic nor GABAergic neurons; co-injection of HA with the H_1R antagonist chlorpheniramine prevented the decrease on TH induced by HA (Escobedo-Avila et al., 2014).

Recent studies describe different pathways to regulate neural stem cell differentiation via regulation of epigenetic modifications, which result in changes on gene expression. DNA demethylation has been related to the brain development control (Hahn et al., 2013; Wheldon et al., 2014). Particularly, the increase of 5-hydroxymethylcytosine (5hmC) along gene bodies has been associated with transcriptional activation during neuronal differentiation (Hahn et al., 2013; Kim et al., 2014). Furthermore, abundance of 5-methylcytosine (5mC) on gene body regions has been related to up-regulation of pre-mRNA splicing (Shukla et al., 2011; Guo et al., 2014; Yearim et al., 2015). These and other epigenetic modifications can be induced by environmental stimuli (Aguilera et al., 2010; van Heesbeen et al., 2013). For example, long-term exposure of cultured ventral midbrain (VM) NSPC to depolarizing potassium concentrations promotes mDA neuron differentiation, increasing binding of Nurr1 to the regulatory regions, and higher transcriptional activity, of *Th* and *Dat* genes, with parallel increases in H3K4me3 and decreased H3K9me3/H3K27me3, although the latter changes observed only in the *Th* promoter (He et al., 2011). Furthermore, VM NSPC treated with the neuropeptide urocortin increases mDA differentiation by inhibition of Histone Deacetylase 1 (HDAC1), resulting in hyperacetylation of histone H3, which allows the binding of Nurr1 to the upstream *Th* regulatory regions (Huang et al., 2015). This suggests that post-translational histone modifications participate in the regulation of the expression of genes involved in brain development.

In this work, we aimed to evaluate the effect of HA on several epigenetic marks on intragenic regions that regulate expression of genes involved in mDA development *in utero*, as well as its long-term effects *in vivo* before birth. We found an enrichment of repressive histone marks, H3K9me3 and H3K27me3, together with a decrease of 5mC at intergenic regulatory regions. Such modifications were associated to significantly lower mRNA levels of genes related to midbrain DA neuron fate specification. Injection of HA at E12 caused a decrease in the number of mDA neurons and modified the trajectory of its axons to the ST at late stages of midbrain development.

MATERIALS AND METHODS

Ultrasound-Guided Injections

All animal procedures were approved by the Institute of Cellular Physiology's Animal Care and Use Committee and conformed to National guidelines (*Norma Oficial Mexicana* NOM-062-ZOO-1999). We used timed-pregnant Wistar rats with embryos at gestational age E12 to perform ultrasound-guided injections as previously reported (Escobedo-Avila et al., 2014). Control (vehicle-injected) or experimental (HA-injected) conditions were performed by triplicate or quadruplicate in different embryos from the same rat, and repeated with six different pregnant dams. Each group was evaluated in a single uterine horn. Rats were deeply anesthetized in a chamber and then maintained with a facemask to administer inhaled sevoflurane (5% for induction and 1% for maintenance). We performed a midline laparotomy, the uterine horns were carefully exposed and the number of embryos was recorded. To visualize the embryos, we used an MHF-1 Ultraview UltraSound System (E-Technologies) with a focal distance of 7 mm. Intraventricular injections were performed through the uterine wall using pulled microcapillaries (borosilicate glass, Sutter Instruments). The glass needles were visualized in the ultrasound imaging system and when in the lateral ventricles, the injection of 2 μl was verified by observing the liquid going out of the needle with the aid of an automatic injector (Quintessential injector, Stoelting). Control embryos received injectable water and experimental embryos were injected with 50 μg of HA dihydrochloride (Sigma-Aldrich), a dose previously determined to decrease TH in the MB (Escobedo-Avila et al., 2014). The osmolarity of this HA solution was 348 mOsm, and HA decreased 0.6 pH units in relation to the vehicle. We have showed (Escobedo-Avila et al., 2014) that the injection of vehicle, or HA at this concentration, did not cause morphological abnormalities in the MB, ruing out damage caused by the osmolarity or pH.

After injection, the uterus was repositioned in its physiological site. The incisions of the abdominal muscle and skin were stitched with separate sutures. Finally, we applied Buprenorphine as analgesic (0.1 mg/kg, Pisa Laboratories) and animals were monitored and left to recover. Two or 6 days after the injections, pregnant rats were euthanized by an overdose of sodium pentobarbital (Pfizer), and identified embryos were recovered for analysis. We performed the following number of successfully injected E12 embryos: vehicle: 53; HA: 59. The number of dams used was 22.

Immunohistochemistry

Embryos were removed and transferred to PBS. Subsequently fixed by immersion in 4% paraformaldehyde solution in PBS at 4°C, overnight (for E14 embryos) and for 6 days (for E18 embryos). Afterward, tissues were cryoprotected overnight in 30% (v/v) sucrose, embedded in Tissue Freezing Medium (Tissue-Tek, Zakura Finetek) and frozen at −80°C. Coronal and sagittal sections of 20 μm were obtained on a cryostat (Leica). For immunohistochemistry, slides were rehydrated in PBS. Tissue sections were treated with immuno-retriever for 30 min at 65°C and subsequently, permeabilized and blocked for 1 ½ h at room temperature with 0.3% Triton X-100 and 5% horse serum in PBS. Slides were incubated overnight at 4°C with the following primary antibodies diluted in PBS containing 5% horse serum: rabbit polyclonal anti-TH (1:1000, Pel-freez), rabbit polyclonal anti-Lmx1a (1:1500, Millipore), mouse monoclonal anti-β-III Tubulin (1:500, Babco Covance). Then, the sections were washed three times for 5 min in PBS and incubated with the secondary antibodies Alexa-Fluor 488 anti-rabbit IgG and Alexa-Fluor 568 anti-mouse IgG (1:500; Molecular Probes) in PBS containing 5% horse serum for 2 h. Nuclei were stained with Hoechst 33258 (1 ng/mL). After three further washes in PBS, the sections were mounted in Aqua Poly/Mount (Polysciences, Inc.) Immunostainings were analyzed with an epifluorescence microscope (Nikon, Eclipse TE2000-U) and photographed with a Nikon digital camera (DMX1200 F). Some images were acquired with a FV1000 Olympus confocal microscope. Negative controls were performed in the absence of primary antibodies and showed no unspecific staining.

Immunohistochemistry of Whole-Mount Brains From Embryos

We perform immunohistochemistry of whole-mount brain as previously reported (Joyner and Wall, 2008). Embryos at E18 stage were incubated in 20% dimethyl sulfoxide (DMSO): 80% methanol (fixative solution) for 24 h at 4°C. Then, the embryos were transferred to 10% hydrogen peroxide diluted in fixative and incubated overnight at room temperature. This treatment effectively bleached the pigment of the embryo and blocked endogenous peroxidase activity. After bleaching, embryos were incubated in 100% methanol at −20°C for 4 h. For staining, bleached embryos were washed twice for 1 h with 2% skim milk and 0.5% Triton X-100 in PBS (PBSMT). Embryos were incubated overnight at 4°C with rabbit polyclonal anti-TH (1:1000, Pel-freez) in PBSMT. After this incubation, the embryos were washed seven times in PBSMT; each wash lasted 1 h. The embryos were then incubated overnight at 4°C with affinity-purified goat anti-rabbit immunoglobulin antibody conjugated to horseradish peroxidase (1:500, Santa Cruz) in PBSMT. The seven washes were repeated. Bound peroxidase-conjugated antibody was visualized using the DAB Substrate Kit for Peroxidase (VECTOR laboratories); reactions were carried out for 10 min at room temperature. Embryos were post-fixed in 4% paraformaldehyde in PBS at 4°C overnight and dehydrated in 50, 80, and 100% methanol (1 h each). Embryos were cleared by placing them in a 1:2 mixture of benzyl alcohol:benzyl benzoate. Immunostainings were visualized with a stereomicroscope (Nikon, SMZ1500) and photographed with a Nikon digital camera (Coolpix S10). This preparation allows to visualize the nigro-striatal as well as the mesolimbic and mesocortical pathways. We measured the area of TH+ staining with ImageJ software in: (a) the midbrain (including the *substantia nigra pars compacta* and the Ventral Tegmental Area); (b) the Medial Forebrain Bundle (MFB); and (c) the forebrain (striatum/cortex, including the Nucleus Accumbens). The average of four embryos was determined per treatment. Analysis is presented as the mean ± standard error of the mean (SEM) and statistical analysis by multiple *t*-test. Since the immunostaining with positive TH was tridimensional, the area of positive label was the preferred parameter to measure.

Quantitative RT-PCR (RT-qPCR) Analysis

Total RNA was extracted with TRIzol (Invitrogen) according to the manufacturer's specifications. The mRNA levels were determined by RT-qPCR performed with cDNA generated from 2 μg of total RNA using the Kit GeneAmp RNA PCR KIT (Applied Biosystems). Primers were synthetized based on the UCSC Genome Browse database from *Rattus norvegicus* (Gibbs et al., 2004; Havlak et al., 2004). Gene expression levels were determined using the following primers (all listed in 5′to 3′ orientation; Sense, S; Antisense, AS): *Lmx1a*, S: GCACGGAAGCTAGACTCAA; AS: GCTCTGCC CAGCAAAGAG; 143 bp. *Msx1*, S: CTGTTGGGGGACTCC TCAA; AS: GCCGCCTGGCTGGGGG; 119 bp. *Foxa2*, S: CAGAAAAAGGCCTGAGGTG; AS: CAGCATACTTTAACTC GCTG; 137 bp. *Nurr1*, S: GTCACAGAGAGACACGGG; AS: GGTAGTTGGGTCGGTTCAA; 121 bp. *Pitx3*, S: CTCGAAGCCCTGCGCTGT; AS: GCCTTCTCCGAGTC ACTGT; 100 bp. *Th*, S: CCACTGGAGGCTGTGGTATT; AS: CCGGGTCTCTAAGTGGTGAA; 145 bp. H_1 receptor, S: CTTCTACCTCCCCACTTTGCT; AS: TTCCCTTTCCC CCTCTTG; 292 bp. H_2 receptor S: TTCTTGGACTCCT GGTGCTGC; AS: CATGCCCCCTCTGGTCCC; 309 bp. *Gapdh*, S: GTGGACCTCATGGCCTACAT; AS: GGATGGAATT GTGAGGGAGA; 160 bp. *Gapdh* was used as an internal control. The qPCR reactions for 96-well plate format were performed using 50 ng of cDNA and the Thermo Maxima SYBR Green/ROX 1 PCR Master Mix (Thermo Fisher Scientific) with a StepOnePlus Real-Time PCR System (Applied Biosystems).

The fold change was calculated by the $2^{-\Delta\Delta Ct}$ method (Livak and Schmittgen, 2001).

Sodium Bisulfite Sequencing

Genomic DNA was isolated by phenol:chloroform:isoamyl alcohol (Sigma-Aldrich) extraction technique as reported (Clark et al., 2006). One microgram of genomic DNA was modified by sodium bisulfite using the EZ DNA methylation kit (ZYMO Research). For sequencing, modified DNA was amplified by PCR using the following primers recognizing *Th*, S: GTAGGTGTTTGTGATAGTGGATG; AS: AAAACCACTCCAACCCTAAATA, with a length of 439 bp. These primers were synthetized based on the UCSC Genome Browse database from *R. norvegicus* (Gibbs et al., 2004; Havlak et al., 2004). The PCR products were purified and cloned using the pGEM-T Easy Vector system (Promega). Eight clones were randomly chosen and sequenced individually. The percentage of modified cytosines was calculated for vehicle- and HA-treated embryos.

Methylated and Hydroxymethylated DNA Immunoprecipitation Assay (MeDIP and hMeDIP)

Genomic DNA was isolated as described above and processed by ultrasonic pulses (GENEQ, GEX500; Cole-Parmer). Initial experiments were set up to obtain fragments of an average size of 300 bp. Such conditions included 3 rounds of pulses of 30 s, with sequences of pulse-on for 5 s and pulse-off for 3 s at 35% amplitude. DNA was immunoprecipitated using a MeDIP/hMeDIP kit (Diagenode). Briefly, 1 μg of fragmented DNA was denatured for 3 min at 95°C and incubated with 2.5 μg of the company-validated mouse monoclonal anti-5 hmC (Diagenode) or 2 μg of mouse monoclonal anti-5mC (Diagenode). The antibody-bound DNA was recovered by immunoabsorption with anti-mouse IgG-coated magnetic beads (Diagenode) for 16 h at 4°C. The immunoprecipitated DNA was amplified by 30 cycles of PCR. Primers were designed from the sequences obtained in the UCSC Genome Browse database from *R. norvegicus* (Gibbs et al., 2004; Havlak et al., 2004). For the mDA differentiation genes, oligonucleotides were designed in exons, which represent regulatory regions for neurogenesis. Exons were chosen based on their higher percentage of CpG content or within a CpG island. Primers used are as follows: *Lmx1a*, exon 2, S: GGGTCATCTCGGATAGGTTT; AS: CAGGCACTTACTTCTCGTAG; 156 bp. *Msx1*, exon 1, S: CGAAACCCATGATCCAGGG; AS: GTCCTCCACTTTGA CACCG; 112 bp. *Foxa2*, exon 3, S: CGCTCATCACCAT GGCCAT; AS: GCCGGTAGAAAGGGAAGAG; 96 bp. *Nurr1*, exon 2, S: CAGTCCGAGGAGATGATGC; AS: GGAAG TTGTGAAGGGAGCC; 133 bp. *Pitx3*, exon 4, S: CTTAG TCCCTGCCAGTACG; AS: GCACCCCTTTTCAGACCCT; 149 bp. *Th*, exon1, S: GAGACAGAACTCGGGACC; AS: CGGGTGACAGCATATCCTC; 145 bp. The efficiency of MeDIP or hMeDIP products of a particular genomic locus was calculated from qPCR by a fast optical 96-well q PCR reaction plate (Applied Biosystems). The qPCR reaction was performed using Thermo Maxima SYBR Green/ROX 1 PCR Master Mix (Thermo Fisher Scientific) with a StepOnePlus Real-Time PCR System (Applied Biosystems). According to the manufacturer inset, data for each sample is reported as recovery of starting material: % MeDIP or hMeDIP/INPUT.

Chromatin Immunoprecipitation to Detect H3K9me3 and H3K27me3

Ventral midbrains were dissected and pooled from 7 embryos treated with HA or vehicle. Tissue was maintained in ice-cold PBS before crosslinking, which was carried out for 10 min, with 1% of formaldehyde. The crosslink reaction was stopped for 5 min with 125 mM glycine and the crosslinked tissue was washed three times with ice-cold PBS for 5 min. After the last wash, tissue was lysed with 500 μL of lysis buffer. Chromatin was sonicated using an Ultrasonic Processor (GENEQ, GEX500; SOVC505-00). After sonication, DNA was extracted and its length evaluated. Quantitation of chromatin was made by the Lowry reaction and 100 μg of material was used per IP. Immunoselection was performed according to the protocol of the OneDay ChIP kit (Diagenode, Kch-oned IP- 180), with anti-H3K9me3 or anti-H3K27me3 (Diagenode). Immunoprecipitation was performed by incubating 20 μL of magnetic beds (16-663 | Magna ChIP™ Protein A+G Magnetic Beads), with the antibody-chromatin complexes for 3 h in a rotating wheel; then the beads-antibody-chromatin complexes were washed three times with ice-cold ChIP buffer 1×. Finally, the DNA was decrosslinked overnight and purified employing the MinElute Reaction Cleanup Kit (Cat No./ID: 28204) following the manufacturer's instructions. ChIP assays were performed by qPCR in a fast optical 96-well qPCR reaction plate (Applied Biosystems) with the same primers used for MeDIP/hMeDIP for *Pitx3* and *Th*. The qPCR reaction was performed using Thermo Maxima SYBR Green/ROX1 PCR Master Mix (Thermo Fisher Scientific) with a StepOnePlus Real-Time PCR System (Applied Biosystems), according to the manufacturer's instructions.

Dopamine Quantification by High-Performance Liquid Chromatography (HPLC)

E18 embryos were recovered after vehicle or HA injection at E12. The striatum was dissected and individually homogenized with a mixture of 0.1 M perchloric acid (Baker), 4 mM $Na_2S_2O_3$ (Sigma), 0.1 mM EDTA (Sigma). The homogenate was centrifuged (12,600 rpm, 20 min at 4°C). Subsequently, the supernatant was filtered with 0.45 μm filters (Millex-HV) and 20 μl were mixed with 7.5 μL of antioxidant solution (0.1 N perchloric acid; 0.02% EDTA and 1% EtOH) and injected into the solvent stream of a HPLC system, using a reversed-phase column (C18, 3 μm; 2.1 × 50 mm; Atlantis, Waters) coupled to a pre-column (Nova-Pack, Waters) with a mobile phase solution containing 0.054 mM EDTA, 50 mM citric acid, and 0.1 mM octansulfonic acid, dissolved in milli-Q water and mixed with methanol in a proportion of 97:3, respectively. The pH was 2.9 and the flow rate 0.35 mL/min. Dopamine detection was performed by a

single-channel electrochemical amperometric detector (Waters model 2465) at 450 mV at a temperature of 30°C, and quantified by peak height measurements against standard solutions with know dopamine concentration, as described (Rocha et al., 2012).

Statistical Analysis

Data from four to six independent experiments are expressed as the mean ± SEM. The differences between groups were analyzed using the unpaired Student's *t*-test comparing the HA- with the vehicle-treated rat embryos. Differences between groups were considered statistically significant when $p < 0.05$.

RESULTS

Intrauterine Administration of HA Decreases TH and Lmx1a Immunoreactivity in the VM

We performed *in utero* microinjections of HA or vehicle, into the ventricular lumen close to the MB of E12 rat embryos, allowing them to develop to E14. Because it was previously reported that intrauterine injection of HA at E12 precludes mDA differentiation at E14 (Escobedo-Avila et al., 2014), we quantified the immunoreactivity of TH and Lmx1a in vehicle- or HA-injected embryos, confirming a significant decrease in TH (**Figure 1A**). We also assessed the effect of HA on VM dopamine progenitors positive to Lmx1a (Nakatani et al., 2010; Yan et al., 2011). We found that HA down-regulates Lmx1a reactivity, without altering β-III Tubulin, in contrast to the vehicle-treated embryos (**Figure 1B**).

Administration of HA Down-Regulates the Expression of Specification and Differentiation Dopaminergic Genes

Based on the Lmx1a-positive domain, we performed dissections selecting the VM of injected embryos 2 days after surgery. Subsequently, we analyzed the expression of DA specification (*Lmx1a, Msx1, and Foxa2*) and differentiation (*Nurr1, Pitx3, and Th*) genes by RT-qPCR. After normalization with *Gapdh*, we found that HA significantly decreases the expression of *Lmx1a*, *Msx1*, and *Th* compared to vehicle-injected embryos (**Figure 1C**). H_1 and H_2 receptors are expressed in the VM; we did not find significant changes in these receptors' expression after HA injection (data not shown).

HA Reduces 5mC at the Exons Regions of Genes Associated With DA Differentiation

Next, we asked if HA affected epigenetic modifications associated to DNA. By bisulfite sequencing, we evaluated the DNA methylation patterns in HA-treated embryos, after MB dissections (**Figure 2A**). We did not observe overall changes in the percentage of modified cytosines on *Th* gene, including exon 1, on HA-treated embryos, compared to vehicle-treated embryos, i.e., the percentages of modified bases were very similar (**Figure 2B**).

One limitation of bisulfite sequencing is that it does not allow discriminating between 5mC and 5hmC. Therefore, in order to evaluate both DNA modifications, we perform a MeDIP and hMeDIP, followed by qPCR in dissected VM (**Figure 2A**). Particularly, we focused on the intragenic regulatory regions of specification (*Lmx1a, Msx1, and Foxa2*) and differentiation (*Nurr1, Pitx3, and Th*) genes. We found that HA-injected embryos showed a significant decrease in 5mC at the exonic regions of the differentiation genes *Pitx3* and *Th*, compared to vehicle-treated embryos (**Figure 2C**). The 5hmC did not show significant changes on specification or differentiation genes neither in HA- nor in vehicle-treated embryos (**Figure 2D**).

HA Treatment Is Associated With an Increase in the H3K9me3 and H3K27me3 Histone Modifications

Due to the histone post-translational modifications may also participate in the modulation of gene expression, we decided to study two particular histone modifications the H3K9 trimethylation (H3K9me3) and H327 trimethylation (H3K27me3). In order to evaluate the effect of HA treatment in the histone modifications H3K9me3 and H3K27me3 we performed a chromatin immunoprecipitation assay (ChIP) after the HA or vehicle treatment, and then evaluate the immunoprecipitated DNA by qPCR analyzing the above-mentioned regions of *Pitx3* (**Figure 2E**) and *Th* (**Figure 2F**) genes. We found that HA-injected embryos showed a significant increase of H3K9me3 and H3K27me3, in contrast with vehicle-treated embryos (**Figures 2E,F**).

HA Injection Has a Long-Term Effect During the Formation of Midbrain Dopaminergic Pathways

We set out to investigate if the effect of HA on mDA 2-days after its injection has a long-term consequence, affecting the formation of nigrostriatal pathway. *In utero* injections of E12 embryos with either HA or vehicle were made, and the embryos were collected after 6 days, when normal development of the nigrostriatal pathway has reached the striatum. TH staining in sagittal sections or whole-mount immunohistochemistry was analyzed in E18 brains. A single injection of HA at early stages was enough to alter the formation of the nigrostriatal pathway; in vehicle-injected embryos, the MFB is apparently normal, whereas after HA administration a decrease in this bundle is observed and aberrant axons innervating the *thalamus* appeared (solid rectangles in **Figure 3A**). To comprehensively analyze the mesencephalic dopaminergic pathways, TH immunohistochemistry was performed in whole-brain mounts. Image analysis was used to quantify the indicated areas positive for TH within the dotted rectangles shown in **Figure 3B**. HA caused a significant reduction in the TH-positive area in the midbrain and the striatum/nucleus accumbens/cortex when compared to vehicle-injected embryos (**Figure 3C**). Also, the quantification of dopamine by HPLC assay in the striatal area

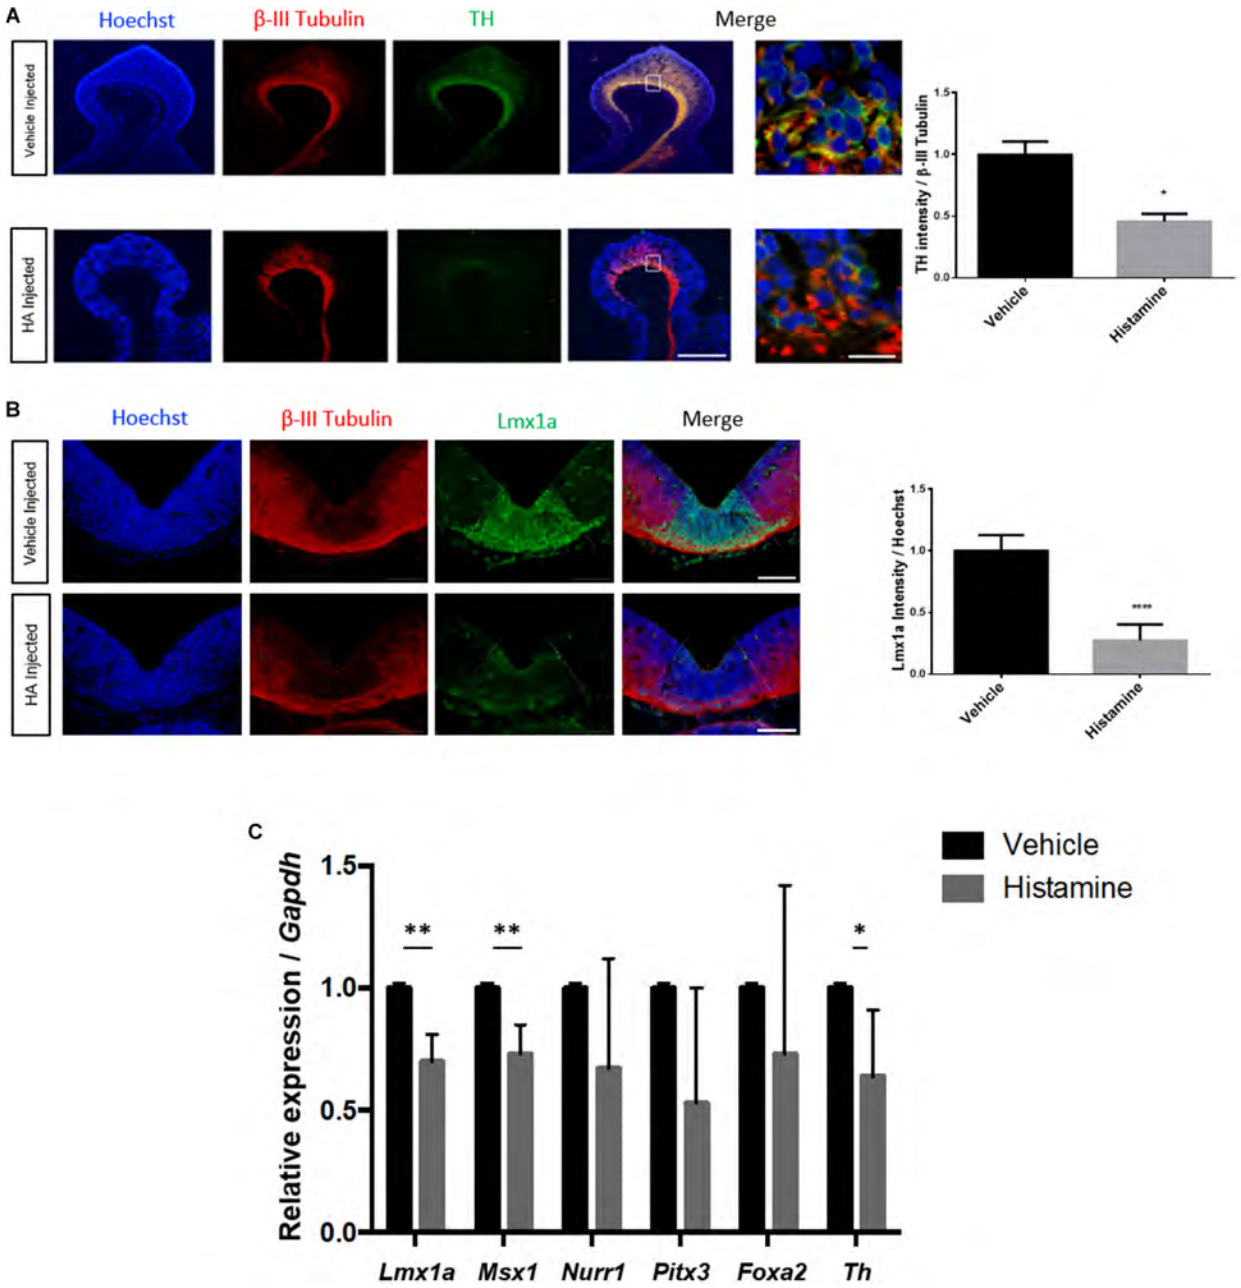

FIGURE 1 | HA decreases TH and Lmx1a immunoreactivity and down-regulates dopaminergic genes in the ventral midbrain (VM) after *in utero* injection. Rat embryos were injected at E12 and analyzed 2 days later. **(A)** Immunohistochemistry showing a significant decrease, caused by HA, in the DA marker TH, in sagittal sections. The neuronal marker β-III Tubulin was unaffected by HA, and was used to normalize TH immunoreactivity. Nuclei were detected with Hoechst. The white square in the merge image is expanded on the right. Scale bar: 150 μm in the low-magnification and 10 μm in the amplification. **(B)** HA significantly reduces the area positive for the dopaminergic progenitor marker Lmx1a, without affecting β-III Tubulin. The quantification of Lmx1a intensity was normalized by the Hoechst signal. The area of Lmx1a-positive DA progenitor cells is delimited by the dotted lines and was dissected to perform RT-qPCR. Scale bar: 200 μm. **(C)** Expression of genes involved in DA differentiation after intrauterine HA or vehicle administration, analyzed at day E14. Data was normalized by *Gapdh* expression. Vehicle-treated embryos were used as the reference for the $2^{-}\Delta\Delta Ct$ analysis. Graphs represent the mean values with SEM from 3 **(A,B)** to 5 **(C)** independent experiments. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{****}p < 0.0001$.

shows a 19% non-significant reduction in HA injected animal compared to vehicle (**Figure 3D**). Together our data suggest that HA injection leads to a decrease in TH staining in the forebrain, which might result in lower dopamine release.

DISCUSSION

Brain development is initiated by formation of defined patterns in the neural ectoderm. As development proceeds, stem

Regions with differences between the two experimental conditions in the nigrostriatal pathway are marked with the white rectangles. ST, *striatum*; SN, *substantia nigra*. Scale bar: 500 μm. **(B)** Ventral views of the whole-mount TH immunostainings of E18 brains from embryos injected with vehicle or HA. The midbrain area within the dotted purple lines, the Medial Forebrain Bundle (MFB) area within the dotted blue lines and the Striatum/Cortex area within the dotted orange lines, are amplified in the intermediate panels, and were used to measure the area of TH staining in 4 independent experiments. Scale bar: 1 mm. **(C)** Quantification of TH staining area of Midbrain, MFB and Striatum/Cortex (this region also includes the Nucleus Accumbens). $*p < 0.05$ and $***p < 0.005$. **(D)** Dopamine content quantification in the striatum of vehicle- or HA-injected embryos by HPLC. The dissection of this area was performed at E18 making sure to remove the cerebral cortex and the basal part of the brain. Solid and empty bars apply to panels **C,D**.

cell differentiation to neurons is defined by the action of morphogenic gradients and transcription factors, expressed in a temporal and sequential order (Gale and Li, 2008). In cultured cortical NSPC, HA has a neuronal-promoting action, involving up-regulation of proneural genes (Molina-Hernández and Velasco, 2008; Rodríguez-Martínez et al., 2012). However, HA administration *in vivo* diminishes proliferation of midbrain NSPC, down-regulating *Th* mRNA levels and the content of

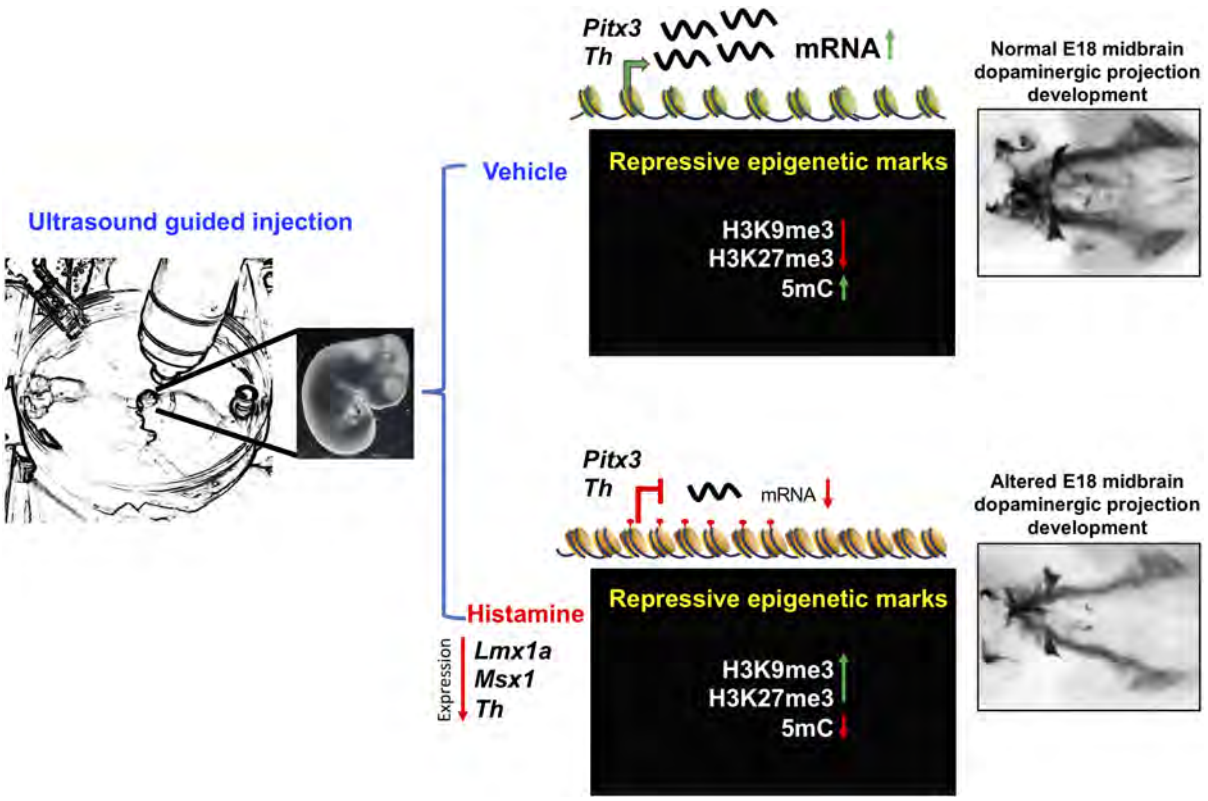

FIGURE 4 | Proposed mechanism of HA action on the regulation of late mDA differentiation genes. Intrauterine administration of HA into the MB of E12 rat embryos, decreases the expression of specification and differentiation dopaminergic genes, such as *Lmx1a*, *Msx1*, and *Th*. The decrease in *Th* expression induced by HA was correlated with the gain of histone repressive marks, H3K27me3 and H3K9me3, together with the loss of 5mC at intergenic regulatory regions. The down-regulation of these key dopaminergic differentiation genes, particularly *Th*, resulted on the alteration of the midbrain dopaminergic projection development at E18.

TH, Lmx1a, and Lmx1b assessed by western blot, 2 days after injection (Escobedo-Avila et al., 2014), but the mechanisms for these actions are just emerging (Molina-Hernández et al., 2013). In the current work, we administered embryos with either HA or vehicle, on a stage previous to the major production of DA neurons (Götz and Huttner, 2005), by ultrasound guided-injections. Injection of HA diminishes the presence of TH as well as the transcription factor Lmx1a in the VM.

Recently, studies about the influence of environment on epigenetics and its importance with regards to the expression of transcription factors during cell commitment have emerged. Regulation of the deposition of 5hmC in intragenic regions during progression of embryonic stem cells to NSPC is crucial for the development of mDA neurons (Kim et al., 2014). In dopaminergic neurons, methylation in one specific CpG site on the first exon of human *TH* gene down-regulates its transcription, allowing the binding of repressive transcription factors such as KAISO and NcoR and recruitment of HDACs, which might act as an additional modulator of *Th* expression (Arányi et al., 2005; van Heesbeen et al., 2013). We found that HA injection significantly decreased expression of early-differentiation genes (*Lmx1a* and *Msx1*) as well as in *Th*, a late canonical mDA differentiation gene.

Presence of 5mC and 5hmC within the exonic regions have been associated with up-regulation of gene expression, through different mechanisms (Hahn et al., 2013; Guo et al., 2014; Kim et al., 2014). Our findings reveal that injection of HA at early stages significantly diminish the percentage of enrichment of 5mC, but only on the differentiation genes *Pitx3* and *Th*. Although DNA methylation has been related to transcriptional repression, in recent years, some reports showed that 5mC within the gene body, specifically in exons, is associated to regulation of pre-mRNA splicing (Lev Maor et al., 2015). Other studies associated the gain of 5hmC at intergenic regions with transcriptional activation of neuronal differentiation genes (Hahn et al., 2013; Guo et al., 2014). We did not observe changes on 5hmC levels, indicating that HA induced gene repression independent of 5hmC, and suggesting that other epigenetic mechanisms participate in mDA gene regulation. Interestingly, many genes associated with neuronal differentiation can be negatively regulated by decreasing 5mC and a gain in histone repressive modifications, such as H3K27me3, at their regulatory regions (Hahn et al., 2013).

During mDA differentiation, epigenetic changes occur in cultured VM NSCP: Nurr1-controlled dopaminergic gene expression was precluded by the interaction of Nurr1 with CoREST and HDAC1, a complex that caused deacetylation of these promoters. Forced expression of Foxa2 allowed the formation of Nurr1-Foxa2 complexes with concomitant

acetylation of H3, associated to open chromatin, in *Th* and *Dat* promoters (Yi et al., 2014). *In vitro* expansion of VM NSCP caused decreased dopaminergic differentiation, which was associated with hypoacetylation on H3 and H4 and increased H3K27me3 in the Foxa2 promoter, as well as globally. Inhibition of HDAC activity up-regulates *Foxa2* transcripts, caused H3 acetylation, decreased methylation of H3K27 and restored dopaminergic induction (Bang et al., 2015). We observed significant increases in the repressive marks H3K27me3 and H3K9me3 in *Pitx3* and *Th* genes, although significant down-regulation was observed only in *Th*. Similar observations were recently reported by Hong et al. (2019), where they manipulated *in vitro* the levels of H3K27me3 in the promoter region of *Th*: treatment with EPZ005687, an inhibitor of histone methylase EZH2 reduces the levels of H3K27me3 and leads to an increase in TH levels; conversely, addition of GSK-J1, which affects the demethylase activity of Jmjd3, augmented H3K27me3 and decreased TH protein levels (Hong et al., 2019). Our data points that not only the H3K27me3 is involved in the regulation of *Th*, but also H3K9me3 participate.

We studied the long-term consequence of deregulation of such genes, in the formation of the MFB, and found that injection of HA caused disrupted and miss-oriented dopaminergic fibers in sagittal sections. Further, a significant reduction in TH-positive staining was found in the MB and the striatum/cortex after HA treatment, in whole-brain mounts. However, we did not observe a complete deterioration of the nigro-striatal, mesolimbic and mesocortical pathways, probably due to the plasticity of the developing brain; accordingly, dopamine level in the striatum were not reduced by HA. In newborn rats injected with 6-hydroxydopamine to degenerate mDA neurons, there is an increase in serotonergic projections (Snyder et al., 1986) and lesioned animals were hyperactive (Miller et al., 1981; Zhang et al., 2001; Avale et al., 2004). It will be of interest to analyze if embryos injected with HA at E12 show changes in locomotor activity at postnatal stages.

The precise mechanisms that link HA and the epigenetic changes reported here deserve further investigation. In cultured VM-NSPC, it has been shown that membrane depolarization and calcium influx is correlated with higher acetylation of Histone 3, trimethylation of K4 of H3 with reductions in the H3K9me3 and H3K27me3 marks (He et al., 2011). HA triggers intracellular calcium increases after receptor activation in VM-NSPC, through production of IP3 and Diacylglycerol by Phospholipase C, but the effects reported here are in the opposite direction: addition of the transcriptional repressive H3K9me3 and H3K27me3; additional signaling transduction mechanism to explore include Phospholipase A2/arachidonic acid production and nitric oxide production/cGMP increases (Molina-Hernández et al., 2012). On the other hand, the participation of the transient population of histaminergic neurons of the raphe nucleus or in the hypothalamus (Vanhala et al., 1994), and the activation of microglia after HA administration, as observed in adult mice (Rocha et al., 2016), cannot be ruled out in our experiments; therefore, it will be interesting to determine their roles in future experiments by ablating HA-producing neurons or microglial cells, respectively. All together, the data reported here describe molecular effects of HA on dopaminergic midbrain development. The reduction in expression of dopaminergic genes correlates with gain of the repressive modifications H3K9me3 and H3K27me3 and the loss of DNA methylation at intergenic regions in *Th*. Moreover, HA induced long-term alterations on mDA neurons, as shown in **Figure 4**. Our results suggest that HA promotes an epigenetic change related to significant reductions in the expression of important dopaminergic genes. Such alterations result in anatomical dysregulation and decreased TH staining in the dopaminergic neurons targets.

In conclusion, this study contributes to the understanding of the molecular actions of HA on mDA development, as well as chromatin structure regulation mediated by extracellular stimuli, during NPSC commitment in the midbrain; such knowledge may contribute to establish different roles of HA during brain development.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

This study was carried out in accordance with Mexican guidelines and following recommendations of Instituto de Fisiologia Celular, UNAM Animal Care and Use Committee, which approved this protocol.

AUTHOR CONTRIBUTIONS

FV-R wrote the manuscript, analyzed the data and performed the majority of experiments, including epigenetics, whole mount stainings and dopamine quantification. LG-C and RG-B performed RT-qPCR and ChIP assays, contributed to the design of experiments and discussion of results. IE-A helped to perform intrauterine injections, data analysis and participated on discussion of results. DC-P contributed to set up techniques, performed results analysis and discussed results. AL-O and LR participated in dopamine quantification by HPLC. IV and ES-R contributed to the experimental design and supervision, reviewed the manuscript, and obtained funding. All authors read and approved the final manuscript.

FUNDING

This work was supported by grants from Dirección General de Asuntos del Personal Académico, Universidad Nacional Autónoma de México (PAPIIT IN213716 and IN213719), Consejo Nacional de Ciencia y Tecnología (CONACyT, CB09/131281), and Red Temática Células Troncales y Medicina

Regenerativa to IV. ES-R was supported by grants from Fondo Sectorial de Investigación en Salud y Seguridad Social (FOSISS, 0261181) and CONACyT (182997 and 284748). Fernanda Vargas-Romero and Lissania Guerra-Calderas received a graduate fellowship from CONACyT (662044 and 588391, respectively).

ACKNOWLEDGMENTS

We thank Dr. Alfredo Varela Echavarría, Dr. Luis A. Herrera Montalvo, and Jorge Landgrave-Gómez M.Sc., for continuous discussion and advice. We also thank the technical support of Francia Carmona B.Sc.

Lactate oxidase

ABSTRACT

Liver slices from starved rats and incubated without other substrates oxidized ethanol at a rate of 4.1 μmols • h^{-1} • g^{-1}. Addition of 10 mmols • L^{-1} lactate increased this rate 2-fold. 4-methylpyrazole (4-MP), an alcohol dehydrogenase (ADH) inhibitor, drastically decreased the rate of ethanol oxidation, but did not inhibit the stimulation due to lactate. In the same context, liver acetaldehyde production, as the main by-product of ethanol oxidation, appeared to be much less inhibited by 4-MP in the presence of lactate. Aminotriazole (a catalase inhibitor), however, completely inhibited the stimulation. Furthermore, 2-hydroxybut-3-ynoate, an alpha-hydroxy acid oxidase inhibitor, completely abolished the stimulated ethanol oxidation promoted by lactate. Moreover, to determine the origin of the H_2O_2 produced, we did liver subcellular fractionation and then analyzed their content in peroxisomes, mitochondria and catalase. We observed that cytoplasm and peroxisomes appears to be the main producers of H_2O_2, and that the acceleration of ethanol oxidation by lactate is completely dependent on catalase. In conclusion, the H_2O_2 necessary to boost the catalase-dependent oxidation of ethanol appears to come from cytoplasm and peroxisomes, and is produced by the enzyme lactate oxidase.

1. Introduction

Most of the oxidation of ethanol to acetaldehyde in the liver is catalyzed by the cytoplasmic enzyme alcohol dehydrogenase (ADH), with the concomitant reduction of $NAD^{\pm}$ to NADH [1,2]. It is well known that the dissociation of the ADH-NADH complex is the rate-limiting step in this reaction [1,3-5]. This has suggested that the rate of oxidation of NADH, mostly through the respiratory chain, is what determines the overall rate of ethanol metabolism [1].

In emergency medicine, in ethanol-intoxicated trauma the onset of metabolic acidosis is often attributed to serum ethanol. Despite ethanol intoxication being associated with acidosis, this event does not necessarily correlate with the rate of lactic acidosis [6]. During hemorrhage, ethanol blunts the respiratory and metabolic compensation resulting in a more severe lactic acidosis, and administration of additional lactate during intoxication and hypovolemia for hemodynamic stabilization may exacerbate a metabolic stress [7].

In turn, lactate has been known to increase the oxidation of ethanol both in vivo and in vitro [8,9]. However, the oxidation of lactate to pyruvate through lactate dehydrogenase (LDH) generates NADH, so it should be expected to slow the metabolism of ethanol, since the NADH produced would inhibit ADH [8]. This paradox has readily prompted two hypotheses to explain the lactate stimulation of ethanol oxidation:

i Lactate increases the concentration of the components of the malate-aspartate shuttle, which increases the rate of transport of reducing equivalents to the mitochondrial matrix [8,9], and
ii Lactate increases the ATP demand through gluconeogenesis, which increases the rate of oxidation of NADH in the respiratory chain [10,11].

In addition, we have demonstrated that an increased rate of hepatic ethanol metabolism resulting from purines administration is due to a coupled oxidation-reduction reaction between H_2O_2 and alcohol, where catalase activity plays a relevant role oxidizing ethanol by reducing hydrogen peroxide [12].

Indeed, our present results indicate that neither increased ATP demand nor increased malate-aspartate shuttle activity play a role on the lactate stimulation of ethanol oxidation in the liver. We instead found that lactate increases the oxidation of ethanol through catalase, coupled to a putative activity of a hepatic lactate oxidase (LOx).

INFORME DE LABORES 2019

2. Materials and methods

2.1. Substrates and inhibitors

Ethanol was used at a final concentration of 10 mM Aminotriazole was used at final concentration of 10 and 20 mM. 4-methylpyrazole (4-MP) was used at 1 mM. Lactate was used at concentrations between 5 and 20 mM in slices and at 20 mM in homogenate fractions and 2-hydroxybut-3-ynoate (2H3) was used at 1 mM. All chemicals were purchased from Sigma (Sigma-Aldrich México), except for 2-hydroxybut-3-ynoate, which was purchased from Enamine LLC (Monmouth, NJ).

2.2. Animals, incubation technique and determinations

Male Wistar rats (250–270 g) fed *ad libitum* were used for all experiments. Rats were anesthetized with sodium pentobarbital and the heart was perfused with cold Krebs buffer to remove the blood from the liver. The liver was then removed and sliced with a chopper, and about 500 mg of liver slices were placed in a 25 ml Erlenmeyer flask containing 5 ml of cold Krebs buffer, pH 7.4, to which ethanol was added to a final concentration of 10 mM. The flasks were placed in a shaking bath at 37 °C. After a pre-incubation period of 30 min, L-lactate was added to a final concentration of 5, 10 or 20 mM and the slices were incubated for a further 3 h. Samples of 160 µl were taken from each flask every hour. Perchloric acid at 16% was used to deproteinize the sample, which was later used for the enzymatic determination of ethanol and lactate. All procedures were performed according to the *Federal Regulations for Animals Care and Experimentation* (Ministry of Agriculture, SAGARPA).

2.3. Subcellular fractionation of liver

The homogenization buffer consisted of 250 mM sucrose, 5 mM MOPS and 1 mM EDTA. We homogenized and fractionated the liver into 4 fractions: A, B, C and P. Fraction A was the supernatant resulting from centrifuging the homogenate at 2,000 g to eliminate nuclei and cellular debris [13]; fraction B was the supernatant resulting from centrifuging fraction A at 25,000 g to eliminate peroxisomes [14]; fraction C was the supernatant resulting from centrifuging fraction B at 100,000 g to eliminate the rest of the mitochondria as well as microsomes, leaving only the cytosol [14,15]. The pellet resulting from the centrifugation at 25,000 g is called the crude peroxisomal fraction (CPF), and was used to isolate peroxisomes in an iodixanol gradient (fraction P), according to a manufacturer's indications of a Peroxisome isolation kit (Sigma Chemical Co.). In addition, we also used a hypotonic buffer with sucrose 25 mM to homogenize the liver with the intent of breaking organelle membranes, and it was centrifuged at 2000g to eliminate debris (the same as fraction A). The supernatant therefore represents 100% of the total activity of adenylate kinase [16]. For the incubation with ethanol and lactate (20 mM), fractions A, B and C were diluted in a 1:1 ratio with homogenization buffer, while fraction P was diluted to a final protein concentration of 1.3 mg/ml.

2.4. Enzymatic assays

The uricase activity was measured by incubating the respective fraction diluted in homogenization buffer in the presence of 1 mM potassium urate for 10 min at 37 °C. Samples were taken every 2 min and the remaining urate was measured with a kit. That of succinate dehydrogenase (SDH) was measured at room temperature in 1.25 ml of 75 mM potassium phosphate buffer, pH 7.4; succinate 48 mM; KCN 2 mM; dichlorophenolindophenol 0.06 mM and phenazine methosulfate 1.08 mM. The reaction was started by adding 5 µl of the respective fraction and lasted 5 min, and followed through DCPIP reduction at 600 nm [17]. The catalase activity was measured at room temperature by incubating the respective fraction in 1 ml of 75 mM potassium phosphate buffer, pH 7.4. The reaction was started by adding 30 mM H_2O_2. The incubation lasted 2 min. The reaction follows H_2O_2 disappearance at 240 nm [18]. In addition, adenylate kinase (AK) activity was measured at room temperature by incubating homogenate (5 µl) in 1 ml of 100 mM TEA buffer, pH 7.5; 130 mM KCl; 6.2 mM MgSO4; 1.7 mM glucose; 0.2 mM $NADP^{\pm}$; 5 U of hexokinase, and 4 U of G6PD. The reaction was started by adding 1.3 mM ADP. The incubation lasted 5 min. The reaction follows $NADP^{\pm}$ reduction at 340 nm [19].

2.5. Quantification of ethanol, lactate, and lipid peroxidation by-products

Lactate was measured enzymatically. Briefly, 20 µl of $NAD^{\pm}$ (100 mM) and 2 µl of rabbit LDH (9.3KU/ml) were added to 980 µl of hydrazine buffer (final volume of 1 ml; pH 9.5). After 60 min incubation, absorbance was read at 340 nm [20]. Ethanol was measured enzymatically with a spectrophotometer. Briefly, 20 µl of $NAD^{\pm}$ (100 mM), 100 µl of thiosemicarbazide (100 mM) and 20 µl of yeast alcohol dehydrogenase (ADH; 988 units/ml) were added to 860 ml of glycine buffer (final volume of 1 ml; pH 9.0). After 10 min incubation, absorbance was read at 340 nm [21].

2.6. Statistical analysis

All data were analyzed by the Program GraphPad Prism, by using an ordinary one-way ANOVA and by a post hoc Newman-Keuls analysis, considering $p < 0.01$ as significant.

3. Results

3.1. Effect of lactate on liver ethanol oxidation

As expected, lactate increased the oxidation of ethanol in liver slices. The relation between lactate concentration and ethanol oxidation is shown in the Fig. 1A. The mean peak increase in ethanol metabolism in the presence of 10 mmols • L^{-1} lactate was of 4.28 µmols • h^{-1} • g^{-1} of liver in the fasted state. In the fed state the lactate stimulation was somewhat weaker, an observation that has already been reported [10], and it was not abolished by 4-MP (1 mmol • L^{-1} [22]), an ADH inhibitor (Fig. 1B). This suggests that the lactate stimulation is completely independent of ADH and NADH. Moreover, as shown in Fig. 1C, the concentration of acetaldehyde increases when the oxidation of ethanol is increased with lactate even in the presence of 4-MP. These results suggest that the lactate stimulation is completely independent of ADH and by extension, independent of NAD+.

3.2. Effect of 3-aminotriazole on lactate-stimulated ethanol metabolism by liver slices from fasted rats

We next used 3-aminotriazole (3AT), an irreversible catalase inhibitor (20 mmols • L^{-1} [23]). As seen in the Fig. 2A, 3AT completely inhibited the stimulation by lactate. This points out to a mechanism mediated by catalase, which also suggests that lactate is somehow causing the production of H_2O_2. The concentration of lactate was also determined in the incubation with lactate 5 mmols • L^{-1} (Fig. 2B). During the 3 h of incubation, the concentration of lactate did not change. Since lactate seems to stimulate the ethanol oxidation by H_2O_2 production, this could suggest that a lactate oxidase (LOx) may be catalyzing the oxidation of lactate to pyruvate, reducing O_2 to H_2O_2. Two lactate oxidases have been reported in the liver: a peroxisomal L-alpha-hydroxy acid oxidase capable of oxidizing lactate to pyruvate, generating H_2O_2, was reported by de Duve & Baudhuin [24]; also, de Bari et al. has reported the existence of a mitochondrial L-lactate oxidase localized in the mitochondrial intermembrane space [25]. Since to our knowledge these two enzymes are the only known capable of producing H_2O_2 from lactate, our attention focused on these two organelles.

INFORME DE LABORES 2019

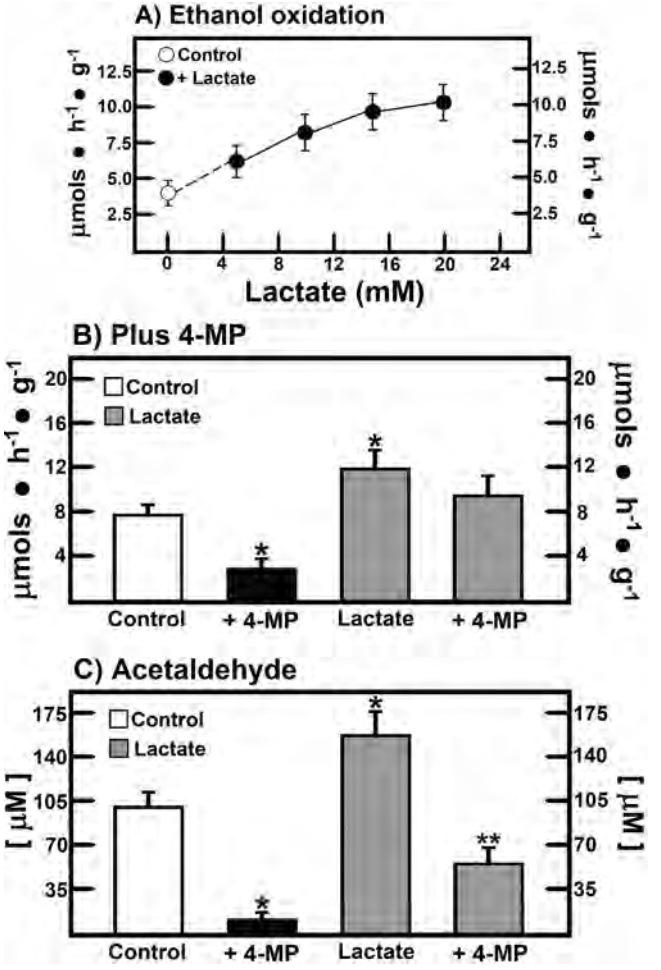

Fig. 1. Rates of ethanol oxidation in rat liver slices. Results are the mean ± SE of 4 individual observations per experimental group. In panel A, the time-curve for ethanol oxidation by liver slices from fasted rats in the presence of increasing concentrations of lactate. In panel B, the effect of 1 mmol • L^{-1} 4-methylpyrazole (4-MP) on ethanol metabolism by liver slices from fed rats in the presence or absence of lactate (20 mmols • L^{-1}); in panel C, the concentration of acetaldehyde produced from the slices is depicted. Experimental groups are designated by symbols at the upper of each panel. Statistical significance: *$p < 0.05$ vs. control group (no additions), and **$p < 0.05$ against the group with lactate.

3.3. Ethanol oxidation by liver subcellular fractions

To determine the origin of the H_2O_2 produced, we homogenized and fractionated the liver into 4 fractions: A, B, C and P. Every fraction was incubated in the presence of ethanol (10 mmols • L^{-1}), with or without lactate (20 mmols • L^{-1}). All fractions were analyzed for their content in peroxisomes, mitochondria, while fractions A, B, and C were analyzed for their catalase content, while fractions A and C were also analyzed for their content in adenylate kinase (Fig. 3A). Uricase was used as the marker of the peroxisomal fraction, succinate dehydrogenase was used as the mitochondrial marker, while adenylate kinase was used as the mitochondrial intermembrane space marker. We considered the enzyme activities of fraction A as 100% of the total. Interestingly, fraction B was very poor in peroxisome content compared to fraction A, though both fractions had similar content of mitochondria (Fig. 3A). Despite this, fraction B still showed a large stimulation in ethanol metabolism albeit smaller than that of fraction A (Fig. 3B). This suggests that peroxisomes are not the main producers of H_2O_2, and it also shows they are not needed for the stimulation (Fig. 3B). However, we wanted to know whether peroxisomes are able to oxidize ethanol by themselves in the presence of lactate.

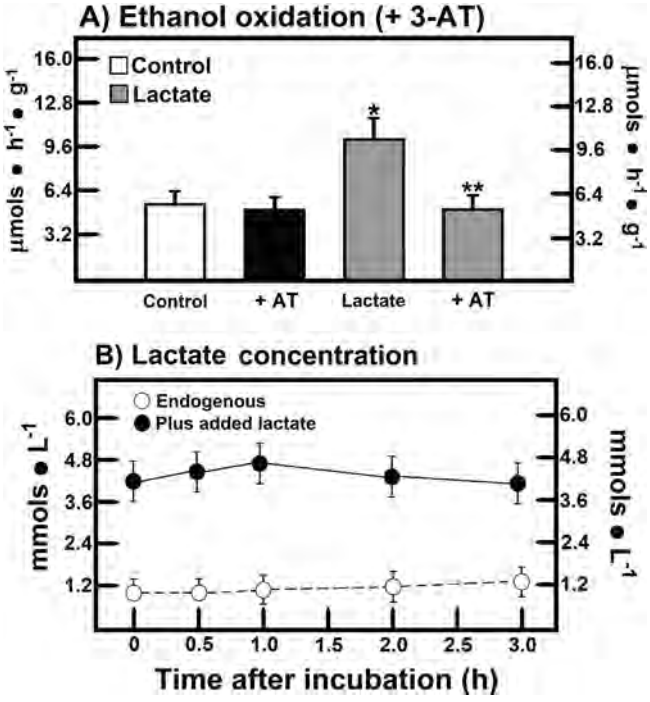

Fig. 2. Effects of lactate and aminotriazole on ethanol metabolism in liver slices from fasted rats. Results are the mean ± SE of 4 individual observations per experimental group in the presence of lactate (10 mmols • L^{-1}) and of 20 mmols • L^{-1} 3-aminotriazole (3-AT; panel A). In panel B, it is shown the lactate concentration from supernatant of liver slices from fasted rats in the presence or absence of lactate (5 mmols • L^{-1}). Abbreviations: 3-AT = 3-aminotriazole. Experimental groups are designated by symbols at the upper of each panel. Statistical significance as indicated in Fig. 1.

3.4. Rate of ethanol oxidation in purified peroxisomes (P)

From the CPF, peroxisomes were isolated using an iodixanol gradient. Purified peroxisomes (fraction P) were incubated with ethanol (10 mmols • L^{-1}) and lactate (20 mmols • L^{-1}) at a final concentration of 1.3 mg • ml^{-1} (at this concentration, the amount of peroxisomes is very similar to that of fraction A, as determined by the activity of uricase). As shown in Fig. 3B, peroxisomes by themselves showed a poor increase in ethanol metabolism in the presence of lactate. Even though the concentration of peroxisomes was much greater than in fraction B, and almost the same as fraction A (Fig. 3A), the lactate-induced increase in ethanol metabolism with purified peroxisomes was less than half that of fraction B. Once more, these results suggest that peroxisomes are not the main producers of H_2O_2, but it also shows that they, by themselves, can contribute somehow to the lactate stimulation of ethanol oxidation.

Fraction C showed negligible SDH and uricase activities, but it showed ample catalase activity (Fig. 3A). Strangely, this fraction also showed a stimulation of ethanol oxidation in the presence of lactate as large as fraction B (Fig. 3B). The putative mitochondrial LOx is localized in the intermembrane space [25], and because SDH is exclusively an internal membrane marker, it says nothing about the integrity of the outer membrane. Therefore, there existed the possibility that the outer membrane was broken during the fractionation, liberating the LOx into the cytosol [26]. To test this, we used AK as a marker of the intermembrane space. We used a hypotonic homogenizing buffer with a sucrose concentration of 25 mmols • L^{-1} to homogenize the liver and break the outer mitochondrial membrane [19]. The homogenate was centrifuged at 2000g (the same as A). As this fraction contains ruptured organelles, its content of AK is considered as 100% of the total. As

INFORME DE LABORES 2019

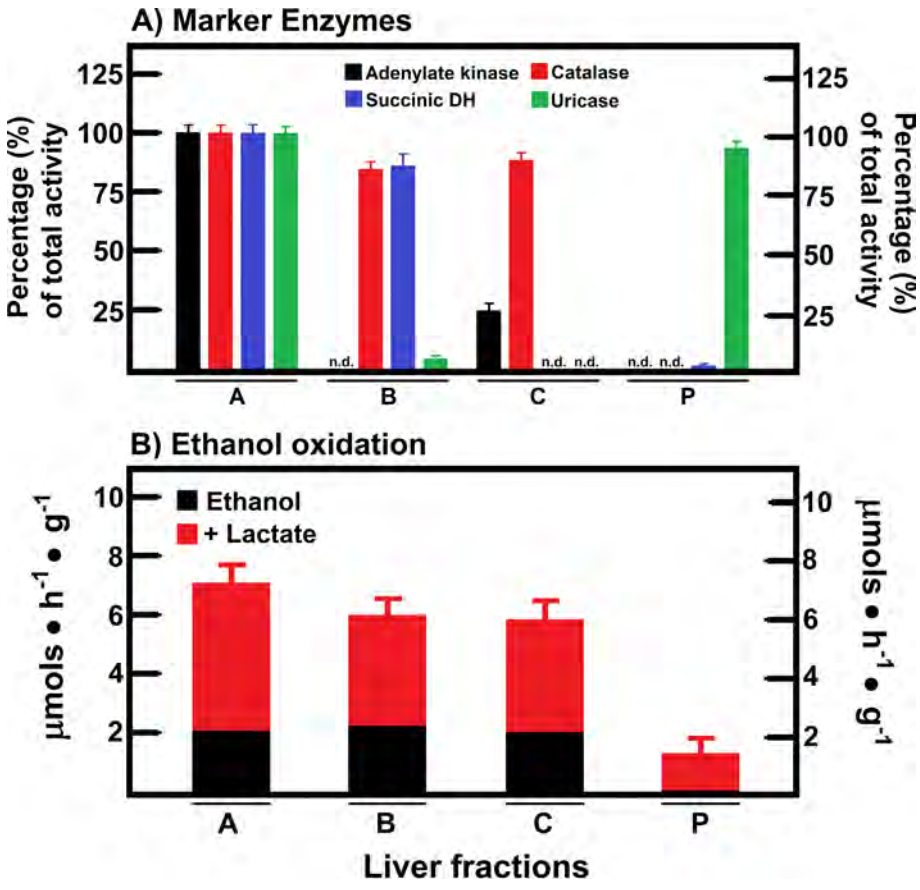

Fig. 3. Ethanol oxidation by liver subcellular fractions identified by "marker enzyme" activities. Results are the mean ± SE of 4 individual observations per experimental group. In panel A, there are shown enzyme activities (adenylate kinase, catalase, succinic dehydrogenase, and uricase) expressed in IU • g^{-1} of liver tissue, where an international unit is defined as the rate corresponding to catalysis of 1.0 µmole of substrate per min. Enzyme activities were to test purity of liver fractions: A) whole homogenate, B) Post-peroxisomes fraction, C) Cytosol, and P) Peroxisomal fraction. Panel B depicts ethanol metabolism by liver fraction B (Post-peroxisomes fraction) in the presence (red) or absence (black) of lactate (20 mmoles • L^{-1}). n.d. = non-determined. Experimental groups are designated by symbols at the upper of each panel. Statistical significance: *p < 0.05 vs. control group (no additions). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

shown in Fig. 3A, the activity of AK from fraction C is 27.7% that of fraction A. Since around 20% of the total AK activity is localized in the cytoplasm and around 70% is located in mitochondria [19], our value of 28% is just above the expected level. Therefore we can conclude that the cytosolic fraction is largely uncontaminated with contents from the mitochondrial intermembrane space.

Since 3AT is not a specific inhibitor of catalase [27], we needed to rule out the possibility that it was inhibiting CYP450. We took advantage of the ability of ethanol to protect catalase from inhibition [28]. Fraction B was incubated in the presence of 20 mmols • L^{-1} of lactate and 10 mmols • L^{-1} 3AT for 20 min to eliminate all catalase present, after which 10 mmols • L^{-1} ethanol was added. Freshly prepared bovine catalase was then added to a final concentration of 4 mg • ml^{-1} (8–20 KU • ml^{-1}). Because there is ethanol present, it now prevents the inhibition of the bovine catalase. As seen in Fig. 4, the addition of catalase completely restored the lactate stimulation; while in the absence of lactate, catalase did not modify the rate of ethanol oxidation. Moreover, adding more catalase in the absence of 3AT does not cause a larger increase in the presence of lactate.

Finally, to show that the enzyme responsible for the lactate stimulation is indeed lactate oxidase, we used 2-hydroxybut-3-ynoate (2H3), a specific and potent irreversible inhibitor that only targets flavin-dependent α-hydroxy acid oxidases, including lactate oxidase [29-31]. Fraction B was incubated in the presence of 1 mM of 2H3 for 15 min to inhibit lactate oxidase, after which lactate and ethanol were added to a final concentrations of 20 and 10 mM, respectively. As seen in Fig. 5, the addition of 2H3 completely inhibited the lactate stimulation; while in the absence of lactate, 2H3 did not modify the rate of ethanol oxidation.

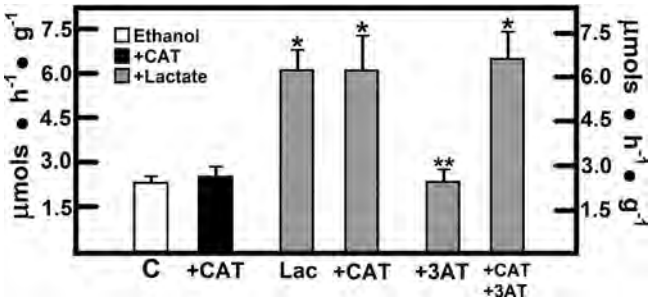

Fig. 4. Rate of ethanol oxidation by the liver post-peroxisomes fraction (B). Results are the mean ± SE of 4 individual observations per experimental group, indicated at the top of the Figure. The additions were: lactate (20 mmoles • L^{-1}), 3-aminotriazole (10 mmoles • L^{-1}), as well as of catalase (4 mg • ml^{-1}). Abbreviations: C = Control, Lac = lactate, CAT = catalase, and 3-AT = 3-aminotriazole. Statistical significance: *p < 0.05 vs. control group (no additions), and **p < 0.05 against the group with lactate.

4. Discussion

The addition of lactate doubled the oxidation of ethanol at 10 mmols • L^{-1} in slices from fasted liver. We found that the inhibition of ADH by 4-MP does not abolish the lactate stimulation. Therefore it can be concluded that the lactate stimulation is completely independent from ADH. On the other hand, 3AT did inhibit the lactate effect, suggesting that the effect is dependent on catalase.

3AT also inhibited the effect during the incubation of fraction B; however, the effect was completely restored when 8–20 KU • ml^{-1} of bovine catalase were added. The addition of catalase by itself (in the absence of 3AT) did not cause an increase in ethanol metabolism in both the absence or presence of lactate, showing that catalase is not rate-limiting. This confirms that catalase is the only ethanol-oxidizing

INFORME DE LABORES 2019

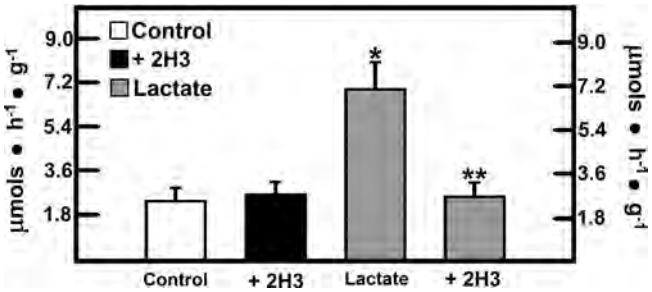

Fig. 5. Rate of ethanol oxidation by the liver post-peroxisomes fraction (B) in the presence of 2H3. Results are the mean ± SE of 4 individual observations per experimental group, indicated at the top of the Figure. The additions were: lactate (20 mmoles • L^{-1}) and 2H3 (1 mmoles • L^{-1}). Abbreviations: C = Control, Lac = lactate and 2H3 = 2-hydroxybut-3-ynoate. Statistical significance: *p < 0.05 vs. control group (no additions), and **p < 0.05 against the group with lactate.

enzyme involved in the lactate-stimulated ethanol oxidation and that aminotriazole is not interfering with any other part of the mechanism. Most importantly, the addition of 2H3 also inhibited the lactate stimulation during incubation of fraction B. 2H3 specifically inhibits flavin-containing α-hydroxy acid oxidases, meaning that this inhibitor can't target the NADH-requiring LDH [32]. This leaves lactate oxidase and membrane-attached lactate dehydrogenase as the only flavin-dependent enzymes capable of oxidizing lactate. However the latter is found only in mitochondria and can only oxidize D-lactate [33]. Since 2H3 by itself does not modify the rate of ethanol metabolism, this conclusively shows that lactate oxidase is responsible for the lactate stimulation observed in this study.

Peroxisomes were not able to oxidize ethanol by themselves, but in the presence of lactate they were able to, presumably due to the putative peroxisomal LOx. However, as evidenced by fraction B, which is almost free of peroxisomes, they are not required to stimulate the oxidation of ethanol. The difference in stimulation between fractions A and B can be attributed to the presence of peroxisomes in fraction A, since the sum of the effects from fractions B and P is very close to that of fraction A. Therefore, peroxisomes significantly contribute to the increased oxidation of ethanol by lactate; furthermore, as shown by fraction C, mitochondria are also not required for the stimulation. Therefore, the cytoplasm appears to produce the bulk of the H_2O_2 generated by lactate while peroxisomes may contribute around 30% of the total stimulation. These results potentially suggest the existence of a cytoplasmic lactate oxidase with a much higher activity than the ones found in both peroxisomes and mitochondria.

The apparent lack of lactate consumption implies that lactate is being replenished as fast as it disappears. Since LDH is the only known enzyme capable of producing lactate, this suggests the possibility that the pyruvate produced by LOx is being reduced back to lactate. The metabolism of ethanol inhibits the Krebs cycle as well as the enzyme pyruvate dehydrogenase [1]; therefore, the metabolism of pyruvate becomes limited to its reduction to lactate and gluconeogenesis. The high NADH concentration due to ethanol metabolism would enhance the already favorable reduction of pyruvate to lactate [1], constantly replenishing the oxidized lactate.

That lactate can increase the oxidation of ethanol is an old albeit largely ignored idea [8,34]. However, the fact that it can do so through catalase is unexpected. The normal concentration of lactate in blood is around 0.5–2 mmols • L^{-1} [33,35] and it increases considerably when there is alcohol in the body [36], reaching up to 15 mmols • L^{-1} during a condition known as alcohol-associated lactic acidosis [37], and may reach up to 25 mmols • L^{-1} during exercise [38]. Crow et al. [8] have shown that 1 mmol • L^{-1} of lactate is enough to significantly increase the oxidation of ethanol in isolated hepatocytes.

It has been shown that exercise can increase the rate of ethanol elimination in humans [1,39]; then, given the large increase in blood lactate due to exercise, it's possible that the increase in metabolism is due to an increase in H_2O_2 production. Since H_2O_2 is a reactive molecule and it is presumed to be deleterious to cells [40,41], one has to ask why the liver has an enzyme whose task is to produce it from such an abundant substrate. It is assumed that the main purpose of catalase is to eliminate H_2O_2 and keep it from building up [40]. However knockout mice and acatalasemic humans seem to develop normally and it is not clear whether they have increased sensitivity to oxidative stress [40,41]. It is known that H_2O_2 can function as a second messenger, including roles in insulin signaling and regeneration [42]; therefore lactate oxidase could be important for insulin signaling during exercise when the concentration of lactate is elevated or during hepatic regeneration. It is also known that besides eliminating H_2O_2, catalase also metabolizes various molecules, mainly xenobiotics, in a reaction dependent on H_2O_2, called the peroxidatic reaction [43,44]. Therefore, it is possible that the main role of catalase is to function as part of the metabolism of xenobiotics in the liver.

ABSTRACT

FFA4 (Free Fatty Acid receptor 4, previously known as GPR120) is a G protein-coupled receptor that acts as a sensor of long-chain fatty acids, modulates metabolism, and whose dysfunction participates in endocrine disturbances. FFA4 is known to be phosphorylated and internalized in response to agonists and protein kinase C activation. In this paper report the modulation of this fatty acid receptor by activation of receptor tyrosine kinases. Cell-activation with growth factors (insulin, epidermal growth factor, insulin-like growth factor-I, and platelet-derived growth factor) increases FFA4 phosphorylation in a time- and concentration-dependent fashion. This effect was blocked by inhibitors of protein kinase C and phosphoinositide 3-kinase, suggesting the involvement of these kinases in it. FFA4 phosphorylation did not alter agonist-induced FFA4 calcium signaling, but was associated with decreased ERK 1/2 phosphorylation. In addition, insulin, insulin-like growth factor-I, epidermal growth factor, and to a lesser extent, platelet-derived growth factor, induce receptor internalization. This action of insulin, insulin-like growth factor I, and epidermal growth factor was blocked by inhibitors of protein kinase C and phosphoinositide 3-kinase. Additionally, cell treatment with these growth factors induced FFA4-β-arrestin coimmunoprecipitation. Our results evidenced cross-talk between receptor tyrosine kinases and FFA4 and suggest roles of protein kinase C and phosphoinositide 3-kinase in such a functional interaction.

1. Introduction

G Protein-Coupled Receptors (GPCR) and Receptor Tyrosine Kinases (RTK) participate in the normal function of organisms and are also involved in the pathogenesis of multiple diseases. Interestingly, there is intense cross-talk among these receptor families, involving both positive and negative modulations. The molecular mechanisms of such cross-talks include the following: GPCR-induced shedding of RTK ligands from the plasma membrane, triggering RTK activation; RTK activation through intracellular GPCR-associated signaling cascades; the formation of GPCR-RTK complexes with subsequent joint receptor signaling, and GPCR signaling attenuation involving direct tyrosine phosphorylation by RTK; GPCR serine/threonine phosphorylation catalyzed by different protein kinases (see (Chen et al., 2008; Doronin et al., 2002b; García-Sáinz et al., 2010; García-Sáinz et al., 2008; Gavi et al., 2006; Gschwind et al., 2001; Medina et al., 2000; Pyne et al., 2007; Sun et al., 2018; Vázquez-Prado et al., 2003) and references therein).

Free Fatty Acid receptor 4 (FFA4, previously known as GPR120), is a GPCR that functions as a free fatty acid sensor that increases incretin secretion by intestinal cells; this modulates insulin release, contributing to glycemic control (Hirasawa et al., 2005). FFA4-deficient mice develop glucose intolerance, obesity, and fatty liver (Ichimura et al., 2012); expression of a dysfunctional variant of this receptor (R270H) is associated with obesity and other metabolic disturbances in humans (Ichimura et al., 2012). FFA4 activation exerts insulin-sensitizing and anti-inflammatory effects on cells (adipocytes and macrophages, respectively) and mice. All these data point to FFA4 as an attractive target for the development of drugs with potential therapeutic action for these metabolic disturbances (obesity, metabolic syndrome, diabetes mellitus) (Liu et al., 2015; Milligan et al., 2015; Sparks et al., 2014; Sun et al., 2010).

Human FFA4 receptors couples with Gαq/11 and activates phospholipase C, leading to the hydrolysis of phosphatidylinositol 4, 5-bisphosphate, generating inositol trisphosphate and diacylglycerol (Hirasawa et al., 2005). Inositol trisphosphate triggers calcium release from intracellular stores, whereas diacylglycerol, together with calcium, activates protein kinase C. There is also evidence that the

INFORME DE LABORES 2019

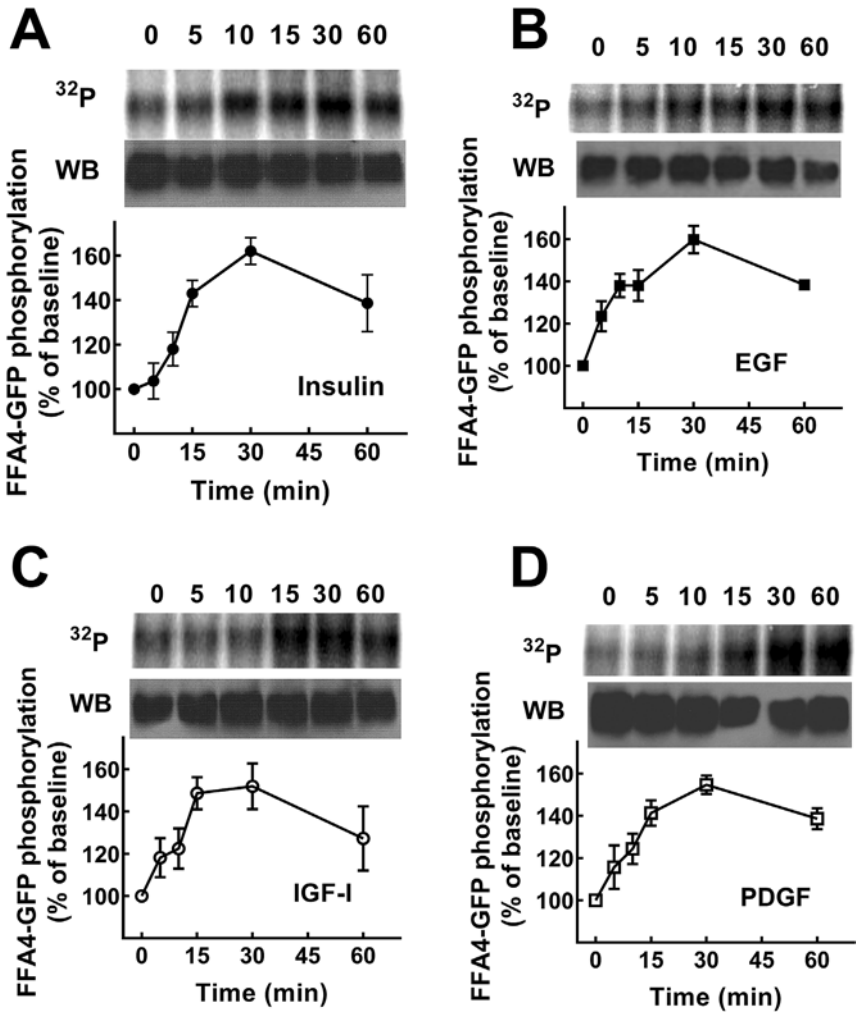

Fig. 1. Growth factor-induced FFA4 phosphorylation time-courses. Cells expressing GFP-tagged FFA4 receptors were incubated for the times indicated in the presence of 100 ng/ml of insulin (INS, panel A; n = 3), EGF (panel B; n = 4), IGF-I (panel C; n = 3) or PDGF (panel D; n = 3). Cells were lysed and receptor phosphorylation determined as indicated (section 2.4). In all cases the means are plotted with vertical lines indicating the S.E.M. of the indicated number (n) of independent experiments using different cell preparations. Representative autoradiographs (^{32}P) and Western blots (anti-GFP) are presented above each graph.

activation of FFA4 receptor induces extracellular signal-regulated kinases (ERK 1/2) activation. ERK 1/2 can be activated by a variety of signaling pathways, including those triggered by GPCR and RTK. The mitogen-activated protein kinase pathway is a master regulator that connects signals generated at the plasma membrane with the cell's nucleus, where cardinal events, such as differentiation and proliferation are controlled (Kolch, 2000). The FFA4 receptor interacts with β-arrestin (Watson et al., 2012), which participates in receptor desensitization and internalization.

Agonist stimulation and activation of protein kinase C induce FFA4 receptor phosphorylation and internalization (Burns and Moniri, 2010; Burns et al., 2014; Butcher et al., 2014; Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017). To the best of our knowledge, RTK-mediated modulation of the FFA4 phosphorylation state, cellular localization, and function has not been reported. In the present work, such a possibility was explored, and our data indicated that RTK-activation induces time- and concentration-dependent FFA4 phosphorylation and internalization and also affects its ability to induce ERK 1/2 activation.

2. Materials and methods

2.1. Materials

Docosahexaenoic acid, phorbol 12-myristate 13-acetate, insulin, insulin-like growth factor-I (IGF-I), wortmannin, and protease inhibitors were purchased from Sigma-Aldrich (St. Louis, MO, USA). Phosphate-free Dulbecco's modified Eagle's medium, fetal bovine serum, trypsin, antibiotics, and other reagents used for cell culture were from Life Technologies (Thermo Fisher Scientific; Carlsbad, CA, USA). Fura-2 AM and Dulbecco's Modified Eagle's Medium, were purchased from Invitrogen (Thermo Fisher Scientific; Carlsbad, CA, USA) and agarose-coupled protein A was from Upstate Biotechnology (Lake Placid, NY, USA). Bisindolylmaleimide I, Gö 6976, and LY294002 were obtained from Calbiochem (Merck-Millipore; Darmstadt, Germany) and platelet-derived growth factor (PDGF) and EGF were obtained from PreproTech (Rocky Hill, NJ, USA). [^{32}P]Pi (8,500–9,120 Ci/mmol) was obtained from PerkinElmer Life Sciences (Boston, MA, USA). Rabbit antisera against the Green Fluorescent Protein (GFP) were generated at our laboratory and have been previously characterized (Avendaño-Vázquez et al., 2005; Sánchez-Reyes et al., 2014). Rabbit polyclonal antibodies against total Extracellular signal-Regulated Kinases (ERK) 1/2 and phospho-ERK 1/2 were from Cell Signaling Technology (Danvers, MA, USA); anti β-arrestin 1/2 mouse monoclonal antibody was from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Secondary antibodies were purchased from Zymed (Thermo Fisher Scientific; Carlsbad, CA, USA) or Jackson ImmunoResearch Laboratories (West Grove, PA, USA). Chemiluminescence kits were from Millipore Corporation (Merck-Millipore; Darmstadt, Germany). Other materials were from previously

published sources (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017).

2.2. Cell lines

HEK 293-derived Flp-In T-Rex 293 cells were used to develop an inducible cell line expressing GFP-tagged human FFA4, as described previously (Hara et al., 2009; Hirasawa et al., 2005; Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017); receptor expression was induced by adding 1 μg/ml of doxycycline hyclate, 12–18 h before the experiments were performed. Cells were maintained in Dulbecco's modified Eagle's medium supplemented with fetal bovine serum and antibiotics, as described (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017).

2.3. Intracellular free calcium concentration

This was determined fluorometrically as described previously (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017). Briefly, cells were loaded with 2.5 μM Fura-2 AM in Krebs–Ringer–Hepes containing 0.05% fatty acid-free bovine serum albumin (pH 7.4) and then washed to eliminate unincorporated indicator with buffer without albumin. Determinations were carried out in an AMINCO-Bowman Series 2 luminescence spectrometer, employing 340- and 380-nm excitation wavelengths and an emission wavelength of 510 nm; the chopper interval was 0.5 s. The intracellular calcium concentration was calculated as described by Grynkiewicz et al. (1985).

2.4. FFA4 phosphorylation

The previously described procedure was used (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017). In brief, cells were incubated in phosphate-free DMEM containing 50 μCi/ml [^{32}P]Pi for 3 h at 37 °C. Labeled cells were stimulated as described and then washed twice with ice-cold phosphate buffered saline solution and solubilized in detergent- and protease and phosphatase inhibitor-containing buffer (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017). Lysates were incubated overnight with protein A-agarose and anti-GFP serum, with constant agitation at 4 °C. Samples were washed and the pellets were solubilized in Laemmli's sample buffer containing 130 mM

INFORME DE LABORES 2019

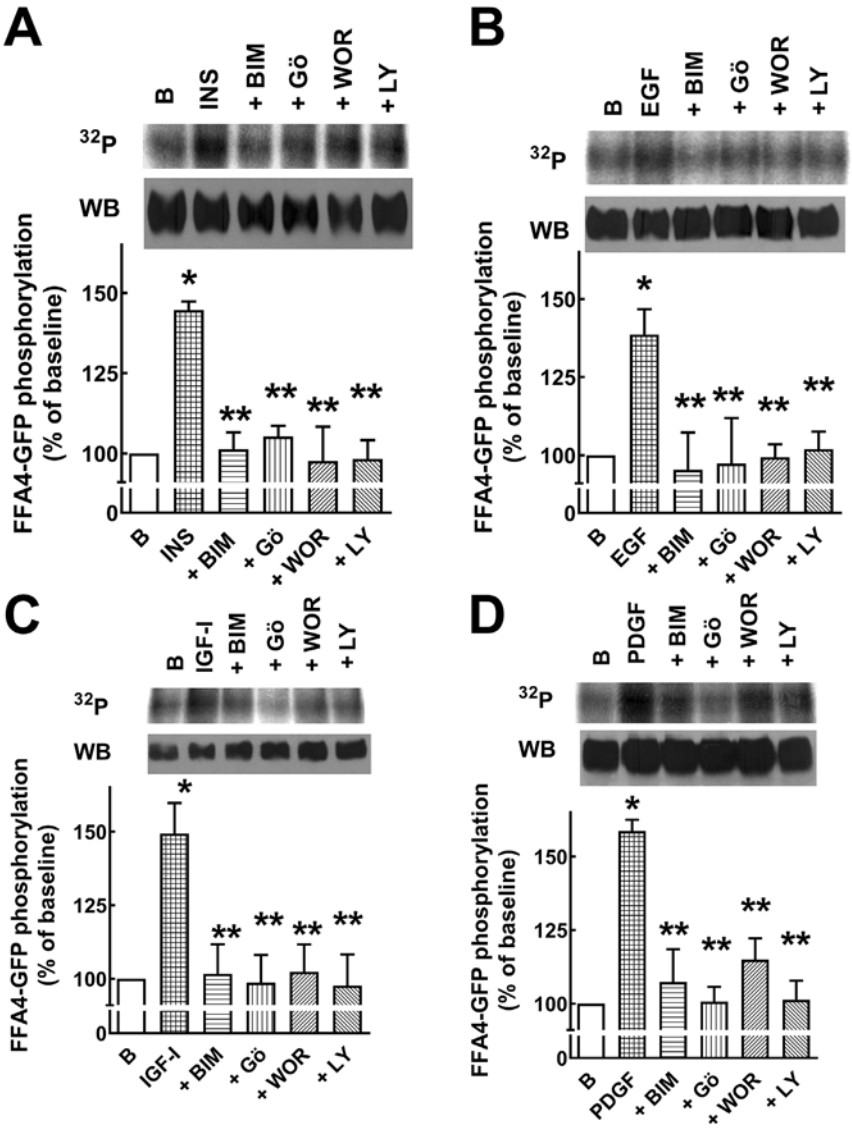

Fig. 3. Effect of protein kinase C and phosphoinositide 3-kinase inhibitors on growth factor-induced FFA4 phosphorylation. Cells expressing GFP-tagged FFA4 receptors were preincubated for 30 min in the absence or presence of 1 μM bisindolylmaleimide I (BIM), 1 μM Gö 6976 (Gö), 100 nM wortmannin (WOR) or 10 μM LY294002 (LY) and then challenged for an additional 30 min with 100 ng/ml of insulin (INS, panel A), EGF (panel B), IGF-I (panel C) or PDGF (panel D). Cells were lysed and receptor phosphorylation determined as indicated (section 2.4). In all cases the means are plotted with vertical lines indicating the S.E.M. of three independent experiments using different cell preparations. In all cases: $^{*}P < 0.005$ vs. baseline, and $^{**}P < 0.005$ vs. preincubation in the absence of inhibitor and presence of the growth factor. Representative autoradiographs (^{32}P) and Western blots (anti-GFP) are presented above each graph.

dithiothreitol. Proteins were separated employing 10% SDS-PAGE and the gels were dried. Receptor phosphorylation was analyzed with a Molecular Dynamics Typhoon PhosphorImager and the ImageJ software. Parallel samples were processed for detection of the receptor (employing anti-GFP antibodies) by Western blotting.

2.5. ERK 1/2 phosphorylation

Cells were incubated as indicated and cellular extracts were obtained by lysing the cells in detergent-, protease inhibitors-, and phosphatase inhibitors-containing buffer (Meizoso-Huesca et al., 2018). Cell extracts were subject to 10% SDS-PAGE and transferred onto nitrocellulose membranes. Samples obtained in parallel were incubated overnight at 4 °C, with anti-phospho-ERK 1/2 or anti-ERK 1/2. The following day, membranes were washed and incubated for 1 h at room temperature with a horseradish peroxidase-conjugated secondary antibody for enhanced chemiluminiscence detection. Densitometric analysis was performed using ImageJ software (http://rsb.info.nih.gov/ij/).

2.6. Confocal microscopy

Cells were seeded onto glass-bottomed Petri dishes and cultured overnight at 37 °C, and receptor expression was induced with doxycycline (1 μg/ml); the next day, cells were washed with medium without serum and further incubated for 3 h. Cells were treated as indicated and were washed with phosphate buffered saline and fixed with 4% paraformaldehyde in 0.1 M phosphate buffer for 20 min at room temperature; samples were then washed three additional times with phosphate buffered saline. Fluorescent images were acquired with an Olympus Fluoview FV10i confocal microscope with a water-immersion objective (60X). To determine receptor internalization, the plasma membrane was delineated utilizing differential interference contrast imaging and fluorescence within this region was excluded for quantification; the fluorescence present in intracellular structures was determined employing ImageJ software (http://rsb.info.nih.gov/ij/) (Collins, 2007; Hartig, 2013; Rasband, 1997–2004) as recommended (employing TFCC, total corrected cellular fluorescence (McCloy et al., 2014) and see also: (https://sciencetechblog.wordpress.com/2011/05/24/measuring-cell-fluorescence-using-imagej/)). At least five images of each of the four different cell cultures employed were taken for each condition. Data were normalized to baseline fluorescence (100%).

2.7. FFA4-β-arrestin coimmunoprecipitation

Experiments were carried out essentially as described previously (Villegas-Comonfort et al., 2017). In brief, cells were incubated in the absence or presence of 30 μM DHA for 15 min (Villegas-Comonfort

INFORME DE LABORES 2019

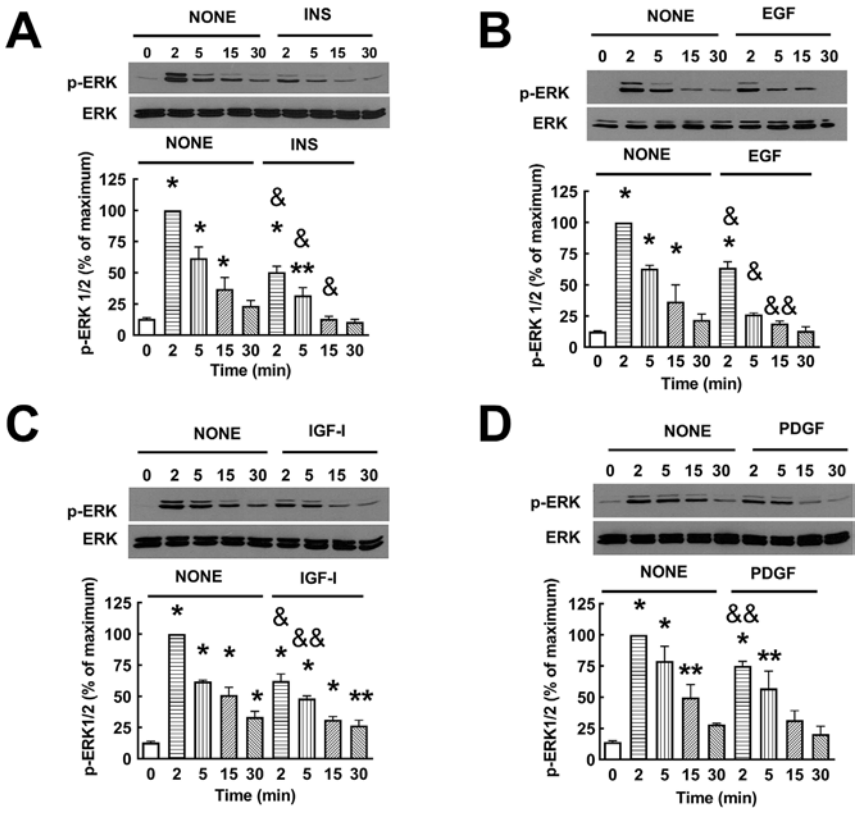

Fig. 4. Effect of preincubation with growth factors on docosahexaenoic acid-induced ERK 1/2 phosphorylation. Cells expressing GFP-tagged FFA4 receptors were incubated for 60 min in the absence (NONE) or in the presence of 100 ng/ml insulin (INS, panel A), EGF (panel B), IGF-I (panel C) or PDGF (panel D), and then were challenged for the times indicated with 30 μM docosahexaenoic acid. Cells were lysed and ERK 1/2 phosphorylation was determined as indicated (section 2.5). Data are presented as percentages of the maximal effect observed (preincubation without growth factor and challenged for 2 min with docosahexaenoic acid). In all cases the means are plotted with vertical lines indicating the S.E.M. of three independent experiments using different cell preparations. $^{*}P < 0.001$ vs. time 0 (baseline), $^{**}P < 0.05$ vs. time 0 (baseline), $^{\&}P < 0.001$ vs. same time, preincubation without growth factor, and $^{\&\&}P < 0.05$ vs. same time, preincubation without growth factor. Representative Western blots (anti-p(phospho)ERK 1/2 and anti-total ERK 1/2) are presented above each graph.

et al., 2017) or for 30 min in the presence of 100 ng/ml of the growth factors. After incubation, cells were washed with ice-cold phosphate buffered saline solution and solubilized in detergent containing buffer, as described for studying FFA4 phosphorylation. Lysates were incubated overnight with protein G-agarose and anti-β-arrestin 1/2 monoclonal antibody (1 μg/sample), with constant agitation at 4 °C. Samples were washed, solubilized, subjected to SDS-PAGE, and electrotransferred onto nitrocellulose membranes; Western blotting was performed using anti-β-arrestin 1/2 and anti-GFP antibodies.

2.8. Statistics

Statistical comparison between groups was performed using analysis of variance with the Bonferroni post-test using the software included in the GraphPad Prism 6 software program. A P value of < 0.05 was considered statistically significant.

3. Results

Cell incubation with 100 ng/ml of insulin (Fig. 1A), EGF (Fig. 1B), IGF-I (Fig. 1C), or PDGF (Fig. 1D) increased, in a time-dependent fashion, the phosphorylation state of FFA4; the time-course and magnitude of these FFA4 phosphorylations was very similar, i. e., these growth factors progressively increased receptor phosphorylation, reaching a maximum (~60% increase over baseline) in 30 min and decreasing at 60 min. Similarly, concentration-response analysis, utilizing 30 min incubation, indicated that the EC_{50} values for these growth factors were very similar (~0.2–0.5 ng/ml) (Fig. 2, panels A–D). Experiments comparing the FFA4 phosphorylation induced by the agonist DHA (30 μM) (Sánchez-Reyes et al., 2014; Villegas-Comonfort et al., 2017) and activation of the RTK receptors (growth factors were employed at a concentration of 100 ng/ml) were performed and are presented in Supplementary Fig. S1). As can be observed, DHA-induced FFA4 phosphorylation was of greater magnitude (2-fold) than those elicited by the growth factors (50–60% increase over baseline).

In order to investigate the signaling pathway(s) involved in RTK-induced FFA4 phosphorylation, the effect of protein kinase C (bisindolylmaleimide I (1 μM) and Gö 6976 (1 μM)) and phosphatidylinositol 3-kinase (wortmannin (100 nM) and LY294002 (10 μM)) inhibitors were tested. Cells were incubated with the inhibitors for 30 min and the peptide growth factors (100 ng/ml) were added (30 min incubation). As shown in Fig. 3, the FFA4-phosphorylations induced by insulin (panel A), EGF (panel B), IGF-I (panel C), and PDGF (panel D) were blocked by these inhibitors; the inhibitors by themselves did not alter baseline receptor phosphorylation at the concentrations tested (data not shown). It is noteworthy, that previous experiments have shown that protein kinase C inhibitors are unable to block agonist-stimulated FFA4 phosphorylation (Sánchez-Reyes et al., 2014).

The functional repercussion of incubation for 60 min with the peptide growth factors was explored next. None of the RTK agonists altered intracellular calcium (data not shown) or the effect of docosahexaenoic acid (30 μM) (Supplementary Fig. S2). The effect of the growth factors on ERK 1/2 phosphorylation was also examined. As depicted in Supplementary Fig. S3, the growth factor peptides by themselves increased ERK 1/2 phosphorylation; EGF was the most efficacious, followed by insulin and then by IGF-I and PDGF. In all cases, the effect of these growth factors was rapid, reaching their maximum at 2–5 min, and decreasing slowly afterward. A clear effect was still consistently observed after 15 min incubation with these agents but this effect further decreased at 30 min and had essentially vanished at 60 min. For this reason, the cells were incubated in parallel in the absence or presence of 100 ng/ml of these peptides for 60 min and then challenged with 30 μM DHA, in order to study whether RTK stimulation altered the response to FFA4 activation, and data were normalized to the maximal response observed (in all cases in cells preincubated without any agent and challenged for 2 min with the fatty acid, DHA (Fig. 4)). In cells preincubated in the absence of any growth factor, DHA induced marked ERK 1/2 phosphorylation that was maximal at 2 min and that decreased afterward (Fig. 4, first set of bars in each panel). As

INFORME DE LABORES 2019

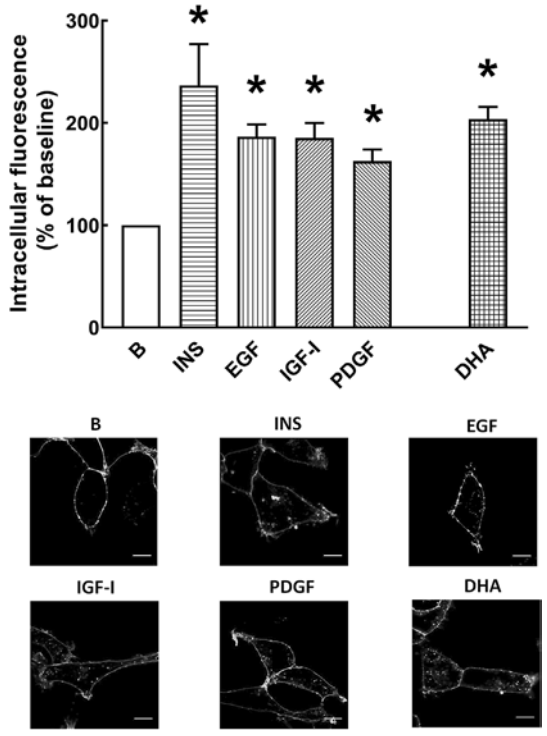

Fig. 5. Effect of growth factors and docosahexaenoic acid on FFA4 internalization (intracellular fluorescence). Cells expressing GFP-tagged FFA4 receptors were incubated for 30 min in the absence of any agent (B, baseline) or the presence of 100 ng/ml insulin (INS; n = 6), EGF (n = 10), IGF-I (n = 3), PDGF (n = 3), or 30 μM docosahexaenoic acid (DHA; n = 6) and then were fixed for observation with a confocal microscope as indicated (section 2.6). Data are presented as percentages of baseline intracellular fluorescence. In all cases the means are plotted with vertical lines indicating the S.E.M. of the indicated number (n) of independent experiments using different cell preparations; in each experiment five cells were analyzed per condition. $^{*}P < 0.001$ vs. baseline. Representative images are presented below the graph. Bar 10 μm.

can be observed, preincubation with any of the growth factors clearly decreased DHA-induced ERK 1/2 phosphorylation (Fig. 4A-D), PDGF being the least effective in this regard (Fig. 4D).

We next examined the possibility that activation of RTK could lead to FFA4 internalization. As illustrated in Fig. 5, the natural FFA4 agonist, docosahexaenoic acid, employed as a positive control, induced marked FFA4 internalization (30 min incubation) as previously reported (Sánchez-Reyes et al., 2014) (Fig. 5). Insulin, IGF-I, and EGF also increased FFA4 internalization after a 30 min incubation; PDGF also was able to induce FFA4 internalization, although the effect was smaller. The possibility that protein kinase C and PI3K could be involved in the internalization processes was tested by employing the inhibitors, bisindolylmaleimide I (1 μM) and wortmannin (100 nM). FFA4 internalization in response to insulin (Fig. 6A), EGF (Fig. 6B), and IGF-I (Fig. 6C) was blocked by the inhibitors. As indicated previously, PDGF-induced FFA4 internalization was of a smaller magnitude and the inhibitor's action was statistically insignificant (Fig. 6D). DHA-induced FFA4 internalization was clearly decreased by bisindolylmaleimide I but was only marginally decreased by wortmannin (Fig. 6E). The inhibitors by themselves did not alter FFA4 localization (Fig. 6F); representative images are presented in Supplementary Fig. S4.

β-Arrestin is known to associate with phosphorylated GPCR and to participate in receptor internalization (Alvarez-Curto et al., 2016; Butcher et al., 2014; DeFea et al., 2000; Kang et al., 2014; Shenoy and Lefkowitz, 2011). Therefore, the possibility that RTK activation might induce FFA4-β-arrestin interaction was hypothesized and experimentally explored through coimmunoprecipitation experiments. As shown in Fig. 7, the data indicated that FFA4 activation by DHA and also growth factor stimulation of endogenous RTK induced FFA4-β-arrestin coimmunoprecipitation.

4. Discussion

The present work shows that the activation of RTK, such as those of insulin, EGF, IGF-I, and PDGF, induced FFA4 phosphorylation in a time- and concentration-dependent fashion. This is consistent with what has been previously observed for other GPCR, including, but not limited to, the following: β_2-adrenoceptors (Doronin et al., 2002a, 2002b); α_{1B}- (Medina et al., 2000) and α_{1D}-adrenoceptors (Rodríguez-Pérez et al., 2009); δ-opioid receptors (Chen et al., 2008); dopamine D_1 receptors (Banday et al., 2007), and angiotensin II AT_1 receptors (García-Caballero et al., 2001); reviewed in (García-Sáinz et al., 2008, 2010; Gavi et al., 2006; Vázquez-Prado et al., 2003).

The ability of protein kinase C and PI3K inhibitors to block RTK-mediated FFA4 phosphorylation indicates that both enzymes are likely involved in such an effect. It is well-known that RTK auto-phosphorylation might lead to their association with the PI3K regulatory subunit, p85, resulting in activation of the catalytic subunit (Blume-Jensen and Hunter, 2001; Manning et al., 2002). Activation of protein kinase C could occur through a similar mechanism, i. e., the association with phospholipase C, triggering phosphatidylinositol 4,5-bisphosphate hydrolysis, generating diacylglycerol, or through other steps in the RTK-associated signaling pathways (Blume-Jensen and Hunter, 2001; García-Sáinz et al., 2010; Medina et al., 2000; Vázquez-Prado et al., 2003).

Roles of protein kinase C and phosphoinositide 3-kinases have been observed in RTK-induced phosphorylation and desensitization of other GPCR, such as α_{1B} and α_{1D}-adrenoceptors (Medina et al., 2000; Rodríguez-Pérez et al., 2009), angiotensin II AT_1 receptors (García-Caballero et al., 2001) and D_1 dopamine receptors (Banday et al., 2007). Other mechanisms involve direct RTK tyrosine phosphorylation of GPCR (for example, the β_2-adrenoceptor by insulin and insulin-like I receptors) (Doronin et al., 2002b; Gavi et al., 2006, 2007; Shumay et al., 2004) and EGF receptor-triggered tyrosine phosphorylation of GRK2, which phosphorylates and desensitizes δ-opioid receptors (Chen et al., 2008). Interestingly, a new mechanism for RTK desensitization of GPCR was recently proposed (Sun et al., 2018). In this study, EGF-induced D_3 dopamine receptor desensitization and down-regulation, involved the Src/Gβγ-dependent tyrosine phosphorylation of GRK2 and its binding to the T142 receptor's residue, which resulted in D_3 dopamine receptor uncoupling from G proteins, endocytosis, and lysosomal receptor degradation (Sun et al., 2018).

FFA4 phosphorylation sites have been identified by several groups (Alfonzo-Méndez et al., 2017; Burns et al., 2014; Butcher et al., 2014; Prihandoko et al., 2016). Five residues at the Ctail (Thr347, Thr349, Ser350, Ser357, and Ser360) were identified as the main agonist-induced phosphorylation sites of the human FFA4 receptor, employing mass spectrometry, mutagenesis, and phosphospecific antibodies (Butcher et al., 2014). Serine-to-alanine substitution of these receptors prevented FFA4 phosphorylation but did not alter ERK 1/2 activation, which appears to be associated with G protein activation (Prihandoko et al., 2016). Interestingly, the latter two serines seem to be particularly relevant for receptor internalization (Prihandoko et al., 2016). Mutagenesis of these five residues markedly reduced, but did not abolish, β-arrestin recruitment; further work by this group (Butcher et al., 2014) allowed identification of acidic residues in proximity to these sites, as structural elements relevant for FFA4-β-arrestin interaction. Mutagenesis/functional analysis have also shown that residues Thr347 and Ser350, are phosphorylation sites that are important for the recruitment of β-arrestin (Burns et al., 2014). We identified phosphorylated Thr242, Ser350, Ser357, and S360 in the FFA4 receptor using mass spectrometry (Alfonzo-Méndez et al., 2017). The sites phosphorylated in the FFA4 receptor in response to RTK activation remain to be determined.

The possibility that FFA4 receptor phosphorylation could entail

INFORME DE LABORES 2019

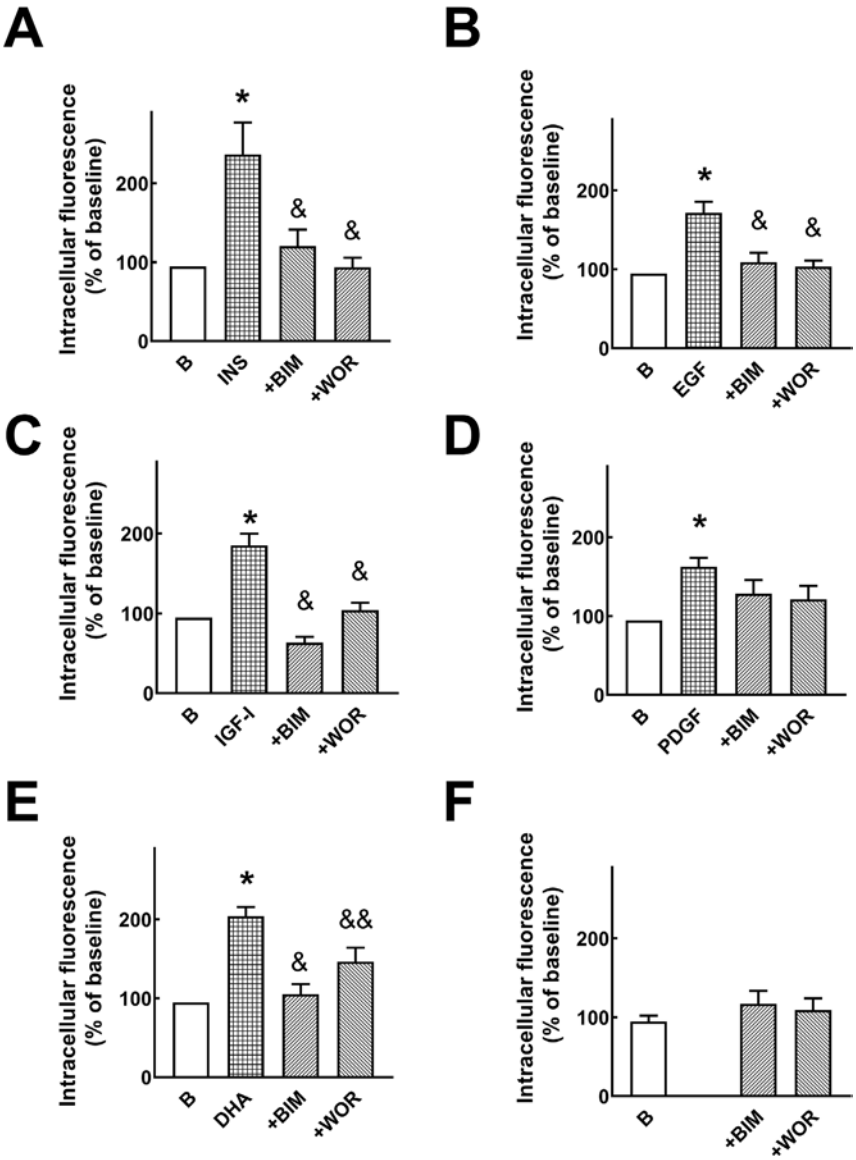

Fig. 6. Effect of bisindolylmaleimide I and wortmannin on growth factor- and docosahexaenoic acid-induced FFA4 internalization (intracellular fluorescence). Cells expressing GFP-tagged FFA4 receptors were preincubated for 30 min in the absence of any agent or in the presence of 1 μM bisindolylmaleimide (+BIM) or 100 nM wortmannin (+WOR) and then challenged with vehicle (B, baseline) or 100 ng/ml insulin (INS, panel A), EGF (panel B), IGF-I (panel C), PDGF (panel D), or 30 μM docosahexaenoic acid (DHA, panel E) (n = 5 in all cases) and then were fixed for observation with a confocal microscope as indicated (section 2.6). Absence of growth factor (panel F)(n= 5). Data are presented as percentages of baseline intracellular fluorescence. In all cases the means are plotted with vertical lines indicating the S.E.M. of the five independent experiments using different cell preparations; in each experiment five cells were analyzed per condition. $^{*}P < 0.001$ vs. baseline, $^{\&}P < 0.005$ vs. growth factor alone, and $^{\&\&}P < 0.05$ vs. growth factor alone.

functional consequences was studied. It was observed that treatment with the different growth factors did not alter the ability of a near-maximal concentration of DHA (30 μM) to increase intracellular calcium. These data indicate that receptor phosphorylation did not exert a direct impact on G protein-mediated signaling. A similar observation was made previously using phorbol myristate acetate to activate protein kinase C directly; i. e. phorbol 12-myristate 13-acetate induced FFA4 receptor phosphorylation without altering its ability to increase intracellular calcium upon agonist-activation (Sánchez-Reyes et al., 2014). RTK-induced FFA4 phosphorylation appears to involve protein kinase C which is consistent with the idea that this protein kinase does not regulate the immediate signaling of this free fatty acid receptor. Data from our laboratory have shown that DHA-induced FFA4 phosphorylation is not diminished by inhibitors of protein kinase C (Sánchez-Reyes et al., 2014). It is well-known that GPCR phosphorylation favors association with β-arrestin and internalization. (Alvarez-Curto et al., 2016; Butcher et al., 2014; DeFea et al., 2000; Kang et al., 2014; Shenoy and Lefkowitz, 2011). RTK activation induced FFA4 phosphorylation, interaction with β-arrestin and internalization; however, the causal relationship among these processes remains to be experimentally determined.

The possibility that other FFA4-triggered downstream processes could be altered by pretreatment with the growth factor evidenced a decrease in the magnitude of the ERK 1/2 phosphorylation response to DHA and an increase in agonist-independent FFA4 internalization. This is also interesting; particularly considering that calcium signaling was not altered. Both processes, that is, ERK 1/2 phosphorylation/activation and receptor internalization, were studied at relatively late times (60 or 30 min after RTK activation, respectively). The latter was studied in this manner, due to the fact that RTK activation induced ERK activation by itself, in the first case and, in the second case, because internalization is a rather complex cellular process that requires time to develop. It should be also borne in mind that ERK activation is a central process in cell physiology, as eloquently stated by Kolch: "… at the heart of signaling networks that govern proliferation, differentiation and cell survival" (Kolch, 2000). Consequently, it is not surprising that multiple pathways, modulated by a large variety of different receptor-activated and metabolic conditions, also involving a diversity of protein interactions, could participate in regulating its function (Kolch, 2000). Due to this time scale and the complexity involved, it is difficult to establish the direct relationship between RTK-induced FFA4 receptor phosphorylation and the effect of growth factors on FFA4-triggered ERK 1/2 phosphorylation. Although fatty acid receptor phosphorylation continues to be considered as a possible causal element, interaction of

INFORME DE LABORES 2019

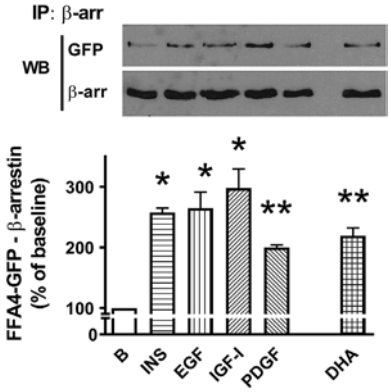

Fig. 7. Effect of growth factors and docosahexaenoic acid on FFA4-β-arrestin coimmunoprecipitation. Cells expressing GFP-tagged FFA4 receptors were incubated for 30 min with vehicle (B, baseline) or 100 ng/ml insulin (INS), EGF, IGF-I, PDGF, or 30 μM docosahexaenoic acid (DHA, 15 min) (n = 3 in all cases) and then coimmunoprecipitation was performed as indicated (section 2.7). Data are presented as percentages of baseline value. In all cases the means are plotted with vertical lines indicating the S.E.M. of the three independent experiments using different cell preparations. $^{*}P < 0.001$ vs. baseline and $^{**}P < 0.05$ vs. baseline. Representative Western blots are presented above the graph.

the signaling pathways modulated by RTK and the GPCR at downstream levels should also be considered. In the case of receptor internalization, there is already evidence indicating that the pharmacological activation of protein kinase C plays a role in the FFA4 internalization associated with receptor phosphorylation (Sánchez-Reyes et al., 2014). Therefore, it appears likely that the protein kinase C activation that participates in growth factor-triggered FFA4 phosphorylation might also lead to the internalization of the free fatty acid receptor.

The present experiments were performed in a cell model transfected with the FFA4 receptor and by stimulating a variety of endogenously expressed growth factor receptors. Although there is general consensus considering the overall response elicited by growth factors, there are many similarities among their actions, but also some differences. This could result of variances in the RTK themselves (specific tyrosine phosphorylation sites), the repertoire of associated signaling elements that are available in specific cells and other elements (Gschwind et al., 2004; Hubbard and Miller, 2007; Schlessinger, 2000). In other words, it is very cell-context-dependent. The expression of RTK varies among cells, tissues, and organs and in response to processes such as development or malignant transformation, and it is difficult to imagine cells devoid of such receptors. FFA4 expression appears to have a much more limited expression (Hirasawa et al., 2005; Miyauchi et al., 2009). Therefore, it is likely that cells expressing this free fatty acid receptor might also express some types of RTK. We hope our findings will promote exploration of this receptor cross-talk in physiological systems, particularly considering the many functions in which FFA4 appears to be involved and its therapeutic potential (Liu et al., 2015; Milligan et al., 2015).

Acknowledgments

The advice and technical support of Dr. Rocío Alcántara-Hernández, Dr. Héctor Malagón, Dr. Claudia Rivera, Juan Barbosa, and Aurey Hernández are gratefully acknowledged. ABSTRACT

Catalases are biotechnologically relevant enzymes because of their applications in food technology, bioremediation, and biomedicine. The dismutation of hydrogen peroxide occurs in two steps; in the first one, the enzyme forms an oxidized compound I (Cpd I) and in the second one, the enzyme is reduced to the ferric state. In this research work, we analyzed the reduction of Cpd I by X-ray radiation damage during diffraction experiments in crystals of CAT-3, a Large-Size Subunit Catalase (LSC) from *Neurospora crassa*. A Multi-Crystal Data collection Strategy was applied in order to obtain the Cpd I structure at a resolution of 2.2 Å; this intermediate was highly sensitive to X-ray and was easily reduced at very low deposited radiation dose, causing breakage of the Fe=O bond. The comparison of the structures showed reduced intermediates and also evidenced the differential sensitivity per monomer. The resting ferric state was reduced to the ferrous state, an intermediate without a previous report in LSC. The chemically obtained Cpd I and the X-ray reduced intermediates were identified by UV-visible microspectrometry coupled to data collection. The differential sensitivity and the formation of a ferrous state are discussed, emphasizing the importance of the correct interpretation in the oxidation state of the iron heme.

1. Introduction

Heme-dependent catalases are ubiquitous enzymes present in most living organisms that play a fundamental role in response to oxidative stress. Catalases have multiple applications in the food industry [1–4], medicine [5,6] and fabrication of biosensors [7–9]. The origin of catalases is monophyletic and, they are grouped in three clades, clade 1 is distributed in bacteria, green algae and plants; clade 2 in bacteria, fungi and some archaea; and clade 3 in bacteria, fungi, animals and some archaea [10–12].

Large-Size Subunit Catalases (LSC) are enzymes with a MW ranging from 75 to 86 kDa and are grouped in clade 2 of the monofunctional heme-dependant catalases [13]. These enzymes dismutate hydrogen peroxide to molecular oxygen and two water molecules in two consecutive reactions. In the first reaction, the iron heme center in the ferric resting state is oxidized by a hydrogen peroxide molecule releasing a water molecule and forming the compound I (Cpd I) (reaction 1), an oxoferryl group associated to a cation-π radical of porphyrin. In the next reaction, a second hydrogen peroxide molecule acts as an electron donor reducing the oxoferryl group and restoring the resting ferric state (reaction 2). This set of reactions is named the catalatic pathway [14]. The Small-Size Subunit Catalases (SSC) are heme depending catalases which have subunits ranging between 50 and 55 kDa and are distributed in clades 1 and 3. The SSC can experience, added to the catalatic pathway, different reactions known as the peroxidant pathway. At low H_2O_2 flux, Cpd I can be reduced by a single electron donor resulting in the formation of compound II (Cpd II) [15], an oxoferryl without the cation-π porphyrin radical. This intermediate can restore the ferric state after a second single electron reduction (reaction 4) [16]. The Cpd II can also be further oxidized by H_2O_2 and form inactive compound III [17].

Catalatic pathway

INFORME DE LABORES 2019

$$E-Fe^{III} + H_2O_2 \rightarrow E[\pi^+]-Fe^{IV}=O + H_2O \quad (1)$$

$$E[\pi^+]-Fe^{IV}=O + H_2O_2 \rightarrow E-Fe^{III} + H_2O + O_2 \quad (2)$$

Peroxidant pathway

$$E[\pi^+]-Fe^{IV}=O + AH \rightarrow E-Fe^{IV}=O + A^{\cdot} + H^+ \quad (3)$$

$$E\text{-}Fe^{IV}=O + AH + H^+ \rightarrow E\text{-}Fe^{III} + A + H_2O \quad (4)$$

Determination of structures through X-ray crystallography is pivotal to an understanding of enzyme function and characterization of molecular mechanisms. The preservation of the structural information, or the changes occurring while X-rays interact with the protein crystal, are critical for the correct interpretation of the three-dimensional structures. Nevertheless, during the data collection of diffraction patterns from protein crystals, the accumulation of high radiation doses affects several crystal parameters such as the unit cell dimensions, resolution, mosaicity and intensity of reflection spots as a direct consequence of the disorder in the structure [18]. At a molecular level, X-ray radiation damage occurs due to the photoelectric effect and inelastic scattering which cause the breakage of S-H, O-H, N-H, and C-H bonds as well as the production of solvated electrons (e^-aq), ·OH, and ·H radicals [19–21]. The presence of the radiolytic species lead to the breakage of other bonds in the protein, including disulfide bridges but also the reduction of metal centers, which are particularly sensitive to ionizing radiation [22].

X-ray radiation damage causes loss of information of the initial state of the crystal, but has also been used as a tool to determine structures of reduced catalytic intermediates that cannot be obtained through chemical procedures [23]. When crystals are reduced at low X-ray doses, the combination of composite datasets and spectroscopic techniques as UV-visible micro spectrometry, XAS and Raman [24–26] allow obtaining information of the reduction process. There are few studies showing crystal structures of oligomeric proteins with a different oxidation state in their monomers in which it has been suggested that these differences are due to the reduction of the initial state [27–29]. Until now we have no knowledge of any reports concerning structural studies that correlate the behaviour of a multimeric metalloenzyme with X-ray dosage.

Most LSC crystal structures deposited in PDB were determined for the ferric state [13,30–32]. There is only one crystal structure for the Cpd I intermediate of a LSC; the catalase from *Penicillium vitale* (PVC, PDB entry 2IUF) for which the prosthetic group is heme *d* [33]. The structures of Cpd I solved for catalases harboring a heme *b* only belong to SSC [16,33,34]. In this work, crystals of the homotetrameric LSC Catalase-3 from *N. crassa* (CAT-3), which harbors a heme *b* prosthetic group, were chemically oxidized to Cpd I and exposed to X-rays during data collection. We report the crystal structures obtained from crystals of CAT-3 describing the differential reduction of the active sites in response to the accumulation of radiation dose. Furthermore, the spectrophotometric analysis of the irradiated crystals reveals the existence of the ferrous state, described for the first time for LSC.

2. Materials and methods

2.1. Protein purification

Protein expression and purification was performed as described in Zarate-Romero et al. 2013 [35]. Briefly, a 5 L culture of *E. coli* BL21 DE3 (pLyss) in LB medium was grown to an OD_{600} of 0.5, supplemented with 30 μM hemin, and induced with 100 μM IPTG. The culture was incubated at 16 °C for 24 h. Cells were recovered by centrifugation at 3,500 × *g* for 15 min. The cell pellet was resuspended in 50 mM sodium phosphate buffer pH 8.0 containing 300 mM NaCl, and 15 mM imidazole, and lysed by sonication. The sonicated suspension was centrifuged for 40 min at 13,000 × *g*, and the supernatant was purified by Ni^{2+} affinity chromatography with a HisTrap column (GE Healthcare). The enzyme was eluted with the previous buffer but increasing imidazole concentration to 300 mM. The eluted protein was dialyzed against 20 mM Tris pH 8.0 at 4 °C employing a 12 kDa cut-off membrane. Anionic exchange chromatography was performed in a High-Q BioRad column using a 0–500 mM NaCl in 20 mM Tris pH 8.0 gradient. CAT-3 was eluted at ~200 mM NaCl. Gel filtration chromatography was performed in a Hi-Load 26/600 Superdex 200 pg column (GE Healthcare) using 20 mM Tris pH 8.0 and 100 mM NaCl at 3 mL/min and 0.1 MPa pressure in an AKTA prime liquid chromatography system (GE Healthcare). Fractions with a Soret's peak were analyzed in SDS-PAGE in non-reducing conditions and those containing most of the catalase activity were pooled. Buffer was exchanged with 10 mM HEPES by using an Amicon ultrafiltration unit with a 30 kDa cut-off membrane (Millipore). Finally, the protein was concentrated to 6 mg/mL in order to set crystallization trials. The concentration of the purified protein was determined by measuring A_{280}. Based on the CAT-3 sequence, the calculated extinction coefficient value was determined to be $\varepsilon_{280} = 321{,}320\ M^{-1}cm^{-1}$ for the tetrameric enzyme.

2.2. UV-visible spectrometry analysis in solution

CAT-3 was resuspended in 100 mM sodium acetate-acetic acid buffer pH 5.5 at a concentration of 0.2 mg/mL. The UV-visible spectrum ranging from 250 to 850 nm was measured using an *Evolution 300* spectrometer (Thermo Scientific). To form Cpd I, 50 μL of the CAT-3 solution was treated with 1 mM peracetic acid (PAA) previously treated with commercial bovine liver catalase (BLC, Sigma Aldrich) to eliminate H_2O_2. After a colour shift from brown to green, the UV- visible spectra was measured.

2.3. Protein crystallization and Cpd I obtaining

Crystals were obtained in space group $P2_12_12_1$ as in Zárate-Romero et al. 2013 [35]. Briefly CAT-3 at 3.5 mg/mL in 10 mM HEPES pH 7.0 was used to set droplets of 1 μL enzyme plus 1 μL of 200 mM ammonium dibasic tartrate and 20% w/v PEG 3350 (condition 38 of PEG/Ion screen, Hampton Research) in the microbatch method [36] and covered with 10 μL of paraffin oil. Crystals appeared 5 days after trial setting and were grown for 3 weeks.

Ferric CAT-3 crystals with an average dimension of 0.5 mm × 0.05 mm x 0.05 mm were soaked in a cryoprotectant solution containing 100 mM MES pH 6.6 and 40% w/v PEG 400. To obtain Cpd I, 100 mM PAA was added to the cryoprotectant solution and after 1 min, the crystal showed a colour shift from brown to green. After soaking in the cryoprotectant solution, the crystals were flash-cooled and stored in liquid nitrogen.

2.4. Data collection and structure determination

Data collection of all of the CAT-3 crystals was performed at X6A beamline of the NSLS. The X-ray deposited dose determination was performed by using *RADDOSE* [18], considering a Gaussian profile for the beam. To determine the CAT-3 soaked with PAA structure, a dataset of 360 frames was collected from one crystal with $\Delta\phi = 0.25^{\circ}$, t = 30 seg, $\lambda = 0.9796$ Å, d = 250 mm. Frames were indexed, integrated and scaled using the *XDS* suite [37]. Files were converted to mtz format using *F2mtz* in the CCP4i suite. Phases were solved by molecular replacement in *Phaser* [38], the search model had the coordinates for the peptide chains of the CAT-3 tetramer (PDB entry 3ZJ5 [35]). The model obtained was refined as a rigid body in *REFMAC5* [39]. Further refinement of coordinates, B-values and occupancies was performed in the *PHENIX* suite [40] and the subsequent construction of the model was performed in *Coot* [41]. CAT-3-PAA structure was deposited at PDB with code 4AJ9.

In order to produce composite datasets, 366 frames were collected from each crystal, with the following conditions, $\Delta\phi = 0.3^{\circ}$, t = 30 seg,

INFORME DE LABORES 2019

λ = 0.9764 Å, d = 210 mm. Each crystal was oriented with the longer axis perpendicular to the X-ray beam and with one of the faces in a plane normal to the beam. The next crystal was oriented in the same position and the initial angle ϕ was rotated 10° from the initial plane. For each new crystal, 10° were added to the initial angle ϕ. A total of 9 crystals were collected in order to cover the ϕ rotation needed (90°) to fulfil a 100% integrity for the composite datasets.

Every single crystal dataset was split in partial datasets, each one covering 10° of the collected data. The frames corresponding to each 10° section were indexed and integrated using *XDS* suite. The integrated partial datasets corresponding to the first 10° from each single crystal were scaled together and a composite dataset was obtained. This procedure was repeated for 10-20°, 20-30° and so on, until the 100-110° partial dataset. Furthermore, a composite dataset for the first 5° of data collection was obtained. All composite datasets were scaled in *XSCALE*; the phases for each composite structure were obtained by molecular substitution in *PHASER* [38] using PDB entry 4AJ9 as a search model. The resultant model was refined as a rigid body in *REFMAC5* [39] and subsequent refinement of coordinates, B-values and occupancies was performed in *PHENIX* suite [40]. The construction of the model was continued with *Coot*.

In order to analyze the presence of ligands near the heme prosthetic group, polder omit difference maps were calculated using *phenix.polder* [42] in the PHENIX suite by eliminating the heme prosthetic group and the neighbouring water molecules. All the structure figures were generated using *CCP4MG* [43]. Coordinates of the determined structures were deposited at PDB with codes 6NSW, 6NSY, 6NSZ, 6NT0 and 6NT1 for 5°, 10°, 20°, 50° and 110° respectively.

2.5. UV-visible spectroscopy coupled to data collection

Collection of UV-visible absorbance spectra from CAT-3 crystals in native state or soaked in PAA was done in beamline BL11-1 at SSRL. Crystals were rotated 360° and a UV-visible spectrum was collected each 10° after an area with strong signal was identified. Rotation was changed to 2° in that area until the orientation with the highest signal was located. The angular position of the crystal was fixed, and then X-ray exposure was done collecting a spectrum every two seconds. The conditions for X-ray irradiation were: slits 0.05 mm × 0.05 mm, λ = 0.9795 Å. The flux conditions were adjusted in order to deposit a dose of 7.7×10^{-4} MGy/s.

3. Results

3.1. CAT-3 compound I in solution

The UV-visible spectra of a solution of CAT-3 in the resting state or incubated with 1 mM PAA were measured. A colour change from brown to green was observed in the sample with PAA added. The resultant spectra of both samples (Fig. 1a) showed the characteristic Soret's band at 406 nm. The 280/406 nm ratio for the resting state is 1, while in the sample treated with PAA this ratio is 2. There were also two peaks observed at 500 nm and 535 nm which slightly decrease in the Cpd I spectrum. The charge-transfer band appears at 619 nm in the resting state, but in the sample that reacted with PAA, this band was displaced to 670 nm. These changes correlate with the presence of Cpd I as has been described for several catalases, e.g. the PVC [33] which is an ortholog of CAT-3 [12], as well as for the SSCs of *Aspergillus niger* (ANC) [15] *Proteus mirabilis* [44], *Helicobacter pylori* [33] and BLC [45].

3.2. Cpd I structure is reduced under data collection of a single dataset

One crystal of CAT-3 (Fig. 1b) was soaked in a cryoprotectant supplied with 100 mM PAA. As in solution, a colour shift was observed (Fig. 1c) and the crystal was immediately flash-cooled in liquid nitrogen. After X-ray diffraction, the exposed area changed to a brown

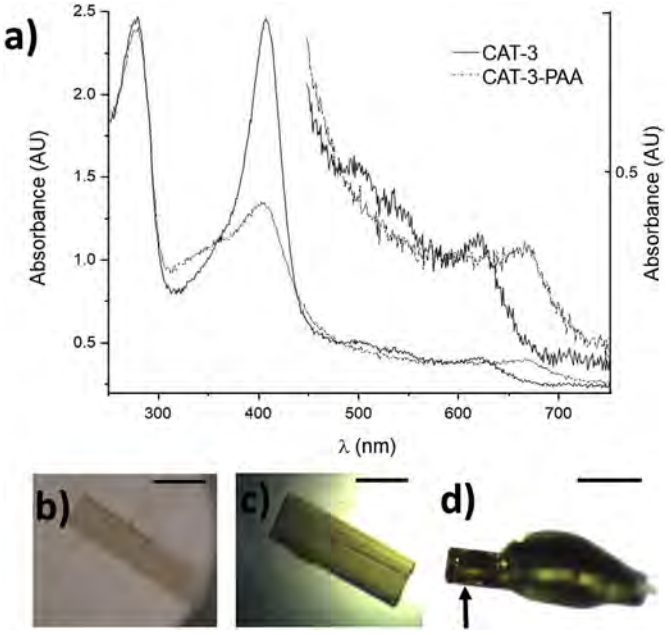

Fig. 1. UV-visible spectra of CAT-3 in solution. a) Spectra of CAT-3 in solution with the Soret's band at 402 nm and the characteristic peaks of the ferric state at 502 nm, 535 nm and the charge-transfer band at 615 nm (line). The CAT-3 treated with PAA (dashed) has decreased in the Soret's band and a shift of the charge-transfer band to 665 nm, the 450–750 nm region is rescaled according to the scale shown in the right for absorbance. b) Crystal of CAT-3 in the ferric state. c) Crystal of CAT-3 treated with PAA, colour shift to green. d) Crystal of CAT-3-PAA after diffraction, the arrow points toward the path of X-ray beam, the green colour shift back to brown after X-ray exposure. The scale bar in b-d) represents 100 μm. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

colour (Fig. 1d). A structure was determined and deposited in the PDB with the entry 4AJ9 at 1.85 Å resolution, and a calculated dose of 1.18 MGy.

The electron density map $2F_o$-F_c of the structure and a polder omit map lacking the heme moiety were analyzed looking for continual electron density at 1.8 Å from the iron atom. The expected peak, characteristic for the Fe = O bond in Cpd I, was not present in any of the maps. In comparison to the structure collected from a crystal in ferric state [35] (Fig. 2a), an acetate ion was found in the access tunnel of each monomer, interacting with the carboxyl group of Asp 155 and the isopropyl group of Val 195. Both the colour shift and presence of acetate suggest that Cpd I was obtained, however, as shown by the lack of continual electron density, it was reduced during data collection.

The PVC is the only LSC with a crystal structure determined for Cpd I (PDB entry 2IUF at 1.71 Å resolution) [33]. The intermediate was obtained by the same method described here and the acetate ions were also observed in the tunnel, additionally showing the oxidation of two methionine residues in the middle of the tunnel (Fig. 2a). The methionine in position 153 is the only of these which is conserved in CAT-3 (Met 231). PVC is also in the G2C group of LSC and among the enzymes with a three-dimensional crystal structure has the highest sequence identity to CAT-3 [13]. The active site of PVC is highly conserved with CAT-3, however instead of heme *b*, the prosthetic group of this catalase is a heme *d*. It is assumed that heme *d* increases the stability of Cpd I in LSC [46]. A serine residue located near the heme site at position 388 has an alternate conformation (Fig. 2b) that was only observed in one crystal structure of CAT-3 crystallized under the same conditions (PDB entry 3ZJ5 at 2.1 Å resolution), but not in any other LSC or SSC structure determined so far. Among the LSC with a known structure, the residue Ser 388 is conserved; in those with heme *d*, the hydroxyl group interacts with the C6 hydroxyl of the heme *d* at ring III.

INFORME DE LABORES 2019

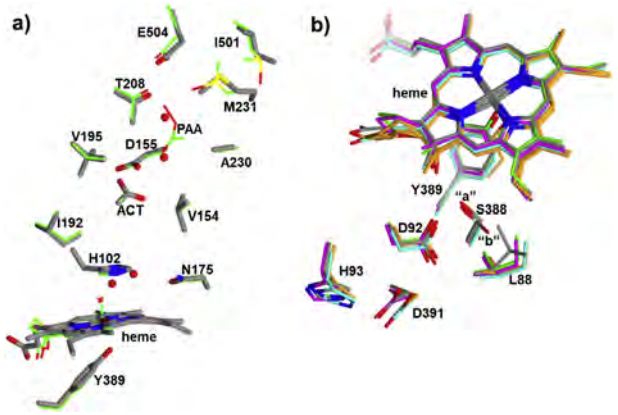

Fig. 2. CAT-3 soaked with PAA in comparison with other LSC. a) Superposition of CAT-3 soaked in PAA (PDB entry 4AJ9) with PVC Cpd I (PDB entry 2IUF) b) Ser 388 and residues forming a hydrogen bond network until the central channel. Conformation "a" is observed in other structures of LSC and in those with heme *d* is hydrogen bonded to the hydroxyl group of heme, alternative conformation "b" is present only in CAT-3 which has Leu 88 instead of isoleucine. Leu 88, D92 and H93 belong to the P-related subunit. In both panels oxygen atoms are presented in red, nitrogen in blue and the carbon atoms are shown in gray for CAT-3 and green for PVC. In panel b), the carbon atoms are shown in cyan for *Scytalidum thermophilum* CATPO, orange for *N. crassa* CAT-1 and magenta for *E. coli* HPII. The water molecules in panel a) are represented as red spheres for CAT-3. Figures were drawn using CCP4MG [43]. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

The alternate conformation of Ser 388 is not found in any of those structures probably due a steric hindrance with the sidechain of a conserved leucine from the monomer related in P found in all other LSC and substituted by the Val 88 in CAT-3. It has also been proposed that in the catalase HPII from *E. coli*, this residue participates in the oxidation of heme *b* to heme *d* in the first cycles of catalysis of hydrogen peroxide [46]. Both conformations of Ser 388 are hydrogen bonded to Asp 92 of the P-related subunit. These residues together with Asp 391 and His 91 from P-related subunit form a hydrogen bond network that connects to the central channel present in every tetrameric catalase described to date.

3.3. Composite datasets and UV-visible spectroscopy of Cpd I and its reduction by X-rays

Through the Multi-Crystal Data collection Strategy [24] and processing of composite datasets, a series of crystal structures with increasing absorbed dose were determined. Data collection and refinement statistics are presented in Table 1. Additionally, in an independent experiment the UV-visible spectra of a CAT-3 crystal soaked in PAA were recorded before the X-ray exposure and at different cumulative dose of X-rays. The first spectrum at 0 MGy (Fig. 3) shows the characteristic peaks for the ferric state, but also for the Cpd I, as was described in the previous section for solutions. Peaks at 498, 532, 565, 615 and 665 nm were observed; the Soret's band is found at 402 nm but the ratio 280/402 nm is ~1 instead of ~2 as occurred in solution. A small shoulder at 344 nm is also present, as was described for ANC. Except for the peak at 565 nm, all other observed peaks correlate with those previously reported in ferric or Cpd I intermediates of heme *b* catalases [15,45]. This absorbance spectrum suggests that there is a mixture of the Cpd I and the ferric resting state in the heme moiety at the beginning of the experiment; the mixed state could be explained by partial reaction of the active sites with PAA during soaking experiments.

The structure with the lowest dose (0.135 MGy) was solved using the frames comprising the first 5° of each collected crystal. A polder omit map of the heme moiety and the neighbouring region was obtained. The polder omit map shows continual electron density surrounding the heme prosthetic group and the bonded oxygen modeled in the final structure for each one of the four monomers (Fig. 4). The Fe = O bond lengths are 1.74 Å, 1.77 Å, 1.76 Å and 1.77 Å for monomer A, B, C and D respectively, correlating with those observed for Cpd I of LSC and SSC (reviewed in Alfonso-Prieto et al. [33]). Occupancies for the oxygen atoms are 0.66, 0.71, 0.60 and 0.57 for monomers A, B, C and D respectively. The water molecule W1 is present in all monomers at a distance between 1.9 Å and 2.7 Å from the bonded oxygen and forms hydrogen bonds with the atom N2 of His 102 and the nitrogen atom from the heme pyrrolic ring III.

The changes in spectra from 0 MGy to 0.127 MGy are shown in Fig. 3; both peaks at 615 nm and 665 nm decrease in a dose dependent manner, however there is also an increment in the absorbance of the small peak at 565 nm and the appearance of a new peak at 594 nm. The Soret's band stretches with increasing dose and its maximum is displaced from 402 nm to 407 nm. All spectra at this dose range describe mixtures of oxidation states which could explain why the Soret's band is wider than in the spectra recorded in solution for the Cpd I or the ferric state. The decrease in the charge-transfer band at 615 nm (from 0.550 AU to 0.480 AU) and at 665 nm (from 0.242 AU to 0.155 AU) was unexpected and unexplained because the reduction of Cpd I at (665 nm) should cause a gradual increase in the absorbance of the ferric resting state (615 nm) after the reduction by two electrons of Cpd I.

The second composite structure was determined by processing the first 10° of each data collection, accumulating a total dose of 0.263 MGy. The polder omit difference maps shows that the continual electron density corresponding to the Fe = O bond of Cpd I of the monomers A and B have disappeared. For both C and D monomers, the continual electron density that belong to the Fe = O bond of Cpd I is still present. The occupancies of the oxygen atoms are 0.61 and 0.62 respectively and the bond lengths are 1.85 Å and 1.82 Å. The increase in the length of bonds can be correlated to the formation of a Fe-OH intermediate as has been shown for catalases through different X-ray crystal structures [16,34] and QM/MM calculations [33,47]. The measured distances and the continual electron density of the 5° and 10° structures confirm the presence of the iron-oxygen bond, but are not enough to distinguish between the Fe = O and the Fe-OH intermediates. The spectrum with the dose closest to that of the 10° structure was acquired at 0.176 MGy. In this spectrum the peak at 665 nm has decreased from 0.242 AU to 0.137 AU which accounts to 50% of its initial absorbance. The peak at 615 nm decreased from 0.550 AU to 0.465 AU, 84.5% from the initial absorbance. At 0.36 MGy, which is the next spectrum with an absorbed dose closer to that of the three-dimensional structure of 10°, the ferric charge-transfer band at 615 nm decreased to 0.43 UA and the Cpd I charge-transfer band at 665 nm decreased to 0.095 UA.

The structure obtained with the data of the 20° section of the collected data has 0.526 MGy of accumulated dose. The F_o-F_c polder omit maps of the active sites show, instead of the continuity in the electron density for the Fe = O bond, a second peak separated from the heme position for all the monomers in the enzyme (Fig. 4), those maps confirmed the reduction of Cpd I in the whole structure. The position of the separated peak supports the presence of both molecules W0 and W1 that correlates with the resting ferric state in catalases [48], peroxidases [24] and myoglobin [26,48].

The structures for 50° and 110° (1.31 MGy and 2.89 MGy respectively) did not show changes in the active sites of the four monomers. In all structures the F_o-F_c polder omit map show two separated peaks as was observed in the 20° structure and in the structures deposited in PDB for the resting enzyme (entries 3EJ6 and 3ZJ5). The UV-visible spectra of the Cpd I crystal at doses of 0.71, 1.07 and 1.27 MGy did not followed the same trend that previous spectra, the absorbance of the charge-transfer band at 615 nm and at 665 nm stopped decreasing in the spectrum at 0.71 MGy at values of 0.413 UA and 0.077 UA

respectively. The last collected spectra had accumulated a dose of 1.27 MGy which is approximately the dose of the 50° crystal structure. Additionally, while the peak at 565 nm still increased in the last three spectra, the peak at 594 nm reached its maximum with a value of 0.692 AU at 0.36 MGy, after this dose, the peak decrease gradually in the last three spectra. In summary, from 0 MGy to 1.27 MGy the peaks at 615 nm and 665 nm decrease its height as the absorbed dose increase, and those at 565 nm and 594 nm increased. The spectra reported for the Cpd II in ANC [15], has two peaks at 539 nm and 570 nm respectively. In our spectra, the peak at 565 nm is in a zone near to 570 nm but the absence of the 539 nm peak cannot allow confirming the formation of Cpd II. The peak at 594 nm is not present in the UV-visible spectra of the catalytic intermediates of any catalase; this peak does not correlate with Cpd I, Cpd II or ferric states. In LSC there are no evidences for the production of the ferrous state in the heme moiety, however in SSC the ferrous state has been obtained by chemical reduction in the BLC, the UV-visible spectra of the intermediate presented peaks at 567 nm and 600 nm [49] or 561 nm and 595 nm [50]. At the beginning of X-ray data collection there were mixed states for the CAT-3 crystal and there are not enough evidences that correlate the increase in the peak at 594 nm to the formation of Cpd II, nevertheless the reduction of the pure ferric state could contribute to clarify the identity of both peaks at 565 nm and 594 nm.

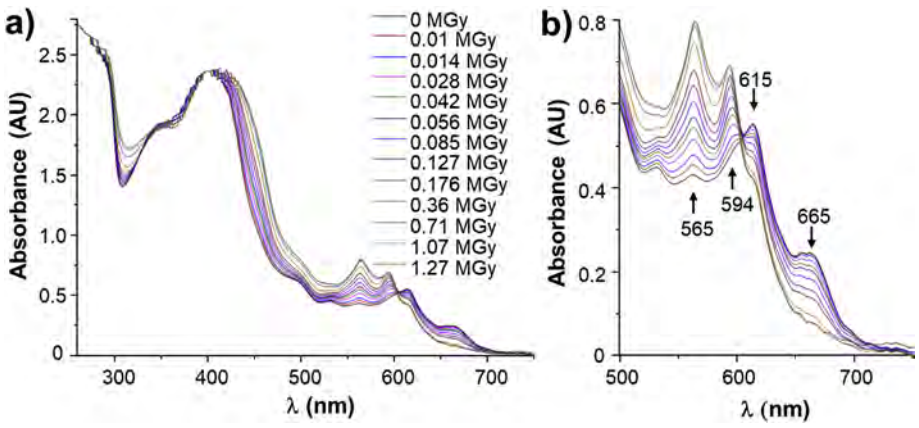

Fig. 3. UV visible spectra of the X-ray reduction of Cpd I CAT-3. a) Spectra of a single crystal treated with PAA. Soret's band and peaks related to Cpd I (665 nm) and ferric state (502 nm, 535 nm and 615 nm) are present before X-ray exposure (0 MGy) at increasing dose peaks at 565 and 594 nm are present. b) Zoom at the 500 nm-700 nm visible spectra.

3.4. X-ray driven reduction of the CAT-3 in the resting ferric state

One crystal of CAT-3 was exposed to X-rays in similar conditions to the used for structural determination. UV-visible spectra of the unexposed and of the irradiated crystal at different absorbed doses were acquired. The initial spectrum, at 0 MGy shows the same peaks that were observed in the CAT-3 solution for the ferric state (Fig. 5), the Soret's band appeared at 400 nm instead of 406 nm, the 280/400 ratio is 1. The peak at 500 nm is present, but the peak expected at 535 nm is displaced at 537 nm in the crystal. The charge-transfer band of the ferric state is observed at 620 nm as in solution. After X-ray exposure at a final dose 1.63 MGy, the peak at 620 nm decreased from 0.368 AU, at 0 MGy, to 0.214 AU, but there was a proportional increase in a peak at 565 nm from 0.220 AU to 0.475 AU, similar to the behaviour in the crystal of Cpd I when was reduced. There was also a small shoulder at 599 nm. In the course of X-ray exposure, the Soret's band was displaced from 400 nm to 406 nm; and a shoulder in 446 nm appeared and increased in a dose dependent manner. At the end of the exposure, the absorbance intensity in the peak at 500 nm decreased from 0.394 AU to 0.342 UA and the peak at 537 nm can be observed as a small shoulder of the peak at 565 nm. The presence of both peaks at 565 nm and 594–599 nm in the X-ray driven reduction of the Cpd I and the resting enzyme confirms the reduction to the ferrous state.

4. Discussion

4.1. Differential reduction in CAT-3 monomers

In both monomers of the crystallographic structure of PVC in the Cpd I state (PDB entry 2IUF at 1.71 Å resolution) [33] the Fe = O bond is clearly defined by the electron density map and the occupancies of the bonded oxygen have a value of 1. In this structure the dose accumulated during data collection was not reported, but in the PDB report for the entry is annotated that it was collected at a rotating anode X-ray source, so it is highly probable that the deposited dose radiation was lower in comparison to crystals collected at a synchrotron beamline, where the flux is generally $\sim 10^3$ times higher. The presence of the unreduced Cpd I in both monomers of the dimer present in the asymmetric unit of the PVC structure is probably due to the lower dose. The sensitivity of metal atoms to X-ray driven reduction in the active sites have been discussed

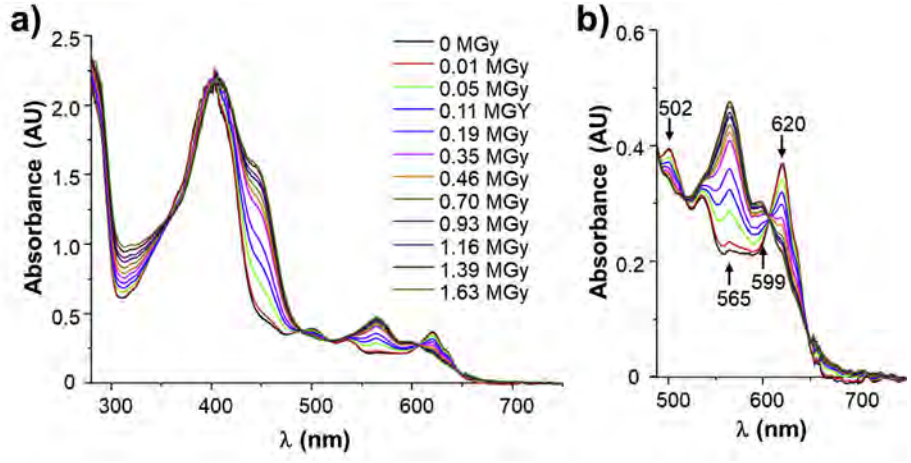

Fig. 5. UV visible spectra of the X-ray reduction of ferric CAT-3. a) Spectra of a single crystal of CAT-3 in the ferric state. Soret's band and peaks related to ferric state (502 nm, 535 nm and 620 nm) are present before X-ray exposure (0 MGy) at increasing dose, a shoulder in the Soret's band at 446 nm, one peak at 565 nm and a shoulder at 599 nm are present. b) Zoom at the 500 nm-700 nm visible spectra.

INFORME DE LABORES 2019

in several research works [23,51,52]. The oxidation state, coordination or even atom occupancy are the parameters affected. Nevertheless, it is not a requirement to report the dose deposited in a crystal when a structure is determined and deposited in the PDB.

There are only a few reports for crystallographic experiments in which the structure of an intermediate of a metalloenzyme is associated to an absorbed dose [23,24,26]. In those, the changes occurred at different rates, but in the most sensitives it is impossible to collect the complete data without affecting the original information, e.g. in horse myoglobin after a crystal accumulated 0.010 MGy the protein is reduced in 10% in comparison to the original oxidation state of the crystal. Furthermore, the use of radioprotectants as ascorbate has minimal effects in protecting the reduced intermediates [26].

In this work, the oxygen bonded to the iron heme in the Cpd I of CAT-3 presents partial occupancies for all monomers in the structure at 0.135 MGy, although at 0.263 MGy the oxygen is bonded to the iron only in monomers C and D with very similar occupancies to that observed in the previous structure, these monomers are related in R and apparently there are not structural relationships that makes the oxidation state to be dependent from each other. The results for UV-visible microspectrometry in the crystal at 0 MGy suggest that there is a partial occupancy since the beginning of the data collection. At this point, the resistance to reduction that has been observed for both C and D monomers, in comparison with the two other monomers cannot be attributed to a higher transformation of them during soaking in PAA, because the occupancy values in the 5° structure were very similar to those at 10°, however only monomers A and B were reduced.

Differential reduction states have been observed in some other enzymes, e.g. the ribonucleotide reductase (R2F) from *Corynebacterium ammoniagenes* [27]. This enzyme is also a homotetramer with two iron atoms in each of the active sites. Authors showed that the sites which were more sensitive to X-ray driven reduction correlated to those with more accessibility to iron during soaking of the apoenzyme in a solution with Fe^{2+} ions, proposing the dependence of a diffusion component during the X-ray reduction process. At temperatures below 110 K solvated electrons are the only species which can diffuse [53,54], the electron are able to migrate through the solvent to the metallic center, as in this case the iron heme. In the CAT-3 structures analyzed in this work (which were crystallized in the space group $P2_12_12_1$) each one of the four monomers has a different surface of contact with the copies of the molecules that forms the crystal. In monomer D the surface contact is 493 $Å^2$, for A is 406.5 $Å^2$, for B is 741 $Å^2$, and for C is 898 $Å^2$. The access to active sites from the surface through the main tunnel is not blocked in any monomer, and the intermolecular contacts do not affect the flux through it, also there is a continual water network which confirms that the tunnels to active site are accessible. If CAT-3 would have the same behaviour that R2F, it would be expected that the oxygen atom in Cpd I of monomers A and D would have a similar occupancy values or the same reduction rate at a given dose. However, as is shown in the structures presented in this work, the reduction of Cpd I occurred before in the A and B monomers. There is not a correlation, at least in our experiments, between the initial occupancy of the Cpd I or the sensitivity to reduction, and the solvent accessibility.

The migration of solvated electrons depends on the accessibility of a water network to the neighbouring of the metallic centers or to residues involved in coordination that allow electron transference through the backbone. As there are only subtle differences between the monomers in the access tunnel (Fig. S1), it is not possible to identify specific structural determinants that control the reactivity of the each monomer. It is possible that this differential sensitivity is tuned by some other specific feature of LSC. LSCs from *N. crassa* (CAT-1 and CAT-3) show cooperativity in kinetic studies, their saturation kinetics fit to a double Hill equation [13]. Molecular dynamic studies of CAT-1 has shown that an “interconnecting channel”, also present in CAT-3, can communicates the P-related subunits in the CAT-3 tetramer, allowing the transportation of substrate molecules between subunits [55]. The interconnecting channel could explain the cooperativity observed in the LSCs kinetic, this hypothesis has not been proven experimentally.

The two subunits that remain oxidized as Cpd I in the 5° structure (C and D) are the R-related subunits; there is no tunnel for solvent communication between the active sites of those subunits but, as previously mentioned, Ser 388 (Fig. 2b) is part of a hydrogen bond network that is connected to the water molecules of the main central channel. This network is communicated to the R-related subunit through the Asp 391, forming a hydrogen bond with a water molecule; this molecule has the same interaction with Asp 391 of the R-related subunit (Fig. S2), being the R-related dimers A-B or C-D. We hypothesize that after the reduction of Cpd I, by means of a proton coupled-electron transfer process, the electrons from one active site can be transferred to Ser 388 and travel through the hydrogen bond network to the R-related metal center. It has been well characterized that proteins are able to transport charge in a controlled way using the protein matrix (backbone, side-chains or hydrogen bonds with solvent) thus defining electron transfer pathways that connect along different protein regions. The role of those pathways has been demonstrated for several proteins by computational and experimental approaches [56,57].

The monomer A is the subunit with lower crystal contacts and may possibly be the more prone to be reduced, and then transfer the exceeding electrons to the heme moiety of B through this electron transfer pathway. This hypothesis could be tested by obtaining of mutants that disrupt the hydrogen bond network. Also it would be interesting to perform an experiment of X-ray driven reduction of CAT-3 in any of the other space groups in which the enzyme has been crystallized [35], in order to analyze if the crystal contacts determine the first R-related dimer which is reduced by X-rays.

4.2. Differences in ferrous state structures

In the structure of CAT-3 in ferric state at 1.95 Å resolution (PDB entry 3ZJ5) [35], there are differences in the position of water molecules of the active site. The monomer B is the only one with 2 water molecules in positions W0 and W1. Every one of the other monomers possesses only one water molecule in position W1 but lack the water in position W0. In the HRP the absence of the water in position W0 has been correlated with the ferrous state [24], on the other hand, for horse Mb has been described an aquo ferrous state, in which there is a water molecule in the sixth coordination site (W0 position) obtained also by X-ray reduction [26].

The identification of the ferrous state in this work establish that CAT-3, and likely all LSC can be found in 4 different oxidation states (Fe^{II} to Fe^{IV+}). The catalysis mediated by CAT-3 occurs in the Fe^{III} and the Fe^{IV+}, an active site of CAT-3 can receive 3 electrons when is in the Fe^{IV+} state. The ferrous state occurs naturally in cytochrome p450, and Mb, but in SSC catalases has been only obtained artificially, chemically with NO [58] or CO [59] as a ligand, or by photoreduction of BLC in a deoxyferrous state [49,50], this photoreduced intermediate was not stable. The mechanisms that allow the catalase to recover the ferric state have not been established. As our experiments were performed at 100 K, it is not possible to make assumptions about its stability at room temperature. It has been reported that in X-ray driven reduction of horse Mb after annealing of reduced crystals, most of the properties in UV-visible and Raman spectra of Mb in the ferric state (MetMb) were recovered [26]. When the CAT-3 crystals of this work were annealed after X-ray exposure, those break immediately after gas release, making impossible the further UV-visible analysis of the crystal (Data not shown). It has been demonstrated that molecular hydrogen (H_2) is the main produced gas in irradiated ethylene glycol samples [60], is important to consider that the precipitant agent in CAT-3 crystals and also the cryoprotectant are PEGs molecules with different lengths (PEG 3350 from the mother liquor and PEG 400 from the cryoprotectant), glycerol was also assayed as cryoprotectant but the crystals lost resolution. On the other hand, water radiolysis produces H_2O_2 [21]. When the crystal

INFORME DE LABORES 2019

was annealed, if there was H_2O_2 present, the enzyme could catalyze the production of O_2 immediately. As annealing procedures for the crystal presented here are destructive, the stability of the ferrous state could be evaluated by performing the UV-visible spectrometric analysis on irradiated samples of CAT-3 in solution.

The UV-visible spectra obtained in the X-ray reduced CAT-3 presented in this work are very similar to that of the deoxyferrous BLC. In the structure of BLC in the ferric state (PDB entry 4BLC at 2.3 Å) the iron heme is pentacoordinated and there are no water molecules in the vicinity of heme moiety, for the ferrous state there is not an associated structure. In the structures of CAT-3 presented here, for those of the reduced Cpd I there is a water W0 at 2.9 Å from the iron heme in the partially reduced structure (monomers A and B of 10° structure) or at 3.3 Å when is fully reduced (110° structure). The structure 3ZJ5 can be associated to the ferrous spectra of X-ray reduced enzyme obtained from the ferric crystals, in this structure, the W0 water molecule is at 3.05 Å of the iron heme in one monomer, while in the three other monomers only the water molecule W1 is present at 4.5 Å.

The behaviour of the peak at 565 nm in both Cpd I and ferric crystals spectra suggest that the reduced intermediates have common features. The reduction of Cpd I to the ferrous state apparently occurs very fast, then both Cpd II and ferric are immediately reduced. As shown in Fig. 4, there are not spectroscopic evidences of presence of Cpd II in the visible spectra. The differences in the absorbance of the peak at 594 nm or 599 nm could be interpreted as differences between the ferrous states obtained from the reduced Cpd-I and the obtained from the ferric, the structural evidence presented here point towards a role for the position of W0 for the high absorbance of the peak at 594–599 nm when is at 3.3 Å from the iron heme, this peak is observed as a shoulder when occupancy of W0 is low (as in the ferric reduced structure), also the presence of a shoulder at 446 nm that is observed in the reduced ferric crystal could be related to the lack of W0 in three of the four monomers. The breakage of heme bonds could also affect the UV-visible spectra of the enzyme, e.g. the peak at 594 nm, however in the analysis of the polder maps of the structures (Fig. 4), there are no changes in the electron density that can be related to alterations of heme structure. Nevertheless, in order to shed light on the role of water W0 in the UV-visible spectra of the ferrous state, the use of techniques which are non-dependant from crystal resolution as EXAFS or Raman spectroscopy would be of great utility.

5. Conclusions

The Cpd I of CAT-3 was totally reduced at a dose lower than 0.263 MGy, this is the dose needed to collect 2/9 of a complete orthorhombic crystallographic dataset, as was supported by X-ray crystallography and UV-visible spectrometry. Reduction of this tetrameric enzyme did not occur simultaneously in the four monomers, but independently. Half of the sites seem to be more sensitive to chemical reduction, which we hypothesized could be due to electron transference between R-related subunits. The ferrous state in heme *b* LSC can be obtained by X-ray reduction, and considering the doses measured here for reduction of ferric catalase, it is probable that several deposited crystal structures, in the PDB, describing a ferric state belong actually to the ferrous state of the enzyme.

Acknowledgment

This work was financed by Consejo Nacional de Ciencia y Tecnología (CONACyT) through project 102370 and by Universidad Nacional Autónoma de México through PAPIIT IN204611. Authors thank the staff at NSLS beamline X6A for data-collection facilities. Beamline X6A is funded by NIGMS (GM-0080) and the U.S. Department of Energy (No. DE-AC02-98CH10886). Authors thank also the staff at SSRL beamline BL11-1 for data collection facilities. Abstract

An experimental *Taenia crassiceps* mouse model was used to assess the role of *Taenia solium* metacestode factor (Fac) in human neurocysticercosis. Intraperitoneal infection with *T. crassiceps* metacestodes or subcutaneous inoculation with a *T. crassiceps* metacestode factor (Fac) produced significant impairment of performance (learning) in the Barnes maze and induced bilateral hippocampal sclerosis in mice. Several staining techniques revealed important cell dispersion, extensive apoptosis and cell loss in the dentate gyrus, hilus and CA1-CA3 regions of both hippocampi, as well as intense deterioration of the adjacent cortex. An outstanding disruption of its histoarchitecture in the surrounding tissue of all these regions and apoptosis of the endothelial cells were also observed.

Introduction

Human beings acquire neurocysticercosis (NCC) by ingesting foods contaminated with *Taenia solium* eggs. The acidic gastric juice breaks up the inter-embryophore cement of the eggs. Then, the sheath-covered embryos are carried to the duodenum, where the pancreatic juice and bile dissolve the external lipid layer of the sheath, allowing the entrance of water and nutrients, which activate the previously dormant embryos. The activated embryos rip their envelopes with the help of their six sharp hooks, and they promptly leave these broken structures, as described in an *in vitro* study (Molinari *et al.*, 1993). Released from their envelopes, activated embryos invade the intestine, as with *Hymenolepis nana* (Miyasato *et al.*, 1977), migrate through the bloodstream and implant in several tissues, such as the striated muscles and central nervous system, where they develop into the metacestode stage.

Neurocysticercosis is considered to be the most common parasitic infestation of the central nervous system and the single most common cause of epilepsy. Seizures, headaches and neurological deficits are described in human neurocysticercosis. Signs of psychiatric disease (65.8%), cognitive decline (87%), altered memory (25%) and attention deficits (100%) among others were reported in a heterogeneous sample of 38 patients (Forlenza *et al.*, 1997). Other features are hydrocephalous, chronic meningitis, and impairment in executive functions, verbal and non-verbal memory, praxis and verbal fluency (Varghese *et al.*, 2016).

Hippocampal atrophy without seizures in patients with calcified neurocysticercosis (cNCC) has been observed, suggesting inflammatory-mediated mechanisms provoked by cysticercosis, which may contribute or even lead to refractory mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE-HS) by mechanisms that need to be clarified (Bianchin *et al.*, 2015; Griper and Welburn, 2017). To address the role that *T. solium* metacestode factor (Fac) (Molinari *et al.*, 1990) could play in the production of hippocampal sclerosis, whose cause in human neurocysticercosis is poorly understood, we developed an experimental *Taenia crassiceps*-mouse model to study and understand the effects of an infection of mice with *T. crassiceps* metacestodes and the subcutaneous inoculation of mice with a *T. crassiceps* factor on hippocampal cells; results showed an extensive and significant apoptosis of dentate gyrus, CA1, CA2, CA3 and hilus cells compared with intact control cells (Zepeda *et al.*, 2017).

In the current research, we extended the time of infection and the inoculation with Fac for 110 days to try to induce a more severe hippocampal injury than that reported recently (Zepeda *et al.*, 2017). Histopathologically, temporal lobe epilepsy (TLE) associated with HS has been characterized by cell death and neuronal cell loss, which is most severe in the CA1 and CA3 regions and in the hilus of the dentate gyrus (DG), volume loss, reactive gliosis, and dispersion of the dentate gyrus granule cells (Sloviter, 1994; Lurton *et al.*, 1998).

INFORME DE LABORES 2019

Materials and methods

Treatment of mice

BALB/c mice (28 days old, 20–22 g) were maintained under standard animal housing conditions with access to Purina chow and water *ad libitum*. *Taenia crassiceps* metacestodes (WFU strain) were maintained in our laboratory via peritoneal passage in female mice, as described (Everhard *et al.*, 2004). Peritoneal fluid from healthy female controls (CPF) and *T. crassiceps* metacestode-infected mice, as well as *T. crassiceps* metacestode factor (Fac), were obtained according to Zepeda *et al.* (2011). To determine the effects of infection with *T. crassiceps* metacestodes and Fac treatment on hippocampal cells and the surrounding tissue, 18 female mice were divided into three groups. The control (Con) group (n = 6) and Factor (Fac) group (n = 6) were inoculated subcutaneously with 0.1 ml CPF, or Fac containing 50 µg of carbohydrates, as determined by the anthrone method (Ashwell, 1957) every 4 days for 100 days. The infected (Inf) group (n = 6) was infected intraperitoneally with up to 40 *T. crassiceps* metacestodes, measuring 2–3 mm in diameter and suspended in 0.2 ml phosphate buffered saline (PBS).

Barnes maze

At 110 days post infection with intraperitoneal *T. crassiceps* metacestodes or subcutaneous inoculation with *T. crassiceps* Fac, the Barnes maze procedure for small rodents was followed to estimate cognitive impairment in learning and memory (Rosenfeld and Ferguson, 2014), with minor modifications. Briefly, a bright illumination overhead was used. The maze was centred below the lights. Mice were tested without the use of a wall or cues. The maze was 90 cm in diameter and 90 cm in height, with 20 escape holes that each had a diameter of 5 cm, and there was only one hole with an escape cage. No hole was plugged in this test. After 30 minutes of habituation, each mouse was gently removed from his home cage and placed onto the maze centre. Then, the overhead lights were turned on. Every mouse's performance was recorded using a Canon VIXIA HF R70 camera (Canon, Melville, NY, USA). If the mouse failed to enter the escape cage within 5 minutes, it was guided gently to the correct location and into the escape cage, where it remained for 2 minutes. Each mouse was tested for two trials/day with an inter-trial interval of approximately 30 minutes. All mice were tested for five consecutive days. Videos were analysed carefully. The Barnes maze test was used to study the behaviour of the control, experimental cysticercotic and Fac treated-mice.

Histology and cellular apoptosis

At 115 days post treatment and infection, all mice were anaesthetized with pentobarbital and perfused transcardially with saline followed by phosphate-buffered 10% formalin. Then, the brains were carefully removed, and intraperitoneal metacestodes were obtained and counted. Two coronal cuts were made in each brain: an anterior cut was made at Bregma −1.43 mm and the other at Bregma −5.19 mm (Paxinos and Franklin, 2013). The intermediate fragments of each brain were fixed with 2.5% paraformaldehyde in PBS for 12 h at room temperature. Next, the fragments of each brain were embedded in paraffin. Coronal sections that were 5 µm thick were prepared on a rotary microtome, placed on poly-L-lysine-coated microscopic slide, and subjected to haematoxylin/eosin (H/E) and DAPI staining to analyse the cellular morphology and histoarchitecture of the dentate gyrus and CA1-CA3 regions. Sections stained with H/E were analysed with an Olympus IX71 microscope and IMAGE PRO-PCUS 60 software. Sections stained with DAPI were analysed with a Zeiss LSM 800 confocal microscope and ZEN version 2.1 software. The presence of DNA strand breaks was evaluated using an *in situ* cell death detection kit (Roche). TUNEL assays were analysed with a confocal microscope Leica TCS-SPS (Carl Zeiss de México-División Microscopía, Ciudad de México).

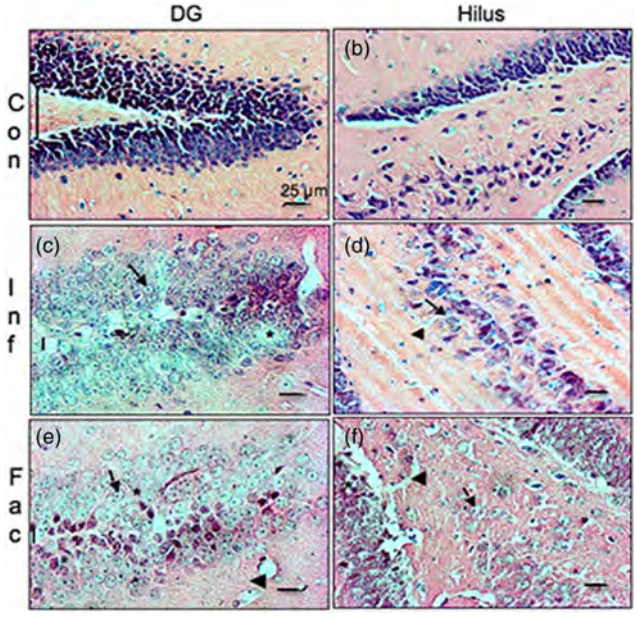

Fig. 2. Haematoxylin/eosin-stained brain section that contains part of the dentate gyrus and hilus from a control mouse (a & b), a mouse infected with *T. crassiceps* metacestodes (c & d), and a mouse inoculated with *T. crassiceps* Fac (e & f). Cell loss (*); bleached nuclei (arrows); tears (arrowheads); gyrus branches angle (vertical bar). Scale bar = 25 µm. 40×.

Data analysis

The numbers of haematoxylin/eosin-stained and TUNEL-positive cells were measured by manual counting (area in μm^2) with the aid of Image J software (National Institutes of Health, Bethesda, MD, USA). For statistical data, one-way analyses of variance and Tukey's test were performed using GraphPad software

(GraphPad Instat, San Diego, CA, USA). Data are presented as the mean ± SD. $P < 0.05$ was considered significant.

Results

Barnes maze

Both intraperitoneal infection with *Taenia crassiceps* metacestodes and subcutaneous inoculation with a *T. crassiceps* metacestode factor (Fac) produced significant impairment on performance in the Barnes maze and induced bilateral hippocampal sclerosis in mice. The performance in the Barnes maze was mainly assessed by the escape latency parameter (mean ± SD), measured in the number of seconds it took to reach and completely hide in the escape hole.

During all time (second trial) to learn this task, both infected and factor mice were significantly slower in reaching and hiding in the escape hole, in comparison with control mice. On the fifth day, all control mice (n = 6) were able to hide in the escape hole in 28 ± 44 s after reaching it. Latency values of control mice were significantly less than those of experimental mice ($P < 0.05$ Con vs Fac, and $P < 0.01$ Con vs Inf.; fig. 1). Infected mice (n = 4) showed difficulty in moving in the maze; on the fourth day only one (25%) was able to hide at 151 s after reaching the escape hole. On the fifth day only one reached the escape hole in 73 s, and stayed there the rest of time without hiding in the hole. On

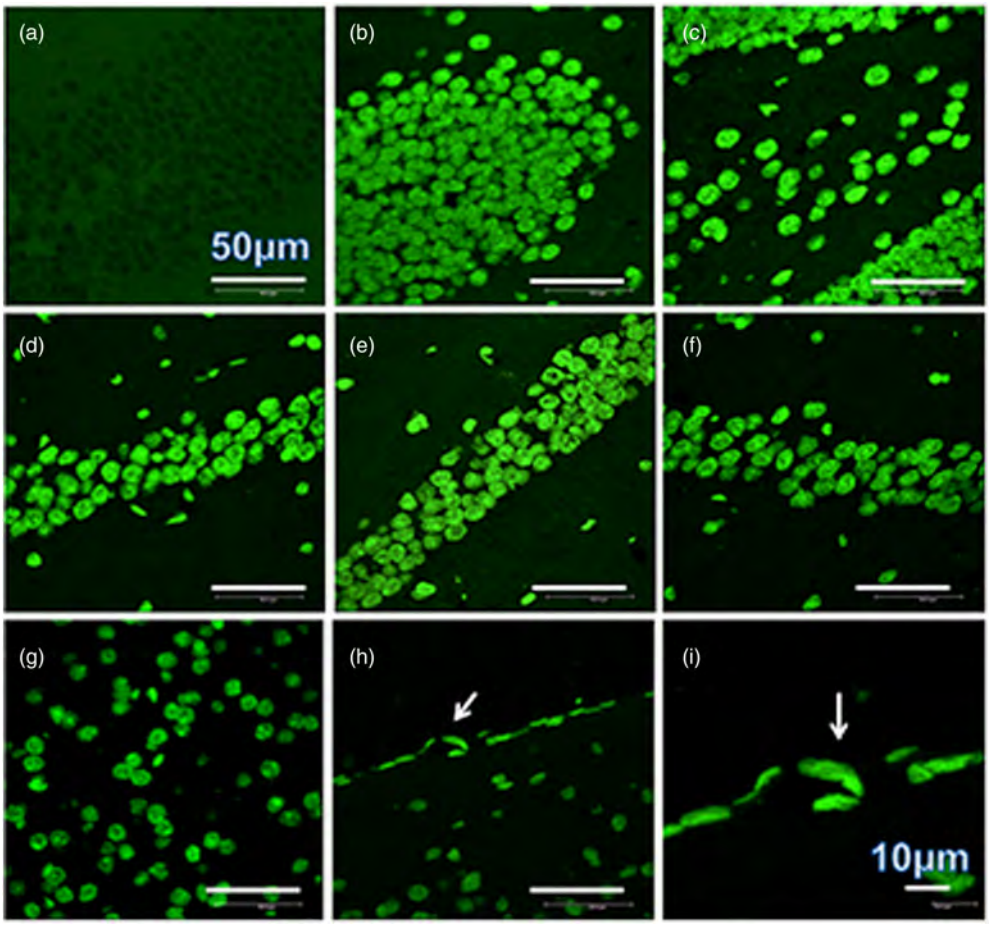

Fig. 6. TUNEL-stained brain sections that contain a portion of dentate gyrus from a control mouse (a), a portion of dentate gyrus and hilus from a mouse infected with *T. crassiceps* Fac (b and c), a portion of CD1, CD2 and CD3 from a mouse inoculated with *T. crassiceps* Fac (d–f), a portion of the adjacent cortex from a mouse inoculated with Fac (g), and the border of the adjacent cortex showing apoptotic endothelial cells within sections of the capillary (arrow) (h). Scale bar = 50 μm. 60×. (i) is an amplification of (h). Scale bar = 10 μm. 200×.

the fifth day Factor mice (n = 6) showed hyperactivity, reaching the escape hole at 67 ± 38 s. Only five mice had hidden at 73 ± 85 s after reaching the escape hole. The sixth mouse did reach the escape hole at 99 s, then left the hole four times to explore several holes and came back, but it never hid (fig. 1).

Histopathological studies

A heavy parasite load was found in the peritoneal cavity of mice infected with *T. crassiceps* metacestodes (485 ± 78 metacestodes per mouse). Haematoxylin/eosin staining showed that all sub-regions of hippocampi from experimental animals were affected in their tissue architecture either in the cellular morphology or in the surrounding tissue. The dentate gyri, as well as the hilus, CA1, CA2 and CA3 cells displayed dispersion, bleached nuclei, cell loss and many tears in the surrounding white matter, compared with the integrity of the cells and the white matter of the control hippocampi. Dentate gyrus branches from experimental mice (fig. 2c, e) formed a smaller angle compared to those of the control hippocampi (fig. 2a). The number of cells that had altered morphology and staining were statistically ($P < 0.001$) more than those of the control mice (fig. 3). DAPI staining displayed generalized pyknosis or hypercondensation of the chromatin of the CA1, CA2 and CA3 nuclei from *T. crassiceps* infected and Fac-treated mice. Apparently, all nuclei in these sub-regions were collapsed, and their number was less than those of the control mice. Additionally, numerous empty spaces among the reduced number of pyknotic nuclei of these sub-regions were observed, which suggested cell loss (fig. 4). Pyknosis is the accepted sign of programmed cell death (Burgoyne, 1999). To evaluate DNA fragmentation, DNA strand breaks were labelled using fluorescein-dUTP. This staining showed generalized and significant TUNEL-positive cells in the three layers of the dentate gyrus, hilus and in cells from the CA1, CA2 and CA3 regions, including the adjacent cortex ($P < 0.01$ Inf and Fac vs. Con). In all these places, many fragmented nuclei were observed, compared to TUNEL-negative nuclei of the control hippocampi. The intensity of the fluorescence of the nuclei in the above-mentioned regions was not homogeneous, suggesting that apoptosis was induced at different times. Nuclei with a lower fluorescence intensity and of reduced size could be among the first in developing apoptosis. Dispersion and cell loss were also observed (figs 5 and 6). Numerous TUNEL-positive cells were also found in the neighbouring cortex. A remarkable finding was the observation of apoptosis of endothelial cells in several places in all the studied regions (figs 6 and 7).

Discussion

In the current research, the experimental *T. crassiceps* mouse model (Zepeda *et al.*, 2017) was used to investigate parasite mechanisms involved in the production of hippocampal sclerosis

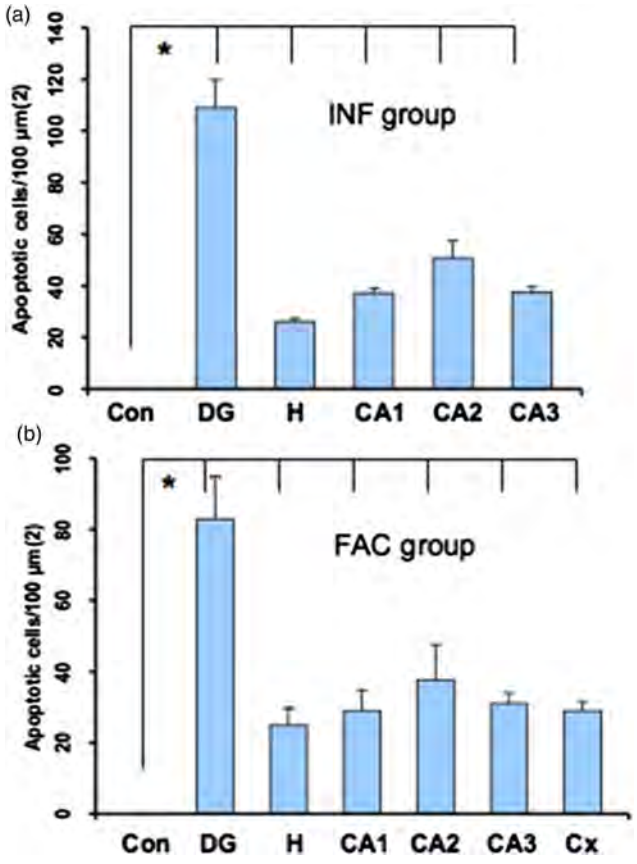

Fig. 7. Statistical data from the sections stained with TUNEL. Bars represent the mean ± SD of the dentate gyrus from control mice (a & b), dentate gyrus (DG), hilus (H), CA1, CA2 and CA3 from infected mice (a), and DG, H, CA1, CA2, CA3 and Cortex (Cx) from factor mice (b). * $P < 0.01$ DG, H, CA1, CA2, CA3 and Cx vs Con.

(HS), in which some patients suffer from neurocysticercosis. A deficit in learning and memory functions was observed using the Barnes maze. This deficit was more pronounced in mice infected with *T. crassiceps* metacestodes, perhaps due to a heavy parasitic load and an intense intraperitoneal inflammatory reaction as described (Zepeda *et al.*, 2010), as well as structural damage of the histoarchitecture of the hippocampi from experimental mice. This damage was characterized by significant cell death (apoptosis), cell dispersion and cell loss, in all sub-regions of the hippocampus either in the infected group or the Fac-treated animals, such as dentate gyrus, hilus, CA1, CA2, CA3, and the adjacent cortex, compared with the integrity of the cells in control mice. Structural damage was also observed in the neighbouring white matter.

The Barnes maze has been used to relate memory loss and long-term potentation (LTP) dysfunction in the hippocampus, which are involved in Alzheimer's disease. Using the Barnes maze, Hadipour *et al.* (2018) found that administration of crocin in rats significantly improves spatial memory indicators such as latency time. The learning deficit in Aβ (beta-amyloid)-treated animals correlated with a reduction of LTP in hippocampal synapses. Crocin significantly reduced the number of TUNEL-positive cells in the CA1 sub-region compared to the Aβ-group. Barbe *et al.* (2016) utilized the Barnes maze to test for long-term memory deficits, with good success. Their results showed in the CA1-3 regions of the hippocampus of mice significantly reduced numbers of neuronal cell bodies overall, and reduced numbers of Pur-alpha+ neuronal cell bodies and dendrites in heterozygous Pur-alpha (+/-) mice, compared to wild-type (+/+) littermates.

Here, in every sub-region studied, a very interesting finding was the observation of apoptotic endothelial cells dispersed in the white matter near the neuronal packages and in the border of the adjacent cortex. This finding suggests that the Fac apoptogenic activity on endothelial cells could impair the blood–brain barrier, allowing the entry of the Fac (that migrated via the bloodstream when the peritoneal cavity of the mouse was infected with *T. crassiceps* metacestodes or the abdominal skin of the mouse was inoculated with Fac) into the brain, so that it can reach the hippocampal cells and other regions of the brain, such as thalamic nuclei (Zepeda *et al.*, 2017). The apoptogenic activity of Fac seems to have been cumulative, as was observed with the TUNEL staining.

The pathological characteristic produced by *T. crassiceps* metacestode infection or by *T. crassiceps* Fac in all sub-regions of the hippocampus resembles human hippocampal sclerosis, such as volume loss, which indicates atrophy (Jeniffer *et al.*, 2015). The learning deficit and hyperactivity are neurological manifestations of structural damage in the hippocampus, which rely on other functions, such as attention, language and spatial memory. Another feature of hippocampal sclerosis described in the literature is the increase of astrocytes during the scarring process in places where there has been cell loss due to some injury (Sloviter, 1994). We looked for this feature using a rabbit antibody anti-GFAP fluorescein mouse, but we could not obtain positive results in this way. So, in the next study, we intend to test this hypothesis.

In humans, NCC damage to the hippocampus caused by the *T. solium* Fac must be a very chronic process, proportional to the number of living parasites; thus, when the neurological deficits are apparent, including epilepsy, the parasites are probably already calcified. Molinari *et al.* (1987) reported that in porcine cysticercosis, the suppression of T-cells was proportional to the number of cysticerci per 1 kg of parasitized meat. Human neurocysticercosis has been associated with hippocampal atrophy, and the results of a study by Del Brutto *et al.* (2017) suggested that NCC-related hippocampal atrophy takes a long time to develop.

Taenia crassiceps Fac are chromatographic Sephadex G-50 fractions containing substances of low molecular weight (< 1250 Da) obtained by ultrafiltration of the peritoneal fluid from female mice infected intraperitoneally with *T. crassiceps* metacestodes (Zepeda *et al.*, 2011). The complete chemical characterization of these substances has not been possible. By preliminary NMR and infrared studies, these Sephadex G-50 fractions contain at least three aromatic components, carbohydrates such as glucose, and can induce a specific antibody response in rabbits and mice, which indicate that this factor is produced by the parasite (data not published). The non-specific way this Fac induces apoptosis in different types of cells, such as testis cells (Zepeda *et al.*, 2011), ovary cells (Solano *et al.*, 2015), spleen cells (Zepeda *et al.*, 2016), and hippocampal cells (Zepeda *et al.*, 2017) is unknown. The learning deficit and the extensive apoptosis of hippocampal cells of experimental mice indicate a close relationship between both structure and function. Thus, it may be reasonable to assume *T. solium* metacestode factor is the causative agent of brain injuries such as hippocampal sclerosis in human neurocysticercosis. It will be important to contrast these results with relevant studies in human neurocysticercosis, as has been noted by Del Brutto *et al.* (2016).

Downloaded from https://www.cambridge.org/core. CDC de la AtmosferaAv: Universidad No. 3000, on 20 Oct 2020 at 08:09:37, subject to the Cambridge Core terms of use, available at https://www.cambridge.org/core/terms. https://doi.org/10.1017/S0022149X18000755

Using the Barnes maze, experimental mice showed a learning deficit closely related to hippocampal injury and very similar to that observed in patients with neurocysticercosis. Apoptosis of hippocampal endothelial cells suggested that *T. crassiceps* metacestode factor was able to break the BBB, enter the brain and produce hippocampal sclerosis.

Acknowledgments. We are grateful to Teresa Cortés and Daniela Rodríguez for performing histological procedures, and Claudia Rivera and Héctor Malagón for providing the healthy mice. ABSTRACT

Porcine Circovirus Type 2 (PCV2) is one of the most important pathogens in pigs around the world. PCV2 is a non-enveloped virus and its capsid is formed by a single protein known as open reading frame 2 (ORF2). The aim of this study was to evaluate the antigenicity and immunogenicity of genetically-encoded protein nanoparticles (NPs) containing ORF2 from PCV2 fused to the first 110 amino acids of the N-terminus of polyhedrin from the insect virus Autographa californica nucleopolyhedrovirus (PH (1 −1 1 0)). Our group has previously described that some polyhedrin fragments self-aggregate forming polyhedra-like particles. We identified a self-aggregating signal within the first 110 amino acids from polyhedrin (PH(1 −1 1 0)). Fusing the ORF2 from PCV2 to the carboxyl terminus from PH(1 −1 1 0) results in the formation of NPs which incorporate the antigen of interest. Using this system we synthesized NPs containing PH(1 −1 1 0) fused to ORF2 (PH(1 −1 1 0)PCV2) and purify them to immunize pigs and evaluate the humoral immune response generated by these NPs comparing them to a commercially available vaccine. Pigs immunized with PH(1 −1 1 0)PCV2 NPs produced antibodies against ORF2 from PCV2 as indicated by western blot and ELISA analysis. Antibodies obtained with PH(1 −1 1 0)PCV2 NPs were comparable to those obtained using a commercial PCV2 vaccine. These antibodies neutralized the infection of a recombinant PCV2 expressing the green fluorescent protein (GFP). These results together suggest that the self-aggregating peptide PH(1 −1 1 0) can be used for the synthesis of subunit vaccines against PCV2.

1. Introduction

Porcine circoviruses (PCV) are small DNA viruses showing worldwide distribution. Nowadays, at least 3 types of PCV have been identified. PCV1 was reported as a non-cytopathic virus contaminant of porcine kidney cells [1]. PCV2 was described for the first time in pigs affected by post-weaning multisystemic wasting syndrome (PMWS) in 1991 in Canada [2–4]. PCV2 is associated to porcine dermatitis and nephropathy syndrome (PDNS), reproductive disorders [3,5–7], respiratory diseases, hepatitis, enteropathy and neurologic syndrome [8]. PCV2 infects monocytes/macrophages and enters to host cells via clathrin-mediated endocitosis [9]. PCV2 also induces lymphocyte depletion, and therefore, facilitates many infectious diseases by bacteria and other viruses [10]. PCV2 contains 2 main genes: open reading frame 1 (ORF1) implicated in viral DNA replication and ORF2 responsible for the formation of the capsid. The ORF2 protein has a molecular weight of 30 kDa [11] and binds to heparan sulfate from the target cells [12]. Antibodies against ORF2 are sufficient to neutralize the infection [4,13]. PCV3 is a novel circovirus species associated to PDNS, reproductive failure and systemic inflammation, which has been isolated recently in the United States, Italy [14], China [15], and Poland [16].

PCV2 is one of the most important pathogens in the pig industry around the world because it causes important economic losses [3,4,17,18]. There are several commercially available vaccines against PCV2 and all of them are based on the ORF2 [4,19]. The first

vaccine against PCV2 was Circovac® (Merial) which is based on an inactivated PCV2 [4]. Recent advances in vaccine development allowed the production of virus-like particles (VLPs) [20]. VLPs are self-assembling nanoparticles (NPs) formed by capsid proteins but without nucleic acids [21,22]. The baculovirus system is preferred to produce VLPs because it allows produce high protein yield with posttranslational changes [23,24]. Currently, there are three VLPs-based vaccines against PCV2, which induce a strong humoral immune response against PCV2: Circoflex® (Boehringer Ingelheim), Circumvent® (Intervet/Merck) and Porcilis PCV® (Shering Plough/Merk). Another PCV2 vaccine is Fostera® PCV which is based on chimeric PCV1/2 containing the genomic backbone of PCV1 with the ORF2 from PCV2 (Zoetis) [4].

Although PCV2 vaccines have been shown to induce antibodies that can neutralize the PCV2 infection [25] and increase the daily weight gain in growing pigs [25,26], the drawbacks of some of them are of special concern. For instance, the purification process of VLPs is time-consuming and specialized laboratory instruments are needed which may increase the cost of vaccination [20,27]. Previously, we reported that a peptide of 110 amino acids derived of the N-terminus of polyhedrin protein (PH(1 1 0)) from *Autographa californica nucleopolyhedrovirus* (AcNPV) self-aggregates forming nanoparticles (NPs) [28]. These NPs can be easily produced and purified by simple centrifugation. Furthermore, producing a fusion protein of PH(1 1 0) with an antigen of interest facilitates the purification of such antigen by centrifugation [29]. These PH (1 1 0)-antigen NPs can be produced with the baculovirus expression system, resulting in very high yields [29].

In this work, we generated NPs containing ORF2 fused to PH (1 1 0) (PH(1 1 0)PCV2 NPs) by the infection of Sf9 cells using a recombinant baculovirus and we characterized these NPs. We immunized pigs with these NPs and evaluated the antibody production against ORF2 by western blot and ELISA. Finally, we evaluated if these antibodies could neutralize the PCV2 infection in PK-15 cells using a recombinant PCV2 expressing the green fluorescence protein (GFP) as reporter of infection.

2. Materials and methods

2.1. Regents

Grace medium (catalog no. 11300-043 or 11605102), Antibiotic-antimycotic 100X containing 10,000 UI of penicilin/ml, 10,000 μg of streptomicin/ml and 25 μg of amphotericin B/ml (catalog no. 15240-062), Dulbecco's Modified Eagle Medium (DMEM) (catalog no. 12800082), Optimem™ (catalog no. 22600134), yeastolate (catalog no. 292805), Platinum® Pfx polymerase (catalog no. 11708039), X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) (catalog no. 15520018), IPTG (Isopropyl ß-D-1-thiogalactopyranoside) (catalog no. 15529019), the Pierce™ BCA Protein Assay (catalog no. 10741395), TMB (3,3′,5,5′-Tetramethylbenzidine) (catalog no. N301), Proteinase K (catalog no. 25530015), DAPI(4′, 6-diamino-2-phenylindole) (catalog no. D3571), sodium dodecyl sulfate (SDS) (catalog no. 18220), the Cyanine3 (Cy3)-conjugated goat anti-mouse IgG (catalog no. A10521), the SuperSignal® West Femto Maximum Sensitivity Substrate (catalog no. 34095), and the baculovirus Bac-to-Bac™ system (catalog no. 10359-016) which contains: pFastBac™ vector, DH10Bac™ *E. coli* competent cells, and Cellfectin® II reagent, an additional pFastBac™ Dual Expression vector (catalog no. 10712-024), and the Lipofectamine® 2000 (catalog no. 11668019) were from Thermo Fisher Scientific (Waltham, MA, USA). Lactalbumin (catalog no. L9010), pluronic acid F-68 (catalog no. P1300), the anti-mouse HRP-conjugated antibody (catalog no. A9044), the anti-pig HRP-conjugated antibody (catalog no. A5670), the bovine serum albumin (BSA) (catalog no. A5611), D-glucosamine hydrocloride (catalog no. G4875), and LB broth, Miller medium (catalog no. L3152) were from Sigma-Aldrich (St. Louis, MO, USA). The fetal bovine serum (FBS) (catalog no. 081105) was from Biowest (Rue du Vieux Bourg, Nuaillé, France). Nitrocellulose membrane (catalog no. HATF00010), pET-28a-c(+) (69864), BL21 cells (69386-3) were from Merck Millipore, Ltd. (Tullagreen, Carrigtwohill. Co. Cork, Ireland). The Qiagen plasmid Midi Kit (catalog no. 12143) was from QIAGEN (Hilden, Germany). The pGEM® T Easy vector (A1360) were from promega (Madison, WI, USA). The Precision Plus Protein™ Dual Color Standards (catalog no. 1610374) was from Bio-Rad (Hercules, CA, USA). The Dako Fluorescent Mounting Medium (catalog no. S3023) was from Agilent (Santa Clara, CA, USA). The following vaccines were used: Fostera® PCV (lote no. 14075700). Circoflex® (lote no. 1601035B) and Circovac® (lote no. L433873). Syringes were 1 and 3 ml and needles were 26G × 1/2″ (0.45 × 12 mm) (brown needles) and 22G × 1 1/4″ (0.7 × 30 mm) (black needles) (for their use in mice and pigs, respectively).

2.2. Cells and virus

Sf9 cells (*Spodoptera frugiperda*) (catalog no. B82501) were obtained from Thermo Fisher Scientific (Waltham, MA, USA) and were maintained in Grace medium supplemented with 10% heat-inactivated FBS (56 °C 30 min), containing 3.33 g/l yeastolate, 3.33 g/l lactalbumin hydrolysate, antibiotic-antimycotic containing 100 UI of penicilin/ml, 100 μg of streptomicin/ml and 0.25 μg of amphotericin B/ml and pluronic acid F-68 to a final concentration of 0.1%. The baculovirus Bac-to-Bac™ system was used for the construction of three recombinant baculoviruses: PH(1 1 0)PCV2, PH (1 1 0)GFP (which induce the expression of GFP or ORF2 from PCV2 fused to PH(1 1 0), respectively), and PH(2 4 5) (which contains the full-length polyhedrin protein). All the recombinant baculoviruses were propagated in Sf9 cells. For the neutralization assay against PCV2, PK15-C1 cells (American Type Culture Collection, ATCC® number PTA-8244™; University Boulevard Manassas, VA 20110-2209 USA) and a recombinant PCV2 expressing GFP were used.

2.3. Recombinant PCV2 viruses

All the recombinant baculoviruses were produced similarly using the Bac-to-Bac™ system following the manufacturer's instructions. Briefly, the recombinant baculovirus PH(1 1 0)PCV2 was produced by a PCR flanking ORF2 from PCV2 isolated from an PCV2-infected Mexican pig. The primers 5′-CCATGGCTATGACGTATCCAAG GAGGCG-3′ and 5′-GTCGACTTAGGGTTTAAGTGGGGGG-3′ and the Platinum® Pfx polymerase were used for the PCR reaction. Baculovirus PH(1 1 0)PCV2 was designed similarly to baculovirus PH (1 1 0)GFP with slight modifications. The stromal interaction molecule 1 (STIM1, a protein localized to the endoplasmic reticulum) was fused to the yellow fluorescent protein (YFP) gene and was inserted under p10 promoter (Pp10) to easily visualize the infected cells. The baculovirus PH(2 4 5) was designed by inserting the full-length *polyhedrin* gene under polyhedrin promoter (PpH).

A recombinant PCV2 was designed by using the plasmid pGEM® T easy vector and the GFP. GFP was inserted into pGEM® T easy vector under the cytomegalovirus earlier promoter (CMV). The complete genome from PCV2 was linearized and inserted into the modified pGEM® T easy vector. PK-15 cells were transfected with the recombinant plasmid with Lipofectamine® 2000.

2.4. Production of specific sera against polyhedrin and ORF2 from PCV2

Sf9 cells were infected with a multiplicity of infection (MOI) of 20 from baculovirus PH(2 4 5). At 72 h postinfection (hpi), infected

INFORME DE LABORES 2019

Sf9 cells were sonicated and polyhedra were recovered and washed 3 times with PBS containing 0.1% of SDS to eliminate residual debris [30]. Finally, polyhedra were washed with PBS to eliminate residual SDS and protein concentration was measured. Five 6-week-old BALB/c female mice were immunized with 50 μg of polyhedra with complete Freund adjuvant coadministration intramuscularly into the leg muscle, 2 and 4 weeks later mice received two booster doses of 50 μg of polyhedra with incomplete Freund adjuvant coadministration subcutaneously at the base of a fold of loose skin (area at the neck). Similarly, five 6-week-old BALB/c female mice were immunized with 50 μl of vaccine Fostera® PCV and two booster doses were given 2 and 4 weeks later, intramuscularly into the leg muscle. Injections had a final volume of 50 μl for both groups of mice and sera were collected for both groups 8 weeks after prime doses.

2.5. Production of PH(1 1 0)PCV2 NPs

In order to produce the PH(1 1 0)PCV2 NPs, the first step was to determine the MOI of the baculovirus PH(1 1 0)PCV2. To do this, Sf9 cells were infected with the recombinant baculovirus PH (1 1 0)PCV2 with a MOI of 0.2, 2 and 20. At 72 hpi, infected Sf9 cells were centrifugated at 3000*g* for 10 min and the pellet was resuspended in PBS. The infected Sf9 cells were lysed by sonication (Qsonica 700, USA) at 500 J/min for 1 min in ice bath (20% of amplitude using a microprobe). PH(1 1 0)PCV2 NPs were purified using three cycles of sonication, and centrifugation at 11,300*g* for 2 min and a wash after each cycle. The PH(1 1 0)PCV2 NPs were resuspended in PBS and were analyzed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) using a 12% acrylamide gel. After electrophoresis, the gel was stained with Coomassie blue for 2 h and then was destained overnight. The MOI of 20 was selected to produce PH(1 1 0)PCV2 NPs. The second step was to determine the time for recovering PH(1 1 0)PCV2 NPs. Briefly, Sf9 cells were infected with a MOI of 20. Aliquots of infected Sf9 cells were taken at 48 and 72 hpi and the infected cells were sonicated for recovering PH(1 1 0)PCV2 NPs as we previously mentioned. PH(1 1 0)PCV2 NPs were resuspended in a volume of 100 μl of PBS and 50 μl of a 1:1000 dilution of these NPs were added to each well of a polystyrene ELISA microplate. The presence of PH(1 1 0)PCV2 NPs was evaluated using hyperimmune sera against PCV2 obtained from mice immunized with Fostera® PCV. The complete ELISA protocol is showed below. The time for recovering PH(1 1 0)PCV2 NPs was 72 hpi. Finally, 100 ml of Sf9 cells were infected with a MOI of 20 of the recombinant baculovirus PH(1 1 0)PCV2 in Erlenmeyer 250-ml flasks and recovered at 72 hpi, sonicated and purified as we mentioned above. All the Sf9 cell cultures contained 2×10^6 cells/ml and were incubated at 27 °C at 100 rpm. PH(1 1 0)GFP NPs were synthesized similarly and protein concentration was determined by the BCA method. NPs were stored at −70 °C.

2.6. Western blot analysis

The recombinant ORF2 from PCV2 was produced by inducing BL21 bacteria transformed with the modified plasmid pET-28a. The recombinant ORF2 from PCV2 was used in western blot for detecting anti-PCV2 antibodies in the vaccinated pigs (see below). 30 μg of PH(1 1 0)PCV2NPs, PH(1 1 0)GFP NPs, lysed Sf9 cells or 20 μg of recombinant ORF2 from PCV2 were boiled for 5 min in Laemmli buffer and run by SDS-PAGE using 10 and 12% acrylamide gels. Antigens were electrophoresed at 50 V for 40 min and then 2 h at 100 V. Proteins were transferred to nitrocellulose membranes at 80 V for 1 h 20 min. The nitrocellulose membranes were blocked in tris-buffered saline (TBS) with 5% of low fat milk overnight. A dilution of 2:4000 of a serum from a PCV2-infected pig was used to detect ORF2 from PCV2 in the denatured PH(1 1 0)PCV2 protein. Similarly, a dilution of 2:4000 of a serum from a mouse immunized with polyhedra was used to detect PH(1 1 0) in the denatured PH(1 1 0)PCV2 and PH(1 1 0)GFP proteins. The sera from pigs immunized with Circoflex® or PH(1 1 0)PCV2 NPs were used to detect specific antibodies against ORF2 from PCV2. Anti-pig or anti-mouse antibodies, both HRP-conjugated, were used at a dilution of 1:5000. The membranes were scanned with C-Digit blot scanner (LI-COR) after the substrate was added.

2.7. Immunofluorescence assay

Sf9 cells were grown in 6-well microplates with sterilized coverslips. The Sf9 cells were infected with the recombinant baculovirus PH(1 1 0)PCV2 or PH(1 1 0)GFP with a MOI of 20. An indirect immunofluorescence assay was realized to visualize the PH(1 1 0) PCV2 NPs. Sf9 cells infected with the recombinant baculovirus PH (1 1 0)GFP also were treated for immunofluorescence against PCV2 and were used as a negative control. At 72 hpi, the Sf9 cells infected by the recombinant baculoviruses PH(1 1 0)PCV2 or PH (1 1 0)GFP were washed 2 times with PBS, fixed with 4% paraformaldehyde for 20 min and permeabilized with PBS containing 0.3% Triton X-100 for 15 min. After each procedure, the coverslips were washed three times. PBS containing 50 mM glycine was added for 10 min. Cells were blocked with 5% BSA in PBS at room temperature for 1 h and hyperimmune sera against ORF2 from PCV2 from mice immunized with Fostera® PCV were used at a dilution of 1:500 and incubated for 1 h at room temperature with 2% BSA in PBS. The secondary antibody anti-mouse Cy3-conjugated was added at a dilution of 1:1000. The cells were incubated with DAPI at a dilution of 1:1000 for 5 min. Finally, the coverslips were mounted with DAKO on microscope slides. The infected Sf9 cells were observed with the Fluoview FV10i microscope (Olympus®) and the images were analyzed with the ImageJ program.

2.8. Transmission electron microscopy (TEM) in infected Sf9 cells

Sf9 cells were infected with the recombinant baculovirus PH (1 1 0)PCV2 using a MOI of 20. At 72 hpi, the infected Sf9 cells were centrifuged, and the pellet was resuspended in PBS. Then, particles were included into an epoxic resin and slices of 90 nm were obtained. Infected Sf9 cells were contrasted with uranil acetate 1% and lead citrate. Samples were observed with the JEOL JEM 12,000 EXII at 80 kv. Three different stocks of Sf9 cells infected with the recombinant baculovirus PH(1 1 0)PCV2 were analyzed.

2.9. Nanoparticle tracking analysis (NTA)

PH(1 1 0)PCV2 NPs were produced as mentioned above. After purification, 0.3 μg of PH(1 1 0)PCV2 NPs were resuspended in 1 ml of sterile water and analyzed with the NanoSight instrument (Malvern Panalytical, Malvern, United Kingdom). Three independent measurements for each condition were conducted and the NP size was obtained from these recordings using the NanoSight software.

2.10. Pig immunization

9 PCV2-free 8-week-old Pietrain/York males and females pigs were obtained from a Mexican farm (the absence of PCV2 was corroborated by PCR, and the absence of antibodies against PCV2 was corroborated by ELISA). Three groups of 3 pigs each were used to evaluate the antibody production against ORF2 from PCV2. All the groups of pigs used in this experiment were isolated in filtered air rooms and maintained with water and food *at libitum* during all

INFORME DE LABORES 2019

the experiment. All the pigs were intramuscularly injected in the muscle of neck as following: the first group was immunized with Circoflex® according to manufacurer's instructions; the second was immunized with 200 μg of PH(1 1 0)PCV2 NPs with emulsion coadministration; and the third was immunized with 2000 μg of PH(1 1 0)PCV2 NPs with emulsion coadministration. This emulsion is based on light paraffin oil (1:1 vol/vol). Blood samples were taken in all the groups of pigs each week and sera were collected by means of centrifugation at 3000*g* for 15 min. Two booster doses were given to all the groups of pigs at 14 and 28 days after the prime dose in all the groups. The sera were stored at −70 °C until their use.

2.11. Indirect ELISA assay for antibodies against PCV2

96-well polystyrene microplates were coated with 50 μl of a dilution of 0.33 μg/ml of the recombinant protein ORF2 from PCV2. Microplates were incubated at 37 °C for 1 h, washed with 350 μl of PBS containing 0.2% Triton X-100 and blocked with PBS-BSA(2% BSA) at 37 °C for 1 h. 50 μl of a 1:200 dilution of sera from pigs diluted to in PBS-BSA were added each well and microplates were incubated at 37 °C for 1 h. After 5 washes, 50 μl of anti-pig antibody (HRP-conjugated) diluted 1:5000 in PBS-BSA were added to each well and microplates were incubated at 37 °C for 1 h. After washes, 50 μl of TMB were added to each well. Microplates were incubated at room temperature for 20 min and the reaction was stopped with 50 μl of a 0.16 M sulfuric acid solution. The microplates were read with an ELISA reader (SkanIt for Multiskan FC 3.1) using a filter of 450 nm. An ELISA positive value was the two-fold mean of the preimmune sera and the antibody titers were determined with the highest sera dilution that gave a positive value in ELISA as reported previously [31].

2.12. Virus seroneutralization assay and flow cytometry

PK-15 cells were maintained in DMEM supplemented with 10% of FBS in 35 mm tissue culture dishes until 90% of confluence and were washed with PBS and incubated with 500 μl Optimem™. PK-15 cells were transfected with 2 μg of the plasmid pGEM® T easy vector containing PCV2 expressing GFP. The supernatant was recovered 72 h post-transfection. 50,000 PK-15 cells were added to each well in 96-well microplates and were incubated for 24 h. 50 μl of the supernatant containing PCV2 expressing GFP (a MOI of 1 of the recombinant PCV2) were mixed with 50 μl of preimmune sera, or a serum from a PCV2-infected pig, or sera from pigs immunized with Circoflex® or PH(1 1 0)PCV2 NPs diluted 1:500 in Optimem™ (after complement inactivation 30 min at 56 °C). The mixtures were incubated for 1 h at 37 °C and were added to each well to allow to PCV2 attach to target cells. 1 h later, the PK-15 cells were washed twice with 200 μl of PBS. Then, 200 μl of Optimem™ supplemented with 1% FBS were added to each well. PK-15 cells were incubated at 37 °C with 5% CO_2 and were recovered at 72 hpi and analyzed by flow cytometry (Attune™). For the flow cytometry, PK-15 cells were recovered in 1.5-ml microtubes and analyzed individually by triplicate. 10,000 events were analyzed, and each event represents a PK-15 cell infected with the recombinant PCV2. Data were obtained with the Attune® Cytometer Software v2.1 (life technologies) and were graphed as histograms. The percentage of inhibition of infection by the recombinant PCV2 was calculated according to the difference between the average intensity of fluorescence of the PK-15 cells infected with the recombinant PCV2 and the average intensity of fluorescence of the PK-15 cells incubated with the mixture of the recombinant PCV2 and sera from different groups of pigs. Cells infected with the recombinant PCV2 were used as a reference for 100% of infection whereas non-infected cells were used to adjust the histograms before analysis.

2.13. Ethics statement and animal welfare

Mice used in this study were housed on a 12 h light/dark cycle with food and purified water *ad libitum*, following the protocol LVD74-5 approved by the Internal Committee for the Care and Use of Laboratory Animals (CICUAL) from Instituto de Fisiología Celular-UNAM. Pigs were fed with an age-based diet and purified water *ad libitum* at the National Center for Diagnostic Services in Animal Health (CENASA) from the National Health Service, Food Safety and Food Quality from Mexico (SENASICA) following the statements of the official Mexican standard NOM-062-ZOO-1999 for the ethical use of animals.

2.14. Statistic analysis

The absorbance of sera from pigs immunized with Circoflex® or PH(1 1 0)PCV2 NPs were compared with the absorbance of preimmune sera from pigs obtained by ELISA. An ELISA positive value was the two-fold mean of the preimmune sera. Data were recorded as mean and standard error. Statistic analysis of the virus seroneutralization assay was carried out by comparing the fluorescence of PK-15 cells incubated with PCV2 expressing GFP mixed with sera from pigs immunized with Circoflex® or PH(1 1 0)PCV2 NPs with the fluorescence of PK-15 cells incubated with PCV2 expressing GFP mixed with preimmune sera. For data with normality, a one-way ANOVA test following by a Tukey's test were used to determine differences with preimmune sera. If not, a Kruskal-Wallis test followed by a Dunn's Multimple Comparison test were used. The statistical significance was $p < 0.05$.

3. Results

3.1. Simple purification of PH(1 1 0)PCV2 NPs

Most of the PCV2 commercial vaccines are based on VLPs [4], and they have been important tools to control diseases associated to PCV2 [32], but their purification process is time-consuming and expensive [20,27]. In this work, we developed a system based on the self-aggregating peptide PH(1 1 0), which forms NPs that are easily purified by centrifugation. This system uses recombinant baculovirus as expression vectors [28,29]. We produced two main recombinant baculoviruses: a baculovirus containing GFP fused to PH(1 1 0) to be used as control and a second baculovirus carrying ORF2 from PCV2 fused to PH(1 1 0) (for generating PH(1 1 0)GFP and PH(1 1 0)PCV2 NPs, respectively) (Fig. 1A). For the production of recombinant proteins using baculoviruses we explored different multiplicities of infection (MOI). A MOI of 20 produced the largest amount of recombinant protein at 72 h postinfection, and a single band of 42-kDa was detected in SDS-PAGE analysis (Fig. 1B). This band corresponds to the expected molecular weight for PH(1 1 0) PCV2.

3.2. PH(1 1 0)PCV2 NPs are recognized by specific sera against PCV2

The next step was to determine if specific sera anti-polyhedrin or anti-PCV2 could identify the antigens PH(1 1 0) and ORF2 from PCV2 present in the PH(1 1 0)PCV2 NPs. Briefly, PH(1 1 0)GFP and PH(1 1 0)PCV2 NPs were run by SDS-PAGE and transferred to nitrocellulose membranes. Then, we evaluated whether the denatured PH(1 1 0)PCV2 protein was recognized by a specific sera against polyhedrin. The serum from a mouse immunized with polyhedra recognized both PH(1 1 0)GFP and PH(1 1 0)PCV2 proteins as

INFORME DE LABORES 2019

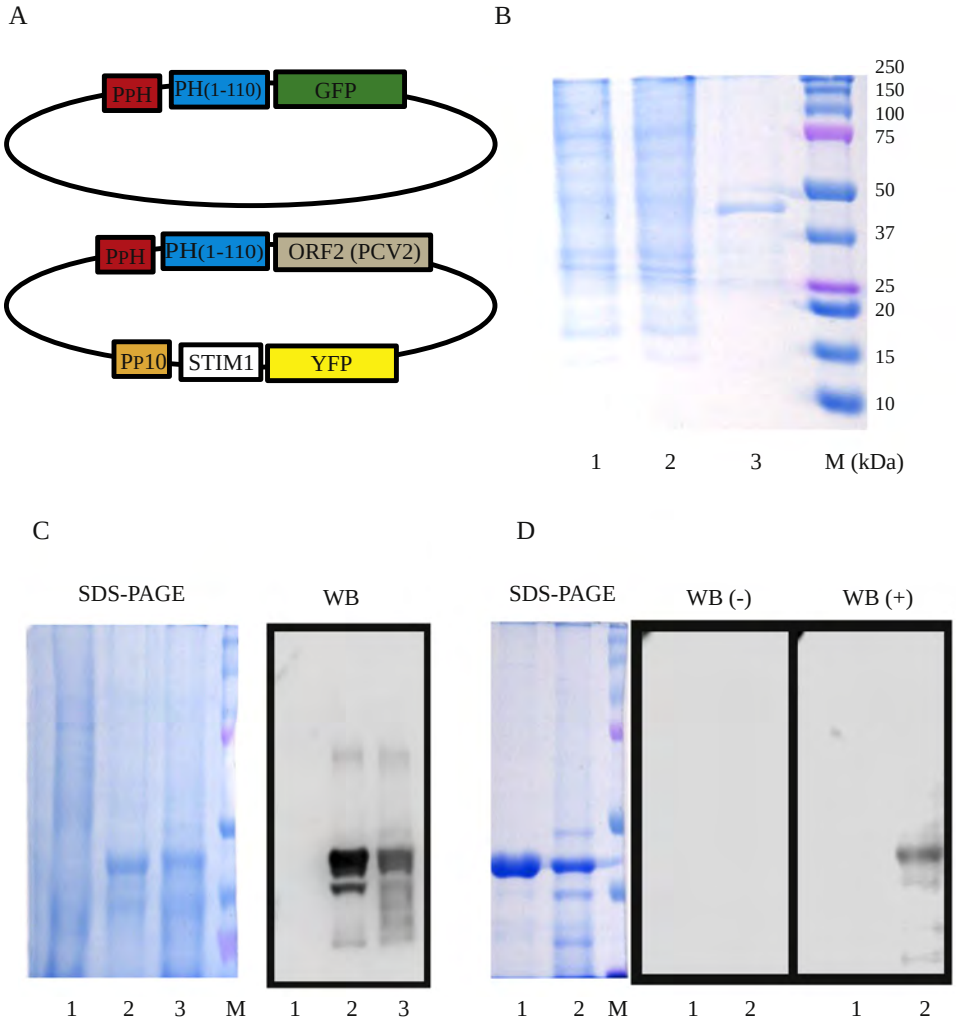

Fig. 1. Design of recombinant baculoviruses carrying the gene for the production of PH(1 1 0)PCV2 nanoparticles (NPs). (A) Cartoon illustrating the distribution of the genes carried by the recombinant baculoviruses genome with PH(1 1 0)GFP (upper panel) and PH(1 1 0)PCV2 (lower panel). (B) Multiplicity of infection (MOI) optimization was carried out by infecting Sf9 cells with 0.2 (lane 1), 2 (lane 2) and 20 (lane 3) MOI of the recombinant baculovirus PH(1 1 0)PCV2. PH(1 1 0)PCV2 and PH(1 1 0)GFP NPs were purified by simple sonication of infected Sf9 cells at 72 h postinfection (hpi), centrifugation and washes with phosphate saline buffered (PBS). Electrophoresis on a 12% polyacrylamide gel under denaturing conditions, gel was stained with Coomassie blue. A 42-kDa protein was observed in Sf9 cells infected with 20 MOI of the recombinant baculovirus PH(1 1 0)PCV2. (C) Evaluation of antigenicity of PH(1 1 0). Non-infected Sf9 cell lysates, PH(1 1 0)GFP NPs and PH(1 1 0)PCV2 NPs (lanes1, 2, and 3, respectively) were run on a 10% polyacrylamide gel under denaturing conditions. Gel was stained with Coomassie blue (SDS-PAGE, left side) and transferred to a nitrocellulose membrane for western blot analysis (right side). A hyperimmune serum of a mouse immunized with polyhedra was used to detect PH(1 1 0) in PH(1 1 0)GFP and PH(1 1 0)PCV2 proteins in the western blot. A 42-kDa protein was observed in both PH(1 1 0)GFP and PH(1 1 0)PCV2 denatured proteins, but it was not observed in non-infected Sf9 cell lysates. (D) Evaluation of antigenicity of ORF2 contained into the PH(1 1 0)PCV2 fusion protein. PH(1 1 0)GFP (lane 1) and PH(1 1 0)PCV2 (lane 2) NPs were run on a 10% polyacrylamide gel under denaturing conditions. Gel stained with Coomassie blue (SDS-PAGE, left side) sows all the proteins loaded, while western blot analysis (right side) illustrates the selective recognition of PH(1 1 0) by the hiperimmune serum. The western blot analysis was conducted by using a PCV2-free pig serum (WB (−)) and a PCV2-infected pig serum (WB (+)). Serum of the PCV2-infected pig recognized a 42-kDa protein only in PH(1 1 0)PCV2 which was not observed in PH(1 1 0)GFP. The molecular weight marker (M) is the same for all the gels and indicates the molecular weight (10–250 kDa). (See the full-length blots in the supplementary Fig. S1). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

expected (Fig. 1C, right side). Both PH(1 1 0)GFP and PH(1 1 0)PCV2 proteins had the expected molecular weight of 42 kDa as indicated by SDS-PAGE (Fig. 1C, left side). A lysate of non-infected Sf9 cells showed several protein bands with different molecular weights by SDS-PAGE, but none of these were recognized by the anti-polyhedrin serum, indicating high specificity. Most importantly, PH(1 1 0)PCV2 protein was recognized by a serum obtained from a PCV2-infected pig. PH(1 1 0)GFP protein was not recognized by this serum (Fig. 1D). A serum from a PCV2-free pig was used as negative control, which did not recognize PH(1 1 0)GFP nor PH (1 1 0)PCV2 proteins. These results demonstrate that antibodies from PCV2-infected pigs recognize the ORF2 antigen present in the PH(1 1 0)PCV2 NPs.

3.3. The ORF2 from PCV2 fused to PH(1 1 0) self-aggregates and forms particles located in the nucleus of infected Sf9 insect cells

Previously, we reported that the peptide PH(1 1 0) derived from the N-terminus of the polyhedrin protein from the baculovirus AcNPV self-aggregates forming NPs into the nuclei of infected cells [28]. This event occurs even when the full-length GFP is fused to the C-terminus of PH(1 1 0) [28]. The PH(1 1 0)GFP particles have a size of 500 nm to 3 μm when observed by confocal microscopy inside the nuclei of infected Sf9 cells [28]. In order to evaluate if PH(1 1 0) retains the capacity of self-aggregation when fused to ORF2 from PCV2, we conducted indirect immunofluorescence assays. Immunofluorescence also allowed us to evaluate the local-

INFORME DE LABORES 2019

ization and morphology of the PH(1 1 0)PCV2 NPs in the infected Sf9 cells.

The PH(1 1 0)PCV2 NPs were amorphous and were located inside the nuclei of the infected Sf9 cells as indicated by the colocalization with the fluorescent DNA marker DAPI (Fig. 2A, upper part). The immunofluorescence was specific for the PH(1 1 0)PCV2 particles, since the serum from mice immunized with Fostera® PCV recognized only these NPs, but not PH(1 1 0)GFP NPs (Fig. 2A, lower part).

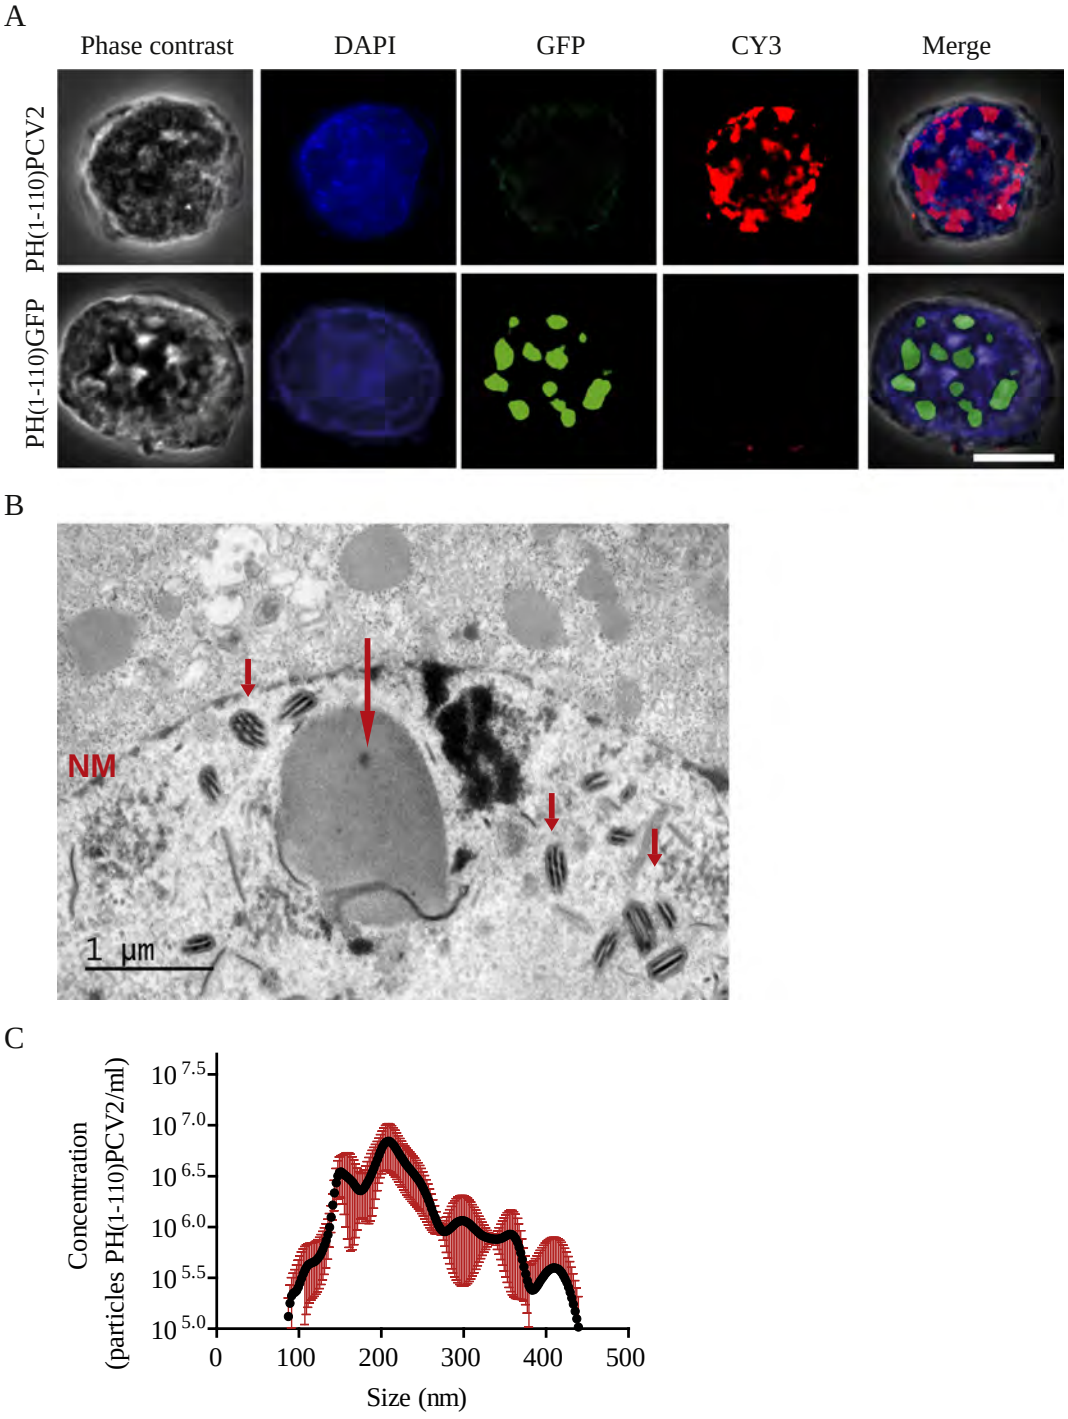

Fig. 2. Characterization of PH(1 1 0)PCV2 NPs: morphology, localization and size. (A) Confocal microscopy images of PH(1 1 0)PCV2 NPs. Sf9 cells were infected with the recombinant baculoviruses PH(1 1 0)PCV2 or PH(1 1 0)GFP. At 72 hpi, cells were processed for specific immunofluorescence against ORF2 from PCV2 using an anti-PCV2 hyperimmune sera from a mouse and a Cy3-conjugated antibody (Section 2). PH(1 1 0)GFP NPs were treated in the same way using the same serum and secondary antibody. The nuclei of cells are stained with 4′, 6-diamino-2-phenylindole (DAPI) dye. Protein PH(1 1 0)PCV2 self-aggregated and formed NPs located in the nucleus of Sf9 cells infected by the recombinant baculovirus PH(1 1 0)PCV2. PH(1 1 0)PCV2 NPs were recognized by a specific serum against PCV2, unlike PH(1 1 0)GFP NPs. All the confocal microscopy images have the same scale. The bar indicates 6 μm. (B) Transmission electron microscopy (TEM) of Sf9 cells infected by the recombinant baculovirus PH(1 1 0)PCV2. Red big arrows indicate the particles produced by the recombinant baculovirus PH(1 1 0)PCV2 and the red short arrows indicate baculoviruses near but outside the particles. NM = nuclear membrane. Barr indicates 1 μm. (C) Nanoparticle tracking analysis (NTA) of PH(1 1 0)PCV2 NPs. Fresh PH(1 1 0)PCV2 NPs were analyzed with the NanoSight instrument (Section 2) in triplicate. The dotted line is the mean value of the particle concentration/ml and the error bars are the standard error. Size of NPs is indicated in nanometers (nm). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

INFORME DE LABORES 2019

3.4. The PH(1 1 0)PCV2 NPs do not contain occluded baculoviruses

The natural role of polyhedron is to form the polyhedra, a crystal structure in which thousands of baculoviruses are occluded, forming what is known as the occluded bodies [33]. Polyhedra is formed in the nuclei of infected cells, and provides stability to occluded baculovirus [30]. We have previously shown by TEM that PH(1 1 0)GFP particles do not occlude baculoviruses [28] unlike wild type polyhedra [33]. Similarly to PH(1 1 0)GFP NPs, PH(1 1 0)PCV2 NPs do no occlude baculovirus inside them, as demonstrated by TEM analysis (Fig. 2B). This observation is particularly relevant for vaccines, since the immunization with contaminating baculoviruses is not desirable for vaccination.

3.5. The PH(1 1 0)PCV2 NPs are polydisperse

Particle size may play an important role in the vaccine development, since NPs between 20 and 200 nm appear to be more immunogenic than larger particles [34]. To further evaluate the dimensions of PH(1 1 0)PCV2 NPs we conducted nanoparticle tracking analysis (NTA) [35]. NTA of PH(1 1 0)PCV2 indicated that these NPs are polydisperse. PH(1 1 0)PCV2 NPs showed three main components: 150, 210 and 300 nm (Fig. 2C).

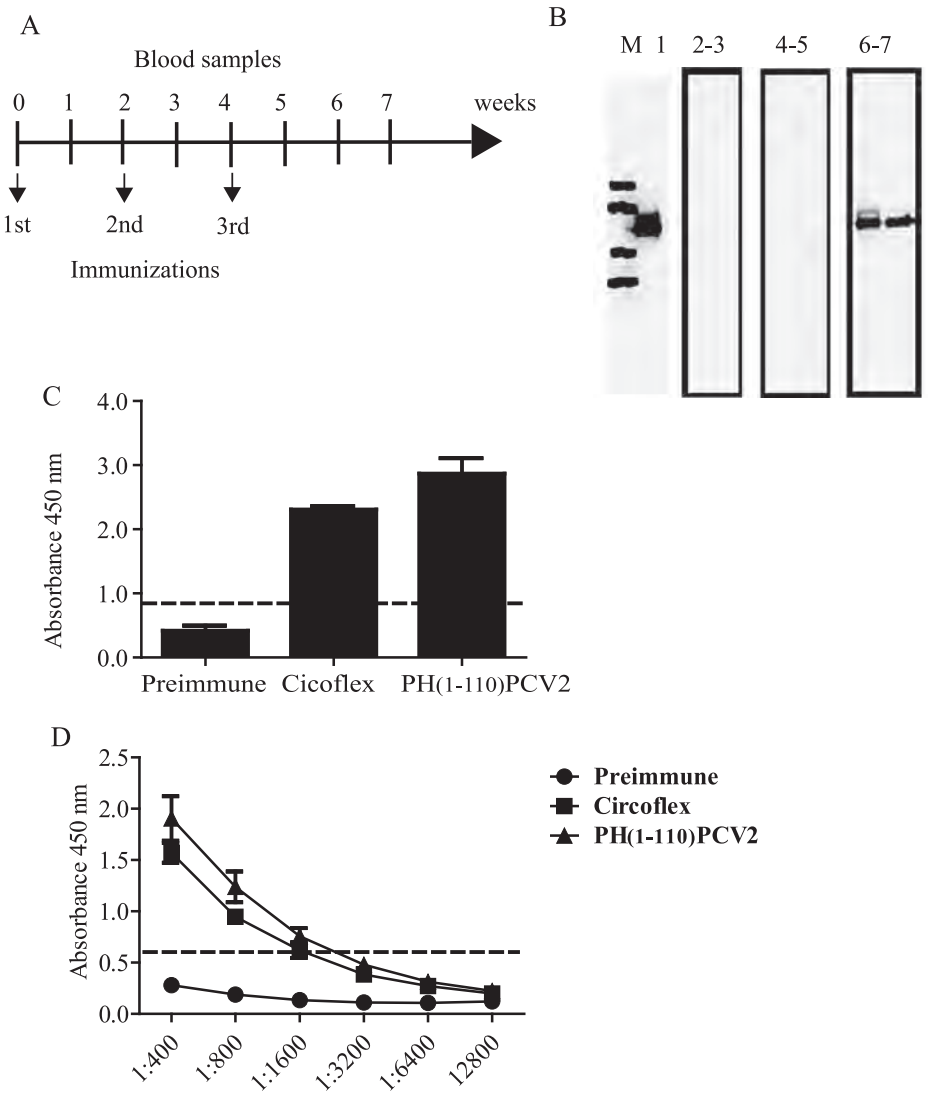

Fig. 3. Immunization of pigs with PH(1 1 0)PCV2 NPs. (A) Diagram illustrating the immunization and bleeding schedules. PCV2-free pigs were immunized with the commercial vaccine Circoflex® or PH(1 1 0)PCV2 NPs with emulsion co-administration based on light paraffin oil. Two booster doses were given to each pig with an interval of 2 weeks. Sera samples were taken every week until 7th week. (B) Western blot analysis of sera from vaccinated pigs. A recombinant ORF2 was produced in bacteria and purified to use as antigen for western blot. The recombinant ORF2 was run by PAGE at 10% and transferred to nitrocellulose membrane strips. Each strip was incubated with a different serum from pigs: infected (lane 1), pre-immune (lane 2 and 3), vaccinated with Circoflex (lane 4 and 5) and vaccinated with PH(1 1 0)PCV2 NPs (lane 6 and 7). M = molecular weight marker representing from top to bottom: 50, 37, 25 and 20 kDa proteins. A sera from a PCV2-infected pig and sera from pigs vaccinated with PH(1 1 0) PCV2 NPs recognized a protein of approximately 30 kDa corresponding to the molecular weight of ORF2 from PCV2 (See the full-length blots in the supplementary Fig. S2). (C) Evaluation of specific antibodies against ORF2 from PCV2 by an indirect ELISA. Sera from 3 pigs for each condition were evaluated for duplicate. All the sera evaluated in this experiment belong at 7 weeks after immunization and were used at a dilution of 1:200. Bars show the mean and standard error. (D) Specific antibody titters against ORF2 from PCV2 from pigs vaccinated with Circoflex® or PH(1 1 0)PCV2 NPs determined by an indirect ELISA. Dilutions of sera were from 1:400 to 1:12,800. Symbols (rhombs, squares and circles) are the mean of the absorbance obtained from the sera and the error bars are the standard error. The dotted line indicates the breaking point of twice the mean of the pre-immune sera and represents the cutoff value for positive pigs. The antibody titers were determined with the highest sera dilution that gave a positive value in ELISA.

INFORME DE LABORES 2019

3.6. Pigs immunized with PH(1 1 0)PCV2 NPs induced neutralizing antibodies against PCV2

To evaluate the efficiency of PH(1 1 0)PCV2 NPs as vaccines we immunized pigs with these NPs and compared them with the commercially available vaccine Circoflex® (Fig. 3A). Pigs immunized with 200 μg of PH(1 1 0)PCV2 NPs generated antibodies based on IgG against ORF2 from PCV2 detected by western blot and ELISA, whereas pigs immunized with Circoflex® induced antibodies against ORF2 from PCV2 detected only by ELISA. These results strongly suggested that PH(1 1 0)PCV2 NPs induced antibodies that recognize both conformational and non-conformational epitopes whereas Circoflex predominantly produced antibodies recognizing conformational epitopes (Fig. 3B and C). Antibody titers generated with PH(1 1 0)PCV2 NPs and Circoflex® were indistinguishable, with titers of 1:1600 (Fig. 3D). PCV2 antibody titers were indistinguishable in pigs immunized with 200 or 2000 μg of PH(1 1 0)PCV2 NPs (Supplementary Fig. S3-D).

In order to determine if the antibodies produced by our vaccine PH(1 1 0)PCV2 contained neutralizing antibodies, we conducted an *in vitro* neutralization assay using the pig kidney cell line PK-15.

To evaluate the infection of PK-15 cells with PCV2, we produced a recombinant virus carrying the gene for the green fluorescent protein (GFP) under the strong CMV promoter (Section 2). In this way we could quantify infection by PCV2 following the fluorescence from GFP by cell cytometry (Section 2).

With this *in vitro* neutralization assay we compared the sera from pigs vaccinate with our PH(1 1 0)PCV2 NPs, pigs vaccinated with Circoflex® and control pigs (pigs vaccinate with saline solution). We also used the serum from a naturally infected pig with PCV2 as positive control.

Preimmune sera did not inhibit PCV2 infection in PK-15 cells. Most interestingly, the sera from pigs immunized with Circoflex® and the sera from the pigs immunized with PH(1 1 0)PCV2 NPs showed neutralizing antibody titers of 1:500 as indicated by the reduction in fluorescence intensity from GFP (Fig. 4A and B). Additionally, the fluorescence intensity of PK-15 cells induced by the infection of the recombinant PCV2 decreased 25–35% when the recombinant PCV2 was mixed with sera from pigs immunized with Circoflex® (Fig. 4A and B). Fluorescence intensity of PK-15 cells decreased 50–60% when the recombinant PCV2 was mixed with sera from pigs immunized with our PH(1 1 0)PCV2 NPs. These results show that the sera from pigs vaccinated with Circoflex® or PH(1 1 0)PCV2 NPs contained neutralizing antibodies against PCV2. These antibodies were as efficient as those found in pigs naturally infected with PCV2 (Fig. 4B).

4. Discussion

PCV2 is one of the most important pathogens in the pig industry around the world causing serious economic losses [3,4,17,18]. Even trough there are several vaccines available in the market today, the need for simpler, easier to produce and less expensive vaccines is always required.

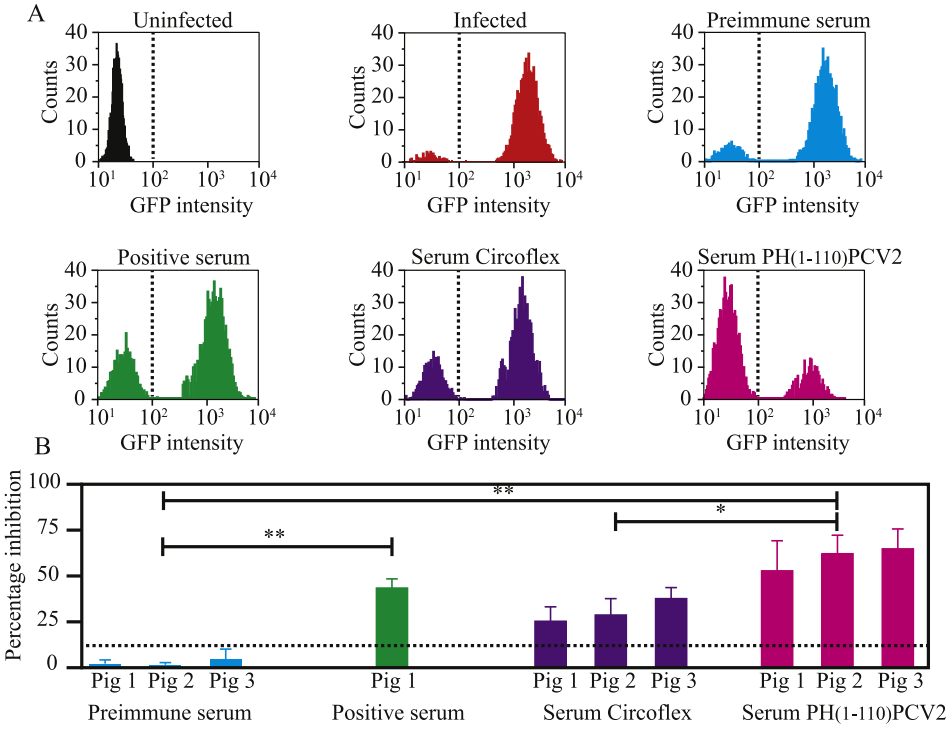

Fig. 4. Neutralization assay against a recombinant PCV2 expressing GFP. (A) Representative histograms obtained form the cell cytometer after counting 10,000 cells for each condition. Fluorescence shows the expression of GFP by a recombinant PCV2 expressing soluble GFP (Section 2). PK-15 cells were transfected with DNA from the recombinant PCV2 and supernatant was recovered 72 h later and used for the neutralization assay. Pre-immune sera and sera from vaccinated pigs with PH(1 1 0)PCV2 NPs or Circoflex® as well as a serum from a positive pig (naturally infected by PCV2) were diluted 1:500 and mixed individually with the recombinant PCV2 using a MOI of 1. PK-15 cells were added to microplates and incubated 24 h. Each mix was added to each well and incubated for 72 h. PK-15 cells were analyzed by flow cytometry. Each sample was analyzed in triplicate and 10,000 events were recorded. Data are the counts of PK-15 cells with different fluorescence intensities of GFP, indicating PK-15 cells infected with the recombinant PCV2. (B) Percentage of inhibition of the fluorescent intensity of GFP in PK-15 cells in the neutralization assay. The percentage of inhibition of fluorescence of GFP was calculated considering the baseline from non-infected PK-15 cells (indicated in black as uninfected) and the infected PK-15 cells with a standard quantity of recombinant PCV2 without sera (indicated as infected in the red histogram). The titers of neutralizing antibodies were 1:500 (since the sera were previously diluted 1:500). Data are presented in percentage and based on the number of cells positive to GFP. Bars show the mean and standard error. The asterisk indicates conditions different from the group injected with PBS ($^{*}p < 0.05$ and $^{**}p < 0.01$). A one-way ANOVA test following by a Tukey's test were used to determine differences with the pre-immune sera. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

INFORME DE LABORES 2019

In an attempt to explore novel pathways for vaccine production, we produced nanoparticles by fusing the ORF2 from PCV2 to the fragment PH(1 1 0) from polyhedron obtained from the baculovirus *Autographa californica*. Polyhedrin is the main constituent from the polyhedral, a crystal structure that occludes baculoviruses and protects them from the environment for years [33].

The use of polyhedra as carriers for vaccines has been recently proposed [36,37]. Nevertheless, polyhedra can withstand acidic pH of the endolysosome of antigen presenting cells such as dendritic cells (DCs), avoiding the maturation process for presenting antigens [36]. However, the peptide PH(1 1 0) derived from the first 110 amino acids from polyhedrin protein retains the self-aggregate property of polyhedra and forms NPs [28], and is processed by antigen presenting, generating antibodies [29]. In the present study we evaluated the use of PH(1 1 0)PCV2 NPs as a PCV2 vaccine candidate.

The main advantages of our system are the downstream processes such as recovery and purification of the PH(1 1 0)PCV2 NPs, because these nanoparticles can be purified using a single centrifugation step, while yielding large amounts of pure protein (Fig. 1D). In addition, our vaccine does not require refrigeration for storage; since these NPs are stable a room temperature for several months. These properties are not met by other vaccines such as VLPs, because they need to be purified by different methods from ultracentrifugation using sucrose or cesium chloride gradients to chromatography [27,38–40]. Thus, the recovery and purification of VLPs-based vaccines are time-consuming and often yields are not very good [20,27]. Therefore, our system based on PH(1 1 0) PCV2 NPs is not only easy to produce and faster than other methods, but also less expensive because requires a simple centrifugation step and yields large amounts of protein.

However, our method is not without some limitations. The main limitations of our system based on PH(1 1 0)PCV2 NPs are the lack of experience in molecular biology for the design of the recombinant baculovirus and the lack of knowledge in genetics and proteomics of some pathogens to adequately identify the antigen (or segment of the antigen) to be used in the fusion protein.

On the other hand, the use of NPs has gained attention for the production of novel antigen delivery systems. NPs have been designed based on proteins [21,22], peptides [41–45] or lipopeptides [46–48] which self-assemble generating NPs with different dimensions. The particle formation is a process that involves the self-interaction among molecules of the same type to form supramolecular assemblies, which may improve the immunogenicity of fused/conjugated antigens [29]. The size of antigens is also important because it plays an important role in the antibody production. Current research has indicated that NPs between 20 and 200 nm are more immunogenic than larger particles because are easily endocyted by DCs and/or enter directly through the lymphatic vessels whereas larger particles cannot [34]. The PH(1 1 0) PCV2 protein generated NPs range from 90 to 450 nm (Fig. 2C). Additionally, these NPs do not contain occluded baculovirus and generate high antibody titers against ORF2 from PCV2.

We also evaluated the *in vitro* protection of the PH(1 1 0)PCV2 NPs through an seroneutralization assay, because a challenge experiment is difficult due to the well known fact that PCV2 infection in pigs is often asymptomatic [49]. In addition, Porcine circovirus disease (PCVD) is not lethal and coinfection by other viruses are required to trigger symptoms in infected animals [3]. The use of immunostimulants has also been suggested before the PCV2 challenge to trigger the development of PCVD, but this has given controversial results, since with this methodology, up to 70% of pigs develop PCVD [50], whereas other similar methodologies do not trigger the PCVD [49]. On the other hand, it has been shown that neutralizing antibodies against PCV2 correlate well with *in vivo* protection [51,52]. For this reason, we decided to develop an *in vitro* neutralization assay using a recombinant PCV2 carrying the gen for GFP. Our results indicated that the pigs immunized with PH(1 1 0)PCV2 NPs or Circoflex® generated antibodies against PCV2 that can neutralize the PCV2 infection in PK-15 cells.

5. Conclusions

Here we show the development of a novel technology to produce vaccines by encapsulating antigens into genetically encoded NPs. Because the antigen and the self-aggregating peptide used for encapsulation are a fusion protein, the incorporation efficiency is 100%. Given the fact that particles can be precipitated by centrifugation, purification of the NPs carrying the antigen of interest is easy, fast and inexpensive. Furthermore, we have shown that the NPs produced with this technology are stable for years at room temperature, preventing the use of a cold chain and extending the life shelf of the vaccine.

Author contribution

JZC and LV conceived the study, standardized the production of PH(110)PCV2 NPs, conducted western blots, ELISA, NTA and neutralization assays, produced figures of the paper and wrote the paper. AS designed the recombinant baculoviruses and plasmids and ACR synthesized the recombinant ORF2 from PCV2, conducted ELISAs and western blots. JISB and RCN isolated PCV2 from infected animals and conducted PCR for cloning. All the authors analyzed and interpreted data, and approved the final manuscript.

Declaration of interest

The pharmaceutical company Sanfer supported partially this research by providing the pigs used in this study.
